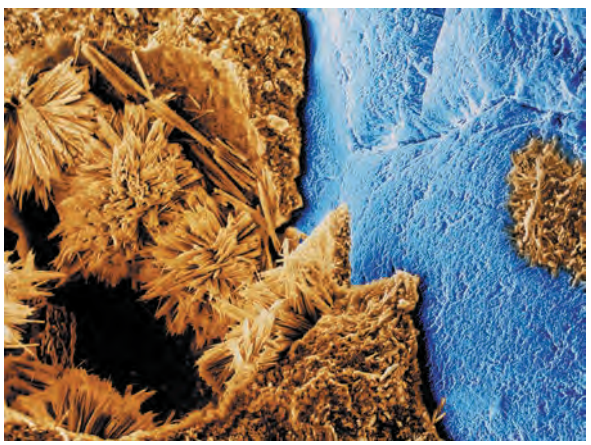
The primary ingredients required for the manufacture of cement are limestone ($CaCO_3$) and silica (SiO_2), along with smaller quantities of alumina (Al_2O_3) and Fe_2O_3. Initially, $CaCO_3$ is calcined at 1070 K. The CaO so formed is then heated with SiO_2, Al_2O_3 and Fe_2O_3 in a rotary kiln at 1570–1720 K. At these temperatures, the material sinters (i.e. becomes partially molten) and forms a *clinker* which is composed of the mixed oxides $3CaO{\cdot}SiO_2$ ('C_3S'), $2CaO{\cdot}SiO_2$ ('C_2S'), $3CaO{\cdot}Al_2O_3$ ('C_3A') and $4CaO{\cdot}Al_2O_3{\cdot}Fe_2O_3$ ('C_4AF'). (These abbreviations are in common use in the cement industry.) Phase diagrams for the system are complicated. The cooled clinker is ground to a powder and gypsum ($CaSO_4{\cdot}2H_2O$) is added; the gypsum controls the setting time of the cement (see later). A typical Portland cement has a composition within the ranges 55–60% $3CaO{\cdot}SiO_2$, 15–18% $2CaO{\cdot}SiO_2$, 2–9% $3CaO{\cdot}Al_2O_3$, 7–14% $4CaO{\cdot}Al_2O_3{\cdot}Fe_2O_3$, 5–6% gypsum and <1% Na_2O or K_2O. White cements (in demand for architectural use) have a reduced iron content and contain only 1% 'C_3A' and increased amounts of 'C_3S' and 'C_2S'. Cements that will be exposed to high levels of sulfates (e.g. in ground water) must also have a reduced 'C_3A' content. This is because sulfates react with calcium aluminate hydrate with an associated 220% increase in the volume of the material, resulting in structural degradation.

The hydration of cement powder is the final step in which it is transformed into a hard material which is insoluble in water. The hydration process is exothermic, and is exemplified for $3CaO{\cdot}SiO_2$ as follows:

$$2(3CaO{\cdot}SiO_2) + 6H_2O \longrightarrow 3CaO{\cdot}2SiO_2{\cdot}3H_2O + 3Ca(OH)_2$$

or, in the notation form used in the cement industry:



$$2\text{'}C_3S\text{'} + 6\text{'}H\text{'} \longrightarrow \text{'}C_3S_2H_3\text{'} + 3\text{'}CH\text{'}$$

For 'C_3S', the enthalpy of hydration is 500 kJ kg^{-1}, compared with 250, 850 and 330 kJ kg^{-1} for 'C_2S', 'C_3A' and 'C_4AF', respectively. The setting period consists of several stages. The addition of water to dry cement initially causes a rapid, and highly exothermic, dissolution of ions and formation of hydrated species. This is followed by a dormant period, and then a final exothermic event which completes the cement setting process. 'C_3S', 'C_2S', 'C_3A' and 'C_4AF' set at different rates ('C_3A' > 'C_3S' > 'C_2S' ≈ 'C_4AF'). The addition of gypsum to the cement mix slows down the setting process, a point that is particularly important for 'C_3A'.

The hardening of cement (or concrete) is ultimately caused by the formation of Si–O–Si bridges. Hydrated 'C_3S' and 'C_2S' exist as extended networks, coexisting with fibrous domains, calcium hydroxide and unhydrated cement grains. This framework (usually referred to as the *cement gel*) contains pores, the total volume of which may be one-quarter of the entire material. Cement contains a number of NMR active nuclei (^1H, ^{29}Si, ^{27}Al and ^{23}Na), and solid state ^{29}Si magic angle spinning (MAS) NMR spectroscopy has been used for structural investigations.

Cement is the binding agent in concrete and constitutes 15–25% of the final material by weight. Water and cement together generate a *cement paste* which, when combined with fine and/or coarse aggregate, results in concrete. Most concrete is now produced ready-mixed and is moved to building sites in cement vehicles consisting of slowly rotating drums to prevent the concrete from setting prematurely. The quality of concrete is determined largely by the ratio of cement to water, and particles of aggregate should be completely surrounded by cement paste. The properties of a given concrete can be tuned by the presence of additives. In addition to its production from almost universally available raw materials, and its strength and adaptability, concrete is fire-resistant. It is now one of the most important building materials worldwide.

The contribution that the calcining of $CaCO_3$ makes to global CO_2 emissions is an environmental concern. As a result of the 1997 Kyoto Protocol, methods of reducing CO_2 emissions are prime objectives for cement manufacturers.

APPLICATIONS

Box 14.9 The rise and fall of fibrous asbestos

In the commercial market, the term asbestos covers fibrous forms of the minerals actinolite, amosite, anthophyllite, chrysotile, crocidolite and tremolite. The ability of the fibres to be woven along with their heat resistance and high tensile strength led to widespread applications of asbestos in fire-proofing materials, brake linings, prefabricated boards for construction, roofing tiles and insulation. As the graph below shows, world production of asbestos was at a peak in the mid-1970s and has since declined. Most of the asbestos mined nowadays is chrysotile, and the world's leading producers are Russia, China, Brazil and Kazakhstan; mine production in the US ended in 2002 because of the decline in the US asbestos market. Continuing applications are largely in roofing materials, gaskets and friction products including brake linings. The dramatic downturn in the use of asbestos is associated with its severe health risks. The respiratory disease asbestosis is caused by the inhalation of asbestos fibres by workers constantly exposed to them. Strict legislation controls the use of asbestos, and demolition or renovation of old buildings often reveals large amounts of asbestos, which can be cleared only under qualified specialists. In most countries, the decline in the use of asbestos is set to continue as further restrictive legislation is passed. Many countries have now banned the processing and use of asbestos. Legislation, such as that enforced in the Republic of Korea in 2009, focuses on products in which asbestos particles may break loose or come into contact with the skin. On the other hand, since 2000, consumption of asbestos increased in parts of Asia, South America and the Commonwealth of Independent States, and this accounts for the upturn in world production in the graph below. Between 2010 and 2015, annual world asbestos production was ≈2 Mt. Although the health risks of asbestos fibres are well known, the huge expansion of nanotechnology raises the question that similar risks may exist with carbon nanotubes, and nanofibres and nanoparticles of other materials. Risk assessment in this area is therefore critical, and is actively being pursued.

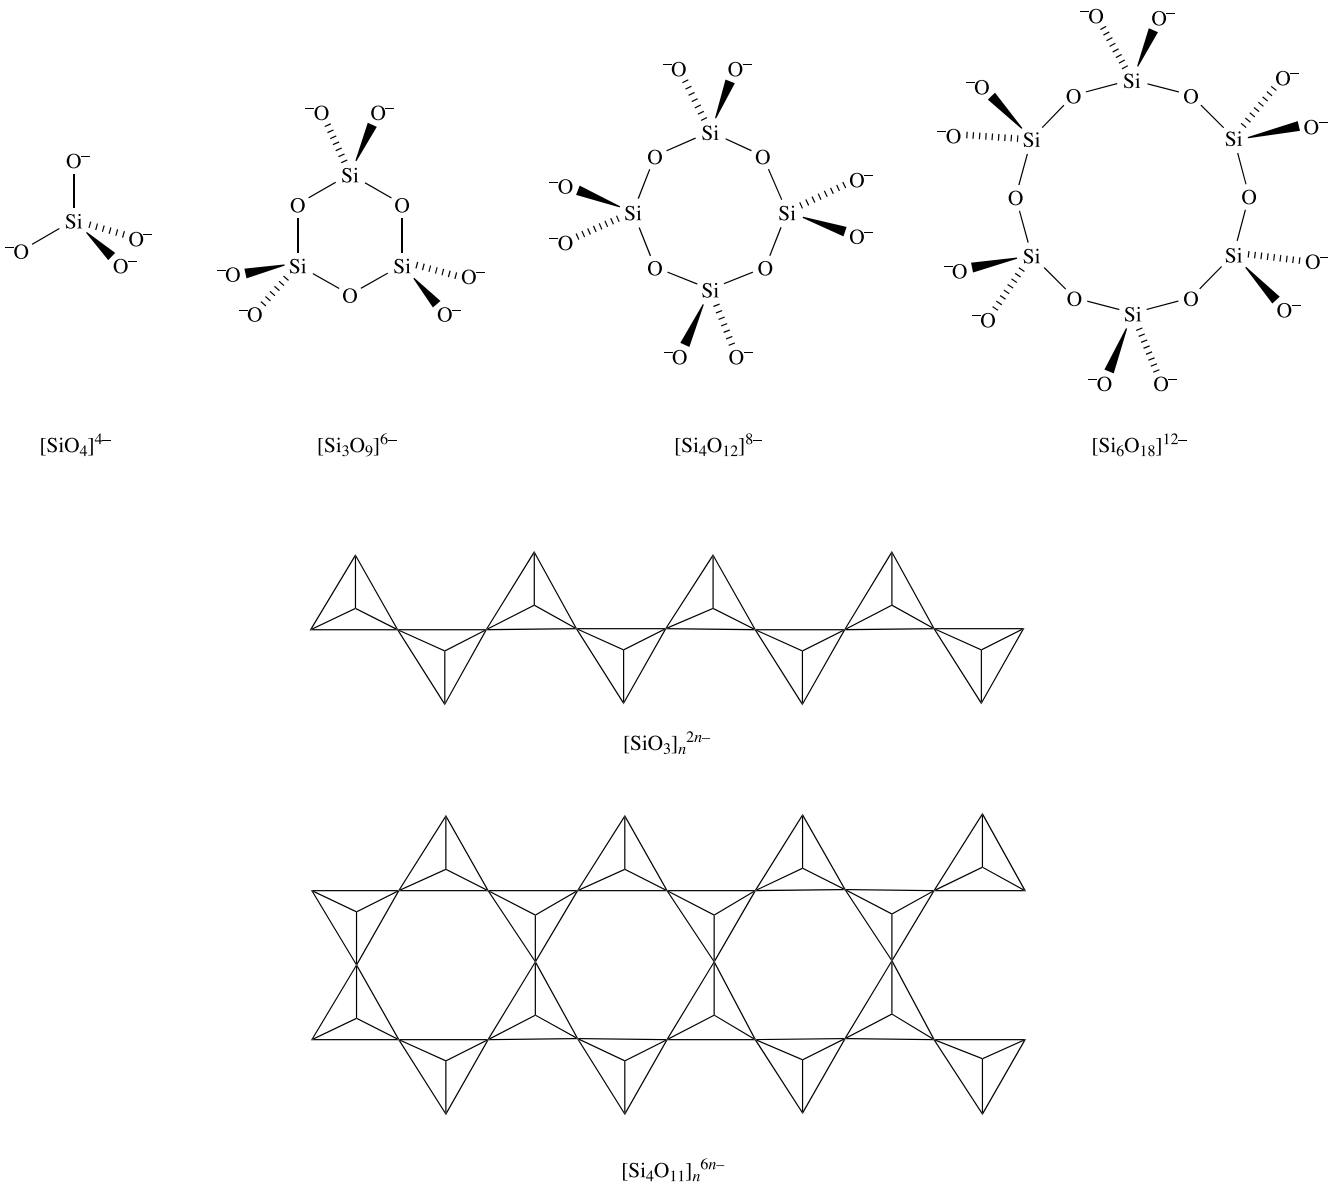

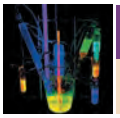

Fig. 14.23. Schematic representations of the structures of selected silicates. Conformational details of the rings are omitted. In the polymeric structures, each tetrahedron represents an SiO_4-unit as shown in structure **14.22**. (See also Fig. 14.25.)

(*beryl*) respectively, while $[Si_4O_{12}]^{8-}$ is present in the synthetic salt $K_8Si_4O_{12}$. Short-chain silicates are not common, although $[Si_3O_{10}]^{8-}$ occurs in a few rare minerals. Cage structures have been observed in some synthetic silicates and two examples are shown in Fig. 14.24.

If SiO_4 tetrahedra sharing two corners form an infinite chain, the Si:O ratio is 1:3 (Fig. 14.23). Such chains are present in $CaSiO_3$ (β-*wollastonite*) and $CaMg(SiO_3)_2$ (*diopside*, a member of the *pyroxene* group of minerals which possess $[SiO_3]_n^{2n-}$ chains). Although infinite chains are present in these minerals, the relative orientations of the chains are different. *Asbestos* (see Box 14.9) consists of a group of fibrous minerals, some of which (e.g. $Ca_2Mg_5(Si_4O_{11})_2(OH)_2$, *tremolite*) contain the double-chain silicate $[Si_4O_{11}]_n^{6n-}$ shown in Figs. 14.23 and 14.25. More extended cross-linking of chains produces layer structures of composition $[Si_2O_5]^{2-}$; ring sizes within the layers may vary. Such sheets occur in *micas* and are responsible for the characteristic cleavage of these minerals into thin sheets. *Talc*, characterized by its softness, has the composition $Mg_3(Si_2O_5)_2(OH)_2$. The Mg^{2+} ions are sandwiched between layers comprising $[Si_2O_5]_n^{2n-}$ sheets and $[OH]^-$ ions. This produces electrically neutral sheets (Fig. 14.26) which are held together by weak interactions, allowing talc to cleave readily in a direction parallel to the sheets. A consequence of this cleavage is that talc is used as a dry lubricant, e.g. in personal care preparations.

Infinite sharing of all four oxygen atoms of the SiO_4 tetrahedra gives a composition SiO_2 (see earlier) but partial replacement of Al for Si in Si_nO_{2n} leads to the anions $[AlSi_{n-1}O_{2n}]^-$ and $[Al_2Si_{n-2}O_{2n}]^{2-}$ etc. Minerals belonging to this group include *orthoclase* ($KAlSi_3O_8$),

APPLICATIONS

Box 14.10 Kaolin, smectite and hormite clays: from ceramics to natural absorbers

Crystalline clays (aluminosilicate minerals) are categorized according to structure. Clays in the *kaolin* or *china clay* group (e.g. *kaolinite*, $Al_2Si_2O_5(OH)_4$) possess sheet structures with alternating layers of linked SiO_4 tetrahedra and AlO_6 octahedra. *Smectite* clays (e.g. *sodium montmorillonite*, $Na[Al_5MgSi_{12}O_{30}(OH)_6]$) also have layer structures, with cations (e.g. Na^+, Ca^{2+}, Mg^{2+}) situated between the aluminosilicate layers. Interactions between the layers are weak, and water molecules readily penetrate the channels causing the lattice to expand; the volume of montmorillonite increases several times over as water is absorbed. *Hormite* clays (e.g. *palygorskite*) possess structures in which chains of SiO_4 tetrahedra are connected by octahedral AlO_6 or MgO_6 units; these clays exhibit outstanding adsorbent and absorbent properties.

Within industry and commerce, terms other than the mineral classifications are common. *Ball clay* is a type of kaolin particularly suited to the manufacture of ceramics. It consists of kaolinite, quartz and mica, and is usually worked from open-cast mines. In 2015, 41% of the ball clay produced in the US was used for tile manufacture, 18% for sanitary ware, and the remainder for pottery and various ceramics. When the clay consists predominantly of kaolinite, it is often referred to simply as kaolin or china clay. These clays are white and soft, and are extracted from open-cast mines using high-pressure water jets. This produces a slurry which is transferred to storage tanks where the clay is separated from feldspar and other silicate minerals. The photograph shows an aerial view of an open-cast china clay mine and groups of circular settling tanks are visible. White kaolinite is of great importance in the paper industry for coatings and as a filler, and in 2015, 45% of the kaolinite produced in the US was consumed in the paper industry. In 2015, the world production of kaolin clays (ball and china clays) was ≈34 Mt. In contrast, world production of smectite and hormite clays was significantly lower.

Smectite clays tend to be referred to as *bentonite*, the name deriving from the rock in which the clays occur. *Fuller's earth* is a general term used commercially to describe hormite clays. Applications of smectite and hormite clays stem from their ability to absorb water, swelling as they do so. Drilling fluids rely on the outstanding, reversible behaviour of sodium montmorillonite as it takes in water: this property is called *thixotropy*. When static, or at low drill speeds, an aqueous suspension of the clay is highly viscous owing to the absorption of water by the lattice and the realignment of the charged aluminosilicate layers. At high drill speeds, electrostatic interactions between the layers are destroyed and the drill-fluid viscosity decreases. Fuller's earth clays are remarkably effective absorbents and two major applications are in pet litter, and in granules which can be applied to minor oil spillages (e.g. at fuel stations).

[Statistical data: US Geological Survey]

Aerial photograph of Gunheath china clay mines in Cornwall, UK.

albite ($NaAlSi_3O_8$), *anorthite* ($CaAl_2Si_2O_8$) and *celsian* ($BaAl_2Si_2O_8$). Feldspars are aluminosilicate salts of K^+, Na^+, Ca^{2+} or Ba^{2+} and constitute an important class of rock-forming minerals which include *orthoclase*, *celsian*, *albite* and *anorthite*. The *feldspathoid* minerals are related to feldspars, but have a lower silica content. An example is *sodalite*, $Na_8[Al_6Si_6O_{24}]Cl_2$ (see Box 16.4). Both the feldspars and feldspathoid minerals are anhydrous.

Zeolites constitute an important class of aluminosilicates, but their ability to absorb water makes them distinct from the feldspars and feldspathoids. In feldspars, the holes in the structure that accommodate the cations are quite small. In zeolites, the cavities are much larger and can accommodate not only cations but also molecules such as H_2O, CO_2, MeOH and hydrocarbons. Commercially and industrially, zeolites (both natural and synthetic) are extremely important. The Al:Si ratio varies widely among zeolites; Al-rich systems are hydrophilic and their ability to take up H_2O leads to their use as laboratory drying agents (molecular sieves). Different zeolites contain different-sized cavities and channels, permitting a choice of zeolite to effect selective molecular adsorption. Silicon-rich zeolites are hydrophobic. Catalytic uses of zeolites (see Sections 25.6 and 25.7) are widespread, e.g. the synthetic zeolite ZSM-5 with composition $Na_n[Al_nSi_{96-n}O_{192}]\cdot\approx 16H_2O$ ($n < 27$) catalyses benzene

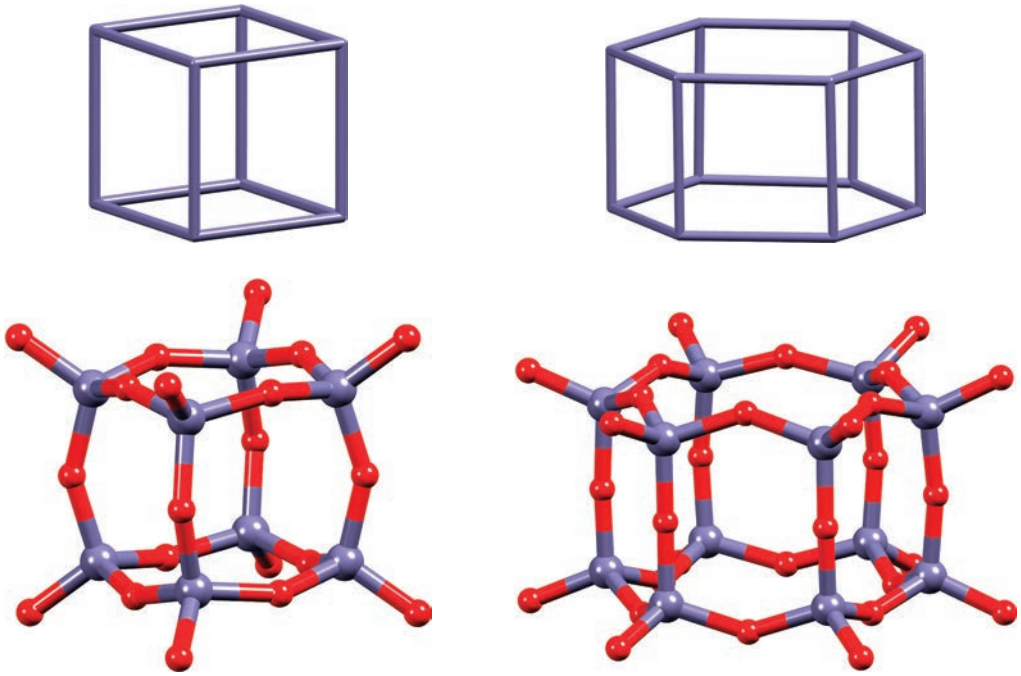

Fig. 14.24. The structures, elucidated by X-ray diffraction, of (a) $[Si_8O_{20}]^{8-}$, determined for the salt $[Me_4N]_8[Si_8O_{20}]\cdot 65H_2O$ [M. Wiebcke *et al.* (1993) *Microporous Materials*, vol. 2, p. 55], and (b) $[Si_{12}O_{30}]^{12-}$, determined for the salt $K_{12}[\alpha\text{-cyclodextrin}]_2[Si_{12}O_{30}]\cdot 36H_2O$ [K. Benner *et al.* (1997) *Angew. Chem. Int. Ed.*, vol. 36, p. 743]. The silicon atoms in (a) and (b) define a cube and hexagonal prism respectively. Colour code: Si, purple; O, red.

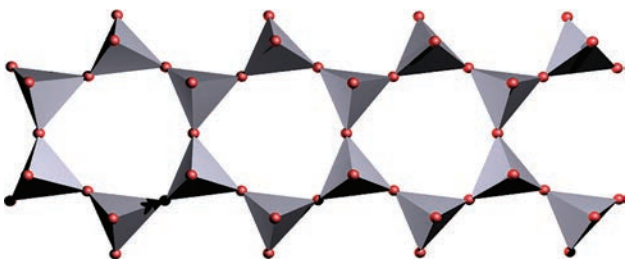

Fig. 14.25. Part of one of the double chains of general formula $[Si_4O_{11}]_n^{6n-}$ present in the mineral tremolite. Compare this representation with that in Fig. 14.23. Each red sphere represents an O atom, and each tetrahedral O_4-unit surrounds an Si atom.

alkylation, xylene isomerization and conversion of methanol to hydrocarbons (for motor fuels). Figure 14.27 illustrates the cavities present in zeolite H-ZSM-5.[†] Electrical neutrality upon Al-for-Si replacement can also be achieved by converting O^- to a terminal OH group. These groups are strongly acidic, which means that such zeolites are excellent ion-exchange (see Section 11.6) materials and have applications in, for example, water purification and washing powders (see Section 12.7).

[†] Zeolites are generally known by acronyms that reflect the research or industrial companies of origin, e.g. ZSM stands for Zeolite Socony Mobil.

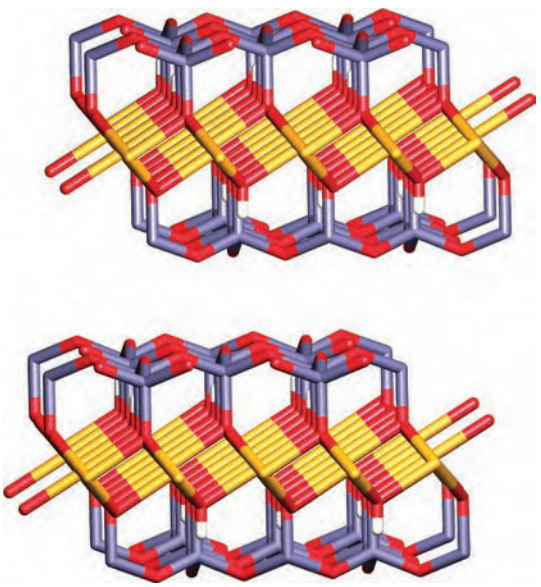

Fig. 14.26. A stick representation of part of two layers in the solid state structure of the mineral talc, $Mg_3(Si_2O_5)_2(OH)_2$. Each Mg^{2+} ion is in an octahedral environment, surrounded by six O atoms. Colour code: Si, purple; O, red; Mg, yellow; H, white.

Zeolites are crystalline, hydrated aluminosilicates that possess framework structures containing regular channels and/or cavities; the cavities contain H_2O molecules and cations (usually group 1 or 2 metal ions).

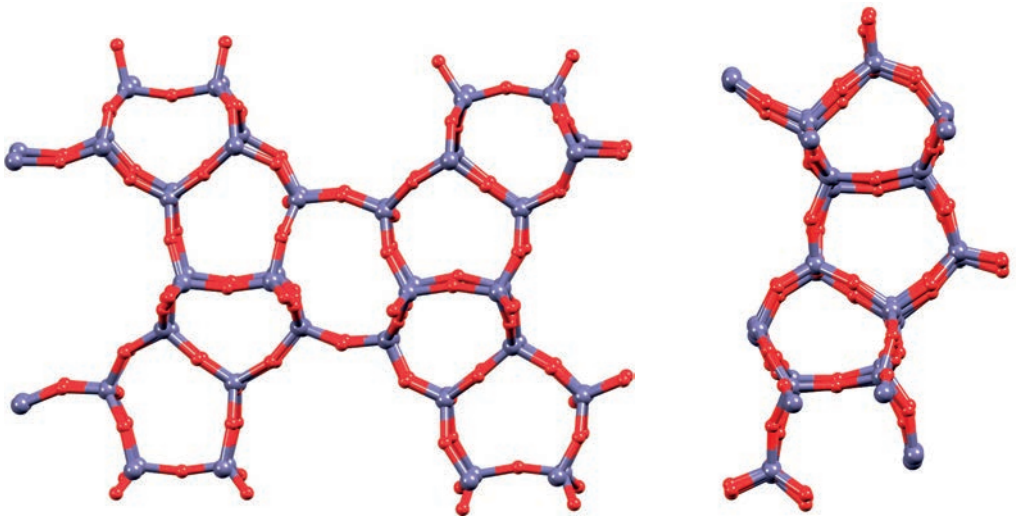

Fig. 14.27. The structure of H-ZSM-5 zeolite ($Al_{0.08}Si_{23.92}O_{48}$) is typical of a zeolite in possessing cavities which can accommodate guest molecules. (a) and (b) show two orthogonal views of the host lattice; the structure was determined by X-ray diffraction for the zeolite hosting 1,4-dichlorobenzene [H. van Koningsveld *et al.* (1996) *Acta Crystallogr., Sect. B*, vol. 52, p. 140]. Colour code: (Si, Al), purple; O, red.

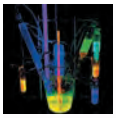
Oxides, hydroxides and oxoacids of germanium, tin and lead

The dioxides of Ge, Sn and Pb are involatile solids. Germanium dioxide closely resembles SiO_2, and exists in both quartz and rutile forms. It dissolves in concentrated HCl forming $[GeCl_6]^{2-}$ and in alkalis to give *germanates*. While these are not as important as silicates, it should be noted that many silicates possess germanate analogues. However, relatively few open-framework germanates (i.e. with structures related to those of zeolites) are known. Although Si and Ge are both group 14 elements, the structural building-blocks in silicates and germanates differ. Whereas silicates are composed of tetrahedral SiO_4-units (Figs. 14.23–14.27), the larger size of Ge allows it to be in GeO_4 (tetrahedral), GeO_5 (square-based pyramidal or trigonal bipyramidal) and GeO_6 (octahedral) environments.[†] For example, the germanate $[Ge_{10}O_{21}(OH)][N(CH_2CH_2NH_3)_3]$, contains 4-, 5- and 6-coordinate Ge atoms. This compound is synthesized by a hydrothermal method (such methods are used for both germanate and zeolite syntheses) using the amine $N(CH_2CH_2NH_2)_3$ to direct the assembly of the 3-dimensional network.

A ***hydrothermal method*** of synthesis refers to a heterogeneous reaction carried out in a closed system in an aqueous solvent with $T > 298$ K and $P > 1$ bar. Such reaction conditions permit the dissolution of reactants and the isolation of products that are poorly soluble under ambient conditions.

[†]Z.-E. Lin and G.-Y. Yang (2010) *Eur. J. Inorg. Chem.*, p. 2895 – 'Germanate frameworks constructed from oxo germanium cluster building units'.



Germanium monoxide is prepared by dehydration of the yellow hydrate, obtained by reaction of $GeCl_2$ with aqueous NH_3, or by heating $Ge(OH)_2$, obtained from $GeCl_2$ and water. The monoxide, which is amphoteric, is not as well characterized as GeO_2, and disproportionates at high temperature (eq. 14.67).

$$2GeO \xrightarrow{970\ K} GeO_2 + Ge \qquad (14.67)$$

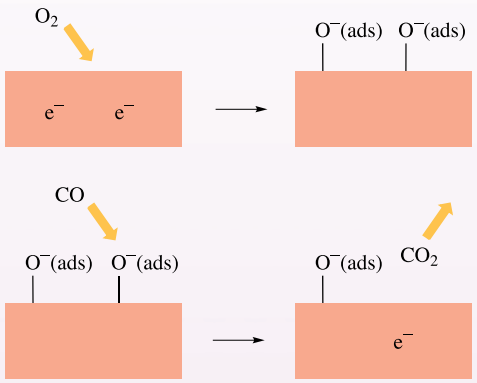
Solid SnO_2 and PbO_2 adopt a rutile-type structure (Fig. 6.24). SnO_2 occurs naturally as cassiterite but can easily be prepared by oxidation of Sn. Tin(IV) oxide is unusual in being an optically transparent, electrical conductor; in Box 14.11, we look at the use of SnO_2 in resistive gas sensors. The formation of PbO_2 requires the action of powerful oxidizing agents such as alkaline hypochlorite on Pb(II) compounds. On heating, PbO_2 decomposes to PbO via a series of other oxides (eq. 14.68). In the last step in the pathway, the reaction conditions favour the decomposition of Pb_3O_4, the O_2 formed being removed. This is in contrast to the conditions used to make Pb_3O_4 from PbO (see the end of Section 14.9).

$$PbO_2 \xrightarrow{566\ K} Pb_{12}O_{19} \xrightarrow{624\ K} Pb_{12}O_{17} \xrightarrow{647\ K} Pb_3O_4 \xrightarrow{878\ K} PbO \qquad (14.68)$$

When freshly prepared, SnO_2 is soluble in many acids (eq. 14.69) but it exhibits amphoteric behaviour and also

APPLICATIONS

Box 14.11 Sensing gases



Tin(IV) oxide is of significant commercial value because it is an optically transparent, electrical conductor. Its three main applications are in gas sensors, as a transparent conducting oxide, and as an oxidation catalyst. We focus here on the first of these uses.

Tin(IV) oxide is classed as a wide band-gap (3.6 eV) n-type semiconductor. In a stoichiometric form, SnO_2 is an insulator. However, intrinsic oxygen deficiency renders it non-stoichiometric (see Section 6.18) and leads to electrical conductance. The conductivity can be increased by doping (e.g. with Pd) which modifies the band structure (see Section 6.8). In the presence of reducing gases such as CO, the electrical conductivity of SnO_2 increases, and it is this phenomenon that is the basis for the use of SnO_2 in resistive gas sensors. Other metal oxides that show a change in electrical conductivity in response to the presence of certain gases include In_2O_3, GeO_2, TiO_2, Mn_2O_3, CuO, ZnO, WO_3, MoO_3, Nb_2O_5 and CeO_2. In commercial sensors, SnO_2 and ZnO are by far the most commonly used metal oxides. Detecting the presence of toxic gases can be carried out by, for example, IR spectroscopic means, but such techniques do not lend themselves to regular monitoring of industrial and domestic environments. Solid state gas sensors are advantageous because they can monitor levels of gases continuously, and are relatively inexpensive. Sensors that detect gases such as CO, hydrocarbons or solvent (alcohols, ketones, esters, etc.) vapours at a parts-per-million (ppm) level are now in common use in underground car parking garages, automatic ventilation systems, fire alarms and gas-leak detectors. The presence of even small amounts of the target gases results in a significant increase in the electrical conductivity of SnO_2, and this change provides a measure of the gas concentration, triggering a signal or alarm if a pre-set threshold level is detected.

The increase in electrical conductivity that arises in the presence of a reducing gas also depends on the presence of O_2. The SnO_2 in a sensor is usually in the form of a porous, thick film which has a high surface area. Adsorption of O_2 onto a SnO_2 surface draws electrons from the conduction band. Below ≈420 K, the adsorbed oxygen is in the form of O_2^-, while above this temperature, O^- and O^{2-} are present. The presence of paramagnetic O_2^- and O^- has been evidenced by using EPR spectroscopy (see Section 4.9). The operating temperature of an SnO_2 sensor is 450–750 K and in the presence of a reducing gas such as CO or hydrocarbon, the SnO_2 surface loses oxygen in a process that may be represented as:

$$CO(g) + O^-(surface) \longrightarrow CO_2(g) + e^-$$

The electrons that are released are conducted through the solid and return to the conduction band, thereby producing an increase in the electrical conductivity of the material. The process is illustrated schematically below where O^-(ads) represents an O^- ion adsorbed on the SnO_2 surface:

Tin(IV) oxide sensors play a major role in the commercial market and can be used to detect CO, CH_4, C_2H_5OH vapour, H_2 and NO_x. Other sensor materials include:

- ZnO, Ga_2O_3 and TiO_2/V_2O_5 for CH_4 detection;
- La_2CuO_4, Cr_2O_3/MgO and $Bi_2Fe_4O_9$ for C_2H_5OH vapour detection;
- ZnO, Ga_2O_3, ZrO_2 and WO_3 for H_2 detection;
- ZnO, TiO_2 (doped with Al and In) and WO_3 for NO_x;
- ZnO, Ga_2O_3, Co_3O_4 and TiO_2 (doped with Pt) for CO detection;
- WO_3 for O_3 detection at a parts-per-billion (ppb) level.

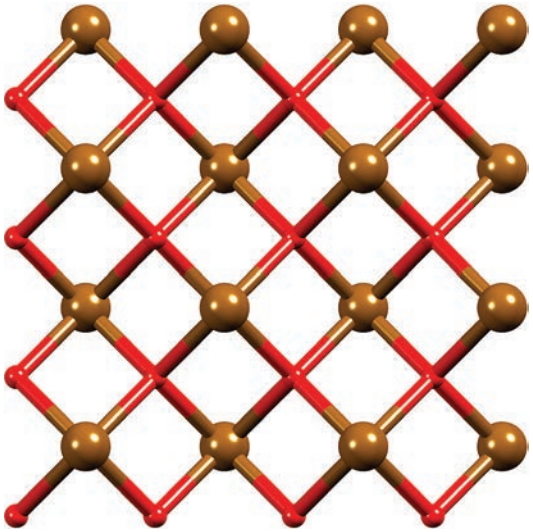

Fig. 14.28. Part of one layer of the SnO and red PbO lattices. Colour code: Sn, Pb, brown; O, red.

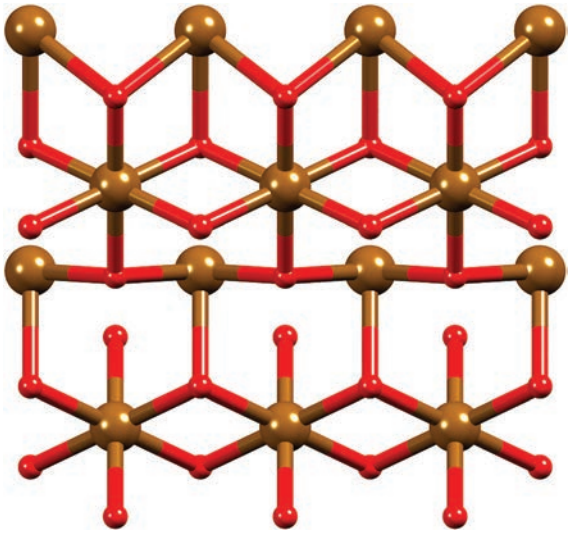

Fig. 14.29. Part of the network structure of Pb_3O_4 (i.e. $2PbO{\cdot}PbO_2$) showing the interconnected chains of octahedral $\{Pb^{(IV)}O_6\}$-units and trigonal pyramidal $\{Pb^{(II)}O_3\}$-units. Colour code: Pb, brown; O, red.

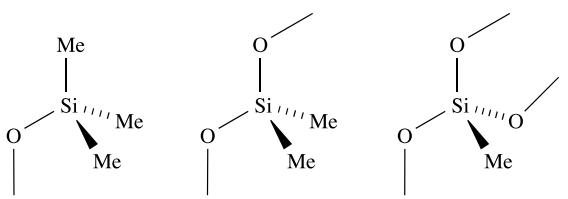
reacts with alkalis; reaction 14.70 occurs in strongly alkaline media to give a stannate.

$$SnO_2 + 6HCl \longrightarrow 2[H_3O]^+ + [SnCl_6]^{2-} \quad (14.69)$$

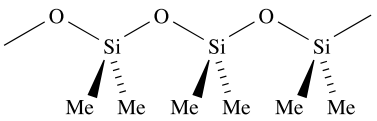
$$SnO_2 + 2KOH + 2H_2O \longrightarrow K_2[Sn(OH)_6] \quad (14.70)$$

In contrast, PbO_2 shows acidic (but no basic) properties, forming $[Pb(OH)_6]^{2-}$ when treated with alkali. Crystalline salts such as $K_2[Sn(OH)_6]$ and $K_2[Pb(OH)_6]$ can be isolated.



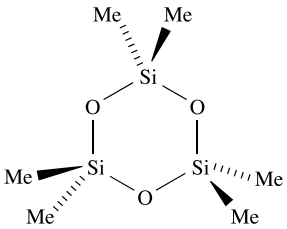
The monoxides SnO (the form which is stable under ambient conditions is blue-black in colour) and PbO (red form, *litharge*) possess layer structures in which each metal centre is at the apex of a square-based pyramidal array (Fig. 14.28). Each metal centre bears a lone pair of electrons occupying an orbital pointing towards the space between the layers, and electronic effects contribute to the preference for this asymmetric structure. Litharge is the more important form of PbO, but a yellow form also exists. While PbO can be prepared by heating the metal in air above 820 K, SnO is sensitive to oxidation and is best prepared by thermal decomposition of tin(II) oxalate. PbO can also be made by dehydrating $Pb(OH)_2$. Both SnO and PbO are amphoteric, but the oxoanions formed from them, like those from GeO, are not well characterized. Of the group 14 elements, only lead forms a mixed oxidation state oxide: Pb_3O_4 (*red lead*) is obtained by heating PbO in an excess of air at 720–770 K, and is better formulated as $2PbO{\cdot}PbO_2$. The solid state structure of Pb_3O_4 consists of chains of edge-sharing $\{Pb^{(IV)}O_6\}$-octahedra linked together by trigonal pyramidal $\{Pb^{(II)}O_3\}$-units (Fig. 14.29). Nitric acid reacts with Pb_3O_4 (according to eq. 14.71), while treatment with glacial acetic acid yields a mixture of $Pb(CH_3CO_2)_2$ and $Pb(CH_3CO_2)_4$, the latter compound being an important reagent in organic chemistry; the two acetate salts can be separated by crystallization.

$$Pb_3O_4 + 4HNO_3 \longrightarrow PbO_2 + 2Pb(NO_3)_2 + 2H_2O \quad (14.71)$$



14.10 Siloxanes and polysiloxanes (silicones)

Although siloxanes are often classed as organometallic compounds, they are conveniently described in this chapter because of their structural relationship to silicates. Hydrolysis of Me_nSiCl_{4-n} ($n = 1$–3) might be expected to give the derivatives $Me_nSi(OH)_{4-n}$ ($n = 1$–3). By analogy with carbon analogues, we might expect Me_3SiOH to be stable (except with respect to dehydration at higher temperatures), but would expect $Me_2Si(OH)_2$ and $MeSi(OH)_3$ to undergo dehydration to $Me_2Si{=}O$ and $MeSiO_2H$ respectively. However, at the beginning of Section 14.9, we indicated that an Si=O bond is energetically less favourable than two Si−O bonds. As a consequence, hydrolysis of Me_nSiCl_{4-n} ($n = 1$–3) yields *siloxanes* which are oligomeric products (e.g. reaction 14.72) containing the tetrahedral groups **14.24–14.26** in which each O atom represents part of an Si−O−Si bridge. Diols can condense to give chains (**14.26**) or rings (e.g. **14.27**). Hydrolysis of $MeSiCl_3$ produces a cross-linked polymer.

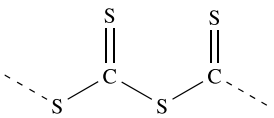


$$2Me_3SiOH \longrightarrow Me_3SiOSiMe_3 + H_2O \quad (14.72)$$

(14.24) **(14.25)** **(14.26)**

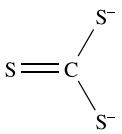
(14.27)

(14.28)



Polysiloxanes (often referred to as silicones) have a range of structures and applications (see Box 14.12), and, in their manufacture, control of the polymerization is essential. The methylsilicon chlorides are co-hydrolysed, or the initial products of hydrolysis are equilibrated by heating with H_2SO_4 which catalyses the conversion of cyclic oligomers into chain polymers, bringing about redistribution of the terminal $OSiMe_3$ groups. For example, equilibration of $HOSiMe_2(OSiMe_2)_nOSiMe_2OH$ with $Me_3SiOSiMe_3$ leads to the polymer $Me_3Si(OSiMe_2)_nOSiMe_3$. Cross-linking, achieved by co-hydrolysis of Me_2SiCl_2 and $MeSiCl_3$, leads, after heating at 520 K, to silicone resins that are hard and inert. Tailoring the product so that it possesses a smaller degree of cross-linking results in the formation of silicone rubbers.

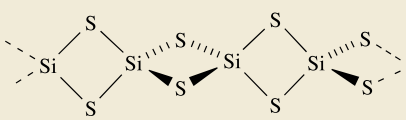
14.11 Sulfides



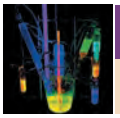
The disulfides of C, Si, Ge and Sn show the gradation in properties that might be expected to accompany the increasingly metallic character of the elements. Some properties of these sulfides are given in Table 14.6. Lead(IV) is too powerful an oxidizing agent to coexist with S^{2-}, and lead(IV) sulfide is not known.

Carbon disulfide is made by heating charcoal with sulfur at 1200 K, or by passing CH_4 and sulfur vapour over Al_2O_3 at 950 K. It is highly toxic (by inhalation and absorption through the skin) and extremely flammable, but is an excellent solvent which is used in the production of rayon and cellophane. Carbon disulfide is insoluble in water, but is, by a narrow margin, thermodynamically unstable with respect to hydrolysis to CO_2 and H_2S. However, this reaction has a high kinetic barrier and is very slow. Unlike CO_2, CS_2 polymerizes under high pressure to give a black solid with the chain structure **14.29**. When shaken with solutions of group 1 metal sulfides, CS_2 dissolves readily to give trithiocarbonates, M_2CS_3, which contain the $[CS_3]^{2-}$ ion **14.30**. The $[CS_3]^{2-}$ ion can also be made by the reaction of CS_2 with group 1 metal hydroxides in polar solvents. Salts of $[CS_3]^{2-}$ are readily isolated, e.g. Na_2CS_3 forms yellow needles (mp 353 K). The free acid H_2CS_3 separates as an oil when salts are treated with hydrochloric acid (eq. 14.73), and behaves as a weak acid in aqueous solution: $pK_a(1) = 2.68$, $pK_a(2) = 8.18$.

$$BaCS_3 + 2HCl \xrightarrow{273\ K} BaCl_2 + H_2CS_3 \qquad (14.73)$$



(14.29)



(14.30)

The action of an electric discharge on CS_2 results in the formation of C_3S_2, **14.31** (compare with **14.19**), a red liquid which decomposes at room temperature, producing a black polymer $(C_3S_2)_x$. When heated, C_3S_2 explodes. In contrast to CO, CS is a short-lived radical species which

Table 14.6 Selected properties of ES_2 (E = C, Si, Ge, Sn).

Property	CS_2	SiS_2	GeS_2	SnS_2
Melting point / K	162	1363 (sublimes)	870 (sublimes)	873 (dec.)
Boiling point / K	319	–	–	–

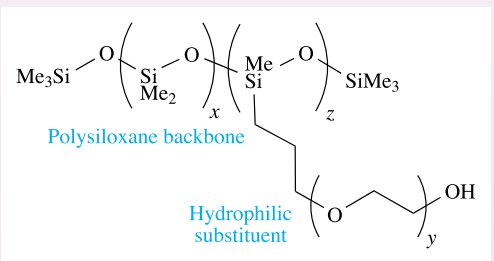
Structure at 298 K	Linear molecule S=C=S	Solid state, chain† 	3-Dimensional lattice with Ge_3S_3 and larger rings with shared vertices†	CdI_2-type structure (see Fig. 6.25)

† At high pressures and temperatures, SiS_2 and GeS_2 adopt a β-cristobalite lattice (see Fig. 6.22c).



APPLICATIONS

Box 14.12 Diverse applications of siloxane polymers (silicones)

Siloxane polymers (known in the commercial market as silicones) have widespread applications including personal care products, greases, sealants, varnishes, waterproofing materials, synthetic rubbers and gas-permeable membranes such as those used in soft contact lenses. Medical applications are increasing in importance, although the use of silicone breast implants is controversial because of claims of the migration of low molecular weight siloxanes from the implant into the surrounding body tissue.

Siloxane surfactants are crucial ingredients in personal care products: they are the components of shampoos and conditioners that improve the softness and silkiness of hair, and are also used in shaving foams, toothpastes, antiperspirants, cosmetics, hair-styling gels and bath oils. These applications follow from a combination of properties, e.g. low surface tension, water-solubility or dispersion in water to give emulsions, and low toxicity. Some of these properties contrast sharply with those required by polysiloxanes used in, for example, greases, sealants and rubbers. Siloxane surfactants contain a permethylated backbone which incorporates polar substituents. For example, polyether groups are hydrophilic and allow the polymers to be used in aqueous media, a prerequisite for use in shampoos and hair conditioners:

Silicone fluids cover a diverse range of polysiloxanes with uses that include lubricants, hydraulic fluids, water repellents, power transmission fluids and paint additives. Polydimethylsiloxane, $\{–SiMe_2O–\}_n$ (PDMS), and polymethylphenylsiloxane, $\{–SiMePhO–\}_n$, fluids are particularly important. Modifying the organic substituents is a means of tuning the properties of the polymer. For example, the introduction of phenyl substituents gives polymers that are able to withstand higher temperatures than PDMS, while the incorporation of fluoroalkyl groups leads to silicone fluids which can be used as low-temperature lubricants.

Silicone rubbers or *elastomers* are cross-linked polymers, the tensile strength of which is increased by adding a filler, usually 'fumed silica' (a form of SiO_2 with a particularly high surface area). Cross-linking takes place during curing (vulcanization) of the elastomer, which can occur at high temperatures or room temperature, depending on the polymer. For the replication of, for example, a plaster or carved wooden surface, room-temperature vulcanization is used to cross-link a polysiloxane paste which is first applied to the surface. After the curing process, the elastomer is peeled away from the surface, giving a mould that can be used to replicate the original feature. One of the applications of silicone elastomers that has significant potential in nanoscience is *soft-lithography*. This technique was first developed in 1998 by Whitesides, and is increasingly being used for the replication of micro- and nanostructures. The structure or pattern to be copied is coated with liquid PDMS which is then cured to give a polysiloxane elastomer. When removed, the PDMS elastomer serves as a high-resolution 'stamp' for structure replication.

Veins surrounding a skeletal head at 'Bodies . . . The Exhibition' which first opened in the US in 2005. The tissue in the body specimens is permanently preserved by using liquid polysiloxanes followed by a hardening process.

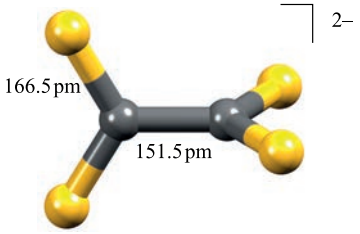
decomposes at 113 K; it has been observed in the upper atmosphere.



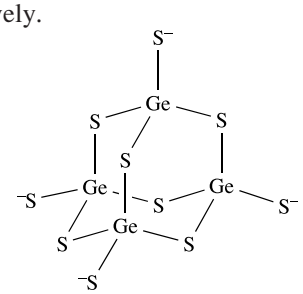
(14.31)

Several salts of the $[C_2S_4]^{2-}$ anion are known and are made by, for example, reaction 14.74. The free acid $H_2C_2S_4$ (an analogue of oxalic acid) has not been isolated.

$$[CH_3CS_2]^- + 2[S_x]^{2-} \longrightarrow [C_2S_4]^{2-} + [HS]^- + H_2S + [S_{2x-4}]^{2-} \qquad (14.74)$$

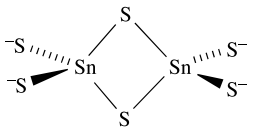
In $[Et_4N]_2[C_2S_4]$, the anion has D_{2d} symmetry, i.e. the dihedral angle between the planes containing the two CS_2-units is 90° (structure **14.32**), whereas in $[Ph_4P]_2[C_2S_4]\cdot 6H_2O$, this angle is 79.5°. Compare these structural data with those for salts of the related oxalate ion, $[C_2O_4]^{2-}$ (structures **14.20** and **14.21**).

(14.32)



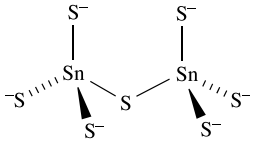
Silicon disulfide is prepared by heating Si in sulfur vapour. Both the structure of this compound (Table 14.6) and the chemistry of SiS_2 show no parallels with SiO_2; SiS_2 is instantly hydrolysed (eq. 14.75).

$$SiS_2 + 2H_2O \longrightarrow SiO_2 + 2H_2S \qquad (14.75)$$



The disulfides of Ge and Sn (Table 14.6) are precipitated when H_2S is passed into acidic solutions of Ge(IV) and Sn(IV) compounds. Some sulfides have cluster structures, e.g. $[Ge_4S_{10}]^{4-}$ (**14.33**), prepared by reaction 14.76.

$$4GeS_2 + 2S^{2-} \xrightarrow{\text{Aqueous solution in presence of } Cs^+} [Ge_4S_{10}]^{4-} \qquad (14.76)$$



Tin(IV) forms a number of thiostannates containing discrete anions, e.g. Na_4SnS_4 contains the tetrahedral $[SnS_4]^{4-}$ ion, and $Na_4Sn_2S_6$ and $Na_6Sn_2S_7$ contain anions **14.34** and **14.35** respectively.

(14.33)

(14.34)

(14.35)

The monosulfides of Ge, Sn and Pb are all obtained by precipitation from aqueous media. Both GeS and SnS crystallize with layer structures similar to that of black phosphorus (see Section 15.4). Lead(II) sulfide occurs naturally as galena and adopts an NaCl-type structure. Its formation as a black precipitate ($K_{sp} \approx 10^{-30}$) is observed in the qualitative test for H_2S (eq. 14.77). The colour and very low solubility of PbS suggest that it is not a purely ionic compound.

$$Pb(NO_3)_2 + H_2S \longrightarrow \underset{\text{black ppt}}{PbS} + 2HNO_3 \qquad (14.77)$$

Pure PbS is a p-type semiconductor when S-rich, and an n-type when Pb-rich (the non-stoichiometric nature of solids is discussed in Section 6.18). It exhibits *photoconductivity* and has applications in photoconductive cells, transistors and photographic exposure meters.

If a material is a ***photoconductor***, it absorbs light with the result that electrons from the valence band are excited into the conducting band. Thus, the electrical conductivity increases on exposure to light.

Worked example 14.7 Tin and lead sulfides

Calculate the solubility of PbS given that $K_{sp} = 10^{-30}$. Is your answer consistent with the fact that PbS is shown as a precipitate in reaction 14.77?

K_{sp} refers to the equilibrium:

$$PbS(s) \rightleftharpoons Pb^{2+}(aq) + S^{2-}(aq)$$

$$K_{sp} = 10^{-30} = \frac{[Pb^{2+}][S^{2-}]}{[PbS]} = [Pb^{2+}][S^{2-}]$$

$$[Pb^{2+}] = [S^{2-}]$$

Therefore, making this substitution in the equation for K_{sp} gives:

$$[Pb^{2+}]^2 = 10^{-30}$$

$$[Pb^{2+}] = 10^{-15}\ \text{mol dm}^{-3}$$

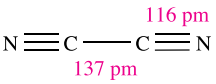
Thus, the extremely low solubility means that PbS will appear as a precipitate in reaction 14.77.

Self-study exercises

1. Describe the coordination environment of each Pb^{2+} and S^{2-} ion in galena. [*Ans.* NaCl structure; see Fig. 6.18]
2. The solubility of SnS in water is 10^{-13} mol dm^{-3}. Calculate a value for K_{sp}. [*Ans.* 10^{-26}]
3. Lead-deficient and lead-rich PbS are p- and n-type semiconductors respectively. Explain the difference between these two types of semiconductors. [*Ans.* see Fig. 6.16 and accompanying discussion]

14.12 Cyanogen, silicon nitride and tin nitride

In discussing bonds formed between the group 14 elements and nitrogen, two compounds of particular importance emerge: cyanogen, C_2N_2, and silicon nitride. Tin(IV) nitride has been prepared more recently.



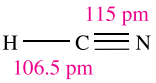
Cyanogen and its derivatives

The $CN^{\bullet}$ radical is a *pseudo-halogen*, i.e. its chemistry resembles that of a halogen atom, X; it forms C_2N_2, HCN and $[CN]^-$, analogues of X_2, HX and X^-. Although C_2N_2 and HCN are thermodynamically unstable with respect to decomposition into their elements, hydrolysis by H_2O, and oxidation by O_2, they and $[CN]^-$ are *kinetically* stable enough for them to be well-established and much studied species.

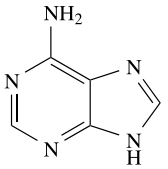
Cyanogen, C_2N_2, is a toxic, extremely flammable gas (mp 245 K, bp 252 K) which is liable to react explosively with some powerful oxidants. Although $\Delta_f H^o(C_2N_2, 298\,K) = +297\,kJ\,mol^{-1}$, pure C_2N_2 can be stored for long periods without decomposition. Reactions 14.78 and 14.79 give two syntheses of C_2N_2; reaction 14.79 illustrates the pseudo-halide like nature of $[CN]^-$ which is oxidized by Cu(II) in an analogous fashion to the oxidation of I^- to I_2. Cyanogen is manufactured by air-oxidation of HCN over a silver catalyst.

$$Hg(CN)_2 + HgCl_2 \xrightarrow{570\,K} C_2N_2 + Hg_2Cl_2 \qquad (14.78)$$

$$2CuSO_4 + 4NaCN \xrightarrow{\text{aqueous solution, } \Delta} C_2N_2 + 2CuCN + 2Na_2SO_4 \qquad (14.79)$$



(14.36)



Cyanogen has the linear structure **14.36** and the short C−C distance indicates considerable electron delocalization. It burns in air with a very hot, violet flame (eq. 14.80), and resembles the halogens in that it is hydrolysed by alkali (eq. 14.81) and undergoes thermal dissociation to $CN^{\bullet}$ at high temperatures.

$$C_2N_2 + 2O_2 \longrightarrow 2CO_2 + N_2 \qquad (14.80)$$

$$C_2N_2 + 2[OH]^- \longrightarrow [OCN]^- + [CN]^- + H_2O \qquad (14.81)$$

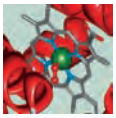
(14.37)

(14.38)

Hydrogen cyanide, HCN, **14.37**, is an extremely toxic and flammable, colourless volatile liquid (mp 260 K, bp 299 K) with a high dielectric constant due to strong hydrogen bonding. It has a characteristic smell of bitter almonds. The pure liquid polymerizes and in the absence of a stabilizer such as H_3PO_4, polymerization may be explosive. In the presence of traces of H_2O and NH_3, HCN forms adenine, **14.38**, and on reduction, gives $MeNH_2$. It is thought that HCN was one of the small molecules in the early atmosphere of the Earth, and played an important role in the formation of many biologically important compounds. Hydrogen cyanide is prepared on a small scale by adding acid to NaCN, and industrially by reactions 14.82 and 14.83.

$$2CH_4 + 2NH_3 + 3O_2 \xrightarrow[1250-1550\,K,\,2\,bar]{Pt/Rh,} 2HCN + 6H_2O \qquad (14.82)$$

$$CH_4 + NH_3 \xrightarrow{Pt,\ 1450-1550\,K} HCN + 3H_2 \qquad (14.83)$$



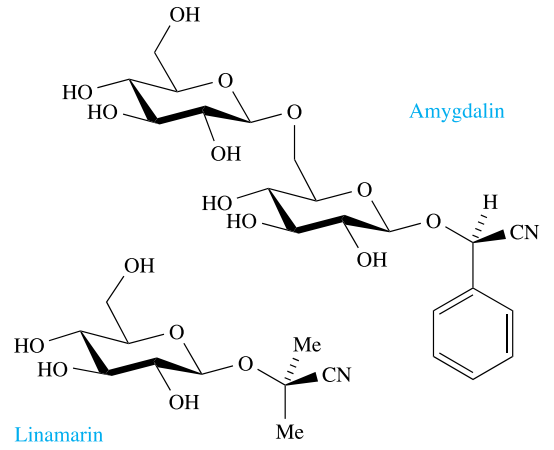
Many organic syntheses involve HCN, and it is of great industrial importance, a large fraction going into the production of 1,4-dicyanobutane (adiponitrile) for nylon manufacture, and cyanoethene (acrylonitrile) for production of acrylic fibres.

In aqueous solution, HCN behaves as a weak acid ($pK_a = 9.31$) and is slowly hydrolysed (eq. 14.84). An older name for hydrocyanic acid is prussic acid.

$$HCN + 2H_2O \longrightarrow [NH_4]^+ + [HCO_2]^- \qquad (14.84)$$

$$2HCN + Na_2CO_3 \xrightarrow{\text{aqueous solution}} 2NaCN + H_2O + CO_2 \qquad (14.85)$$

The neutralization of aqueous HCN by Na_2CO_3, $NaHCO_3$ or $Na[HCO_2]$ generates NaCN, the most important salt of the acid. It is manufactured by reaction 14.85, and has widespread uses in organic chemistry (e.g. for the formation of



BIOLOGY AND MEDICINE

Box 14.13 Hydrogen cyanide in plant material

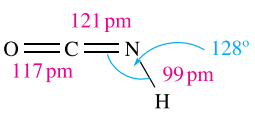
A number of plants (e.g. cassava, sugar cane, some varieties of white clover) and fruits are natural sources of HCN. The origins of the HCN are cyanoglucosides such as *amygdalin* (e.g. in almonds, peach and apricot stones, apple seeds) and *linamarin* (in cassava). The release of HCN from certain plants (cyanogenesis) occurs in the presence of specific enzymes. For example, the enzyme *linamarase* is present in the cell walls of cassava plants. Crushing or chewing cassava root results in release of linamarase, allowing it to act on its cyanoglucoside substrate linamarin. Initially $Me_2C(OH)CN$ is released, and this rapidly produces HCN. Cassava is an important root crop grown in tropical regions as a source of starch, e.g. it is used for the production of tapioca. Cassava plants may be either a sweet or a bitter variety. The HCN content ranges from 250 to 900 mg kg^{-1} depending on variety (compare this with a lethal dose of HCN of 1 mg per kg body weight). Bitter cassava contains the greatest amounts of cyanoglucosides, and in order to produce it as a foodstuff, it must be subjected to careful treatment of shredding, pressure and heat. This cleaves the cyanoglucoside, thereby removing HCN prior to human consumption of the foodstuff. A beneficial side effect of cyanoglucosides in plants is that they act as a natural, chemical defence, for example, against insects and rodents.

Further reading

D.A. Jones (1998) *Phytochemistry*, vol. 47, p. 155 – 'Why are so many plants cyanogenic?'

Apricot stones contain amygdalin.

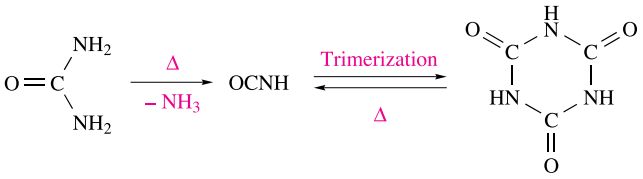
C–C bonds). NaCN is also used in the extraction of Ag and Au (see eq. 22.4). At 298 K, NaCN and KCN adopt an NaCl-type structure, each $[CN]^-$ ion freely rotating (or having random orientations) about a fixed point in the lattice and having an effective ionic radius of ≈190 pm. At lower temperatures, transitions to structures of lower symmetry occur, e.g. NaCN undergoes a cubic to hexagonal transition below 283 K. Crystals of NaCN and KCN are deliquescent, and both salts are soluble in water and are highly toxic. Fusion of KCN and sulfur gives potassium thiocyanate, KSCN.



Mild oxidizing agents convert $[CN]^-$ to cyanogen (eq. 14.79) but with more powerful oxidants such as PbO or *neutral* $[MnO_4]^-$, cyanate ion, **14.39**, is formed (reaction 14.86). Potassium cyanate reverts to the cyanide on heating (eq. 14.87).

$$PbO + KCN \longrightarrow Pb + K[OCN] \qquad (14.86)$$

$$2K[OCN] \xrightarrow{\Delta} 2KCN + O_2 \qquad (14.87)$$

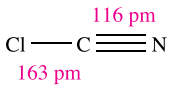


(14.39)

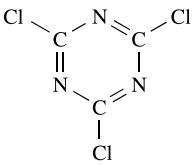
(14.40)

Two acids can be derived from **14.39**: HOCN (cyanic acid or hydrogen cyanate) and HNCO (isocyanic acid, **14.40**). It has been established that HOCN and HNCO are not in equilibrium with each other. Isocyanic acid ($pK_a = 3.66$) is obtained by heating urea (eq. 14.88) but rapidly

trimerizes, although heating the trimer regenerates the monomer.



keto-Tautomer of cyanuric acid



(14.88)

The fulminate ion, $[CNO]^-$, is an isomer of the cyanate ion. Fulminate salts can be reduced to cyanides but cannot be prepared by oxidation of them. The free acid readily polymerizes but is stable for short periods in Et_2O at low temperature. Metal fulminates are highly explosive. Mercury(II) fulminate may be prepared by reaction 14.89 and is a dangerous detonator.

$$2Na[CH_2NO_2] + HgCl_2 \longrightarrow Hg(CNO)_2 + 2H_2O + 2NaCl \quad (14.89)$$

(14.41)

(14.42)

Cyanogen chloride, **14.41** (mp 266 K, bp 286 K), is prepared by the reaction of Cl_2 with NaCN or HCN, and readily trimerizes to **14.42**, which has applications in the manufacture of dyestuffs and herbicides.

Self-study exercises

1. Draw resonance structures for $[NCO]^-$ and $[CNO]^-$.
2. Draw structures of each of the $[HCO_2]^-$ (eq. 14.84) and $[HCO_3]^-$ ions.
3. Describe the bonding in cyanogen using appropriate hybridization schemes.

Silicon nitride

Silicon nitride, Si_3N_4, has wide applications as a ceramic and refractory material and in the form of whiskers (see Section 28.6). It is a white, chemically inert amorphous powder, which can be formed by reaction 14.90, or by combining Si and N_2 above 1650 K.

$$SiCl_4 + 4NH_3 \xrightarrow{-4HCl} Si(NH_2)_4 \xrightarrow{\Delta} Si(NH)_2 \xrightarrow{\Delta} Si_3N_4 \quad (14.90)$$

The two most important polymorphs, α- and β-Si_3N_4, possess 3-dimensional structures containing distorted tetrahedral Si atoms, and 3-coordinate, near-planar N atoms. The detailed crystal structures and the presence of lattice defects have been the subject of debate for many years.[†] A denser, harder polymorph, γ-Si_3N_4, has been obtained by high-pressure, high-temperature (15 GPa, >2000 K) fabrication. This polymorph has the spinel structure (see Box 13.7): the N atoms form a cubic close-packed structure in which two-thirds of the Si atoms occupy octahedral holes and one-third occupy tetrahedral holes. The oxide spinels that we discussed in Box 13.7 contained metal ions in the +2 and +3 oxidation states, i.e. $(A^{II})(B^{III})_2O_4$. In γ-Si_3N_4, all the Si atoms are in a single (+4) oxidation state. Another refractory material is Si_2N_2O, made from Si and SiO_2 under N_2/Ar atmosphere at 1700 K. It possesses puckered hexagonal nets of alternating Si and N atoms, the sheets being linked by Si–O–Si bonds.

Tin(IV) nitride

Tin(IV) nitride, Sn_3N_4, was first isolated in 1999 from the reaction of SnI_4 with KNH_2 in liquid NH_3 at 243 K followed by annealing the solid product at 573 K. Sn_3N_4 adopts a spinel-type structure, related to that of γ-Si_3N_4. Tin(IV) nitride is the first nitride spinel found to be stable under ambient conditions.

14.13 Aqueous solution chemistry and salts of oxoacids of germanium, tin and lead

When GeO_2 is dissolved in basic aqueous solution, the solution species formed is $[Ge(OH)_6]^{2-}$. With hydrochloric acid, GeO_2 forms $[GeCl_6]^{2-}$. Although GeO_2 is reduced by H_3PO_2 in aqueous HCl solution and forms the insoluble $Ge(OH)_2$ when the solution pH is increased, it is possible to retain Ge(II) in aqueous solution under controlled conditions. Thus, 6 M aqueous HCl solutions that contain 0.2–0.4 mol dm^{-3} of Ge(II) generated *in situ* (eq. 14.91) are stable for several weeks.

$$Ge^{IV} + H_2O + H_3PO_2 \longrightarrow H_3PO_3 + Ge^{II} + 2H^+ \quad (14.91)$$

Table 14.1 lists standard reduction potentials for the M^{4+}/M^{2+} and M^{2+}/M (M = Sn, Pb) couples. The value of $E^o(Sn^{4+}/Sn^{2+}) = +0.15$ V shows that Sn(II) salts in aqueous solution are readily oxidized by O_2. In addition, hydrolysis of Sn^{2+} to species such as $[Sn_2O(OH)_4]^{2-}$ and $[Sn_3(OH)_4]^{2+}$ is extensive. Aqueous solutions of Sn(II) salts are therefore usually acidified and complex ions are

[†]See: C.-M. Wang, X. Pan, M. Rühle, F.L. Riley and M. Mitomo (1996) *J. Mater. Sci.*, vol. 31, p. 5281; F.L. Riley (2000) *J. Am. Ceram. Soc.*, vol. 83, p. 245; A. Kuwabara, K. Matsunaga and I. Tanaka (2008) *Phys. Rev. B*, vol. 78, article 064104; D. Legut, U.D. Wdowik and P. Kurtyka (2014) *Mater. Chem. Phys.*, vol. 147, p. 42.

then likely to be present, e.g. if $SnCl_2$ is dissolved in dilute hydrochloric acid, $[SnCl_3]^-$ forms. In alkaline solutions, the dominant species is $[Sn(OH)_3]^-$. Extensive hydrolysis of Sn(IV) species in aqueous solution also occurs unless sufficient acid is present to complex the Sn(IV). Thus, in aqueous HCl, Sn(IV) is present as $[SnCl_6]^{2-}$. In alkaline solution at high pH, $[Sn(OH)_6]^{2-}$ is the main species and salts of this octahedral ion, e.g. $K_2[Sn(OH)_6]$, can be isolated.

In comparison with their Sn(II) analogues, Pb(II) salts are much more stable in aqueous solution with respect to hydrolysis and oxidation. The most important *soluble* salts are $Pb(NO_3)_2$ and $Pb(CH_3CO_2)_2$. The fact that many water-insoluble Pb(II) salts dissolve in a mixture of $[NH_4][CH_3CO_2]$ and CH_3CO_2H reveals that Pb(II) is strongly complexed by acetate. Most Pb(II) oxo-salts are, like the halides, sparingly soluble in water; $PbSO_4$ ($K_{sp} = 1.8 \times 10^{-8}$) dissolves in concentrated H_2SO_4.

The Pb^{4+} ion does not exist in aqueous solution, and the value of $E^o(Pb^{4+}/Pb^{2+})$ given in Table 14.1 is for the half-reaction 14.92 which forms part of the familiar lead–acid battery (see eqs. 14.3 and 14.4). For half-reaction 14.92, the fourth-power dependence of the half-cell potential upon $[H^+]$ explains why the relative stabilities of Pb(II) and Pb(IV) depend upon the pH of the solution (see Section 8.2).

$$PbO_2(s) + 4H^+(aq) + 2e^- \rightleftharpoons Pb^{2+}(aq) + 2H_2O(l)$$
$$E^o = +1.45\,V \qquad (14.92)$$

Thus, for example, PbO_2 oxidizes concentrated HCl to Cl_2, but Cl_2 oxidizes Pb(II) in alkaline solution to PbO_2. It may be noted that, thermodynamically, PbO_2 should oxidize water at pH = 0, and the usefulness of the lead–acid battery depends on there being a high overpotential for O_2 evolution.

Yellow crystals of $Pb(SO_4)_2$ may be obtained by electrolysis of fairly concentrated H_2SO_4 using a Pb anode. However, in cold water, it is hydrolysed to PbO_2, as are Pb(IV) acetate and $[NH_4]_2[PbCl_6]$ (see Section 14.8). The complex ion $[Pb(OH)_6]^{2-}$ forms when PbO_2 dissolves in concentrated KOH solution, but on dilution of the solution, PbO_2 is reprecipitated.

KEY TERMS

The following terms were introduced in this chapter. Do you know what they mean?

- ❑ catenation
- ❑ metastable
- ❑ intercalation compound
- ❑ Zintl ion
- ❑ piezoelectric

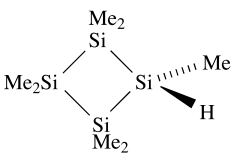
PROBLEMS

14.1 (a) Write down, in order, the names and symbols of the elements in group 14. (b) Classify the elements in terms of metallic, semi-metallic or non-metallic behaviour. (c) Give a *general* notation showing the ground state electronic configuration of each element.

14.2 Comment on the trends in values of (a) melting points, (b) $\Delta_{atom}H^{o}(298\,K)$ and (c) $\Delta_{fus}H^{o}(mp)$ for the elements on descending group 14.

14.3 How does the structure of graphite account for (a) its use as a lubricant, (b) the design of graphite electrodes, and (c) the fact that diamond is the more stable allotrope at very high pressures?

14.4 Figure 14.10 shows a unit cell of K_3C_{60}. From the structural information given, confirm the stoichiometry of this fulleride.



14.5 Give four examples of reactions of C_{60} that are consistent with the presence of C=C bond character.

14.6 Comment on each of the following observations.

(a) The carbides Mg_2C_3 and CaC_2 liberate propyne and ethyne respectively when treated with water, reaction between ThC_2 and water produces mixtures composed mainly of C_2H_2, C_2H_6 and H_2, but no reaction occurs when water is added to TiC.

(b) Mg_2Si reacts with $[NH_4]Br$ in liquid NH_3 to give silane.

(c) Compound **14.43** is hydrolysed by aqueous alkali at the same rate as the corresponding Si–D compound.

(14.43)

14.7 (a) Suggest why the NSi_3 skeleton in $N(SiMe_3)_3$ is planar. (b) Suggest reasons why, at 298 K, CO_2 and SiO_2 are not isostructural. Under what conditions can phases of CO_2 with silica-like structures be made?

14.8 Predict the shapes of the following molecules or ions: (a) ClCN; (b) OCS; (c) $[SiH_3]^-$; (d) $[SnCl_5]^-$; (e) Si_2OCl_6; (f) $[Ge(C_2O_4)_3]^{2-}$; (g) $[PbCl_6]^{2-}$; (h) $[SnS_4]^{4-}$.

14.9 The observed structure of $[Sn_9Tl]^{3-}$ is a bicapped square-antiprism. (a) Confirm that this is consistent with Wade's rules. (b) How many isomers (retaining the bicapped square-antiprism core) of $[Sn_9Tl]^{3-}$ are possible?

14.10 Compare and contrast the structures and chemistries of the hydrides of the group 14 elements, and give pertinent examples to illustrate structural and chemical differences between BH_3 and CH_4, and between AlH_3 and SiH_4.

14.11 Write equations for: (a) the hydrolysis of $GeCl_4$; (b) the reaction of $SiCl_4$ with aqueous NaOH; (c) the 1:1 reaction of CsF with GeF_2; (d) the hydrolysis of SiH_3Cl; (e) the hydrolysis of SiF_4; (f) the 2:1 reaction of $[Bu_4P]Cl$ with $SnCl_4$. In each case suggest the structure of the product containing the group 14 element.

14.12 Rationalize the following signal multiplicities in the ^{119}Sn NMR spectra of some halo-anions and, where possible, use the data to distinguish between geometric isomers [^{19}F 100% $I = \frac{1}{2}$]: (a) $[SnCl_5F]^{2-}$ doublet; (b) $[SnCl_4F_2]^{2-}$ isomer A, triplet; isomer B, triplet; (c) $[SnCl_3F_3]^{2-}$ isomer A, doublet of triplets; isomer B, quartet; (d) $[SnCl_2F_4]^{2-}$ isomer A, quintet; isomer B, triplet of triplets; (e) $[SnClF_5]^{2-}$ doublet of quintets; (f) $[SnF_6]^{2-}$ septet.

14.13 What would you expect to form when:

(a) Sn is heated with concentrated aqueous NaOH;
(b) SO_2 is passed over PbO_2;
(c) CS_2 is shaken with aqueous NaOH;
(d) SiH_2Cl_2 is hydrolysed by water;
(e) four molar equivalents of $ClCH_2SiCl_3$ react with three equivalents of $Li[AlH_4]$ in Et_2O solution?

14.14 Suggest one method for the estimation of each of the following quantities:

(a) $\Delta_r H^o$ for the conversion: GeO_2(quartz) ⟶ GeO_2(rutile);
(b) the Pauling electronegativity value, χ^P, of Si;
(c) the purity of a sample of $Pb(MeCO_2)_4$ prepared in a laboratory experiment.

14.15 By referring to Fig. 8.6, deduce whether carbon could be used to extract Sn from SnO_2 at (a) 500 K; (b) 750 K; (c) 1000 K. Justify your answer.

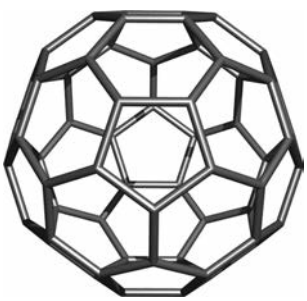
14.16 Comment on the following observations:

(a) the pyroxenes $CaMgSi_2O_6$ and $CaFeSi_2O_6$ are isomorphous;
(b) the feldspar $NaAlSi_3O_8$ may contain up to 10% of $CaAl_2Si_2O_8$;
(c) the mineral *spodumene*, $LiAlSi_2O_6$, is isostructural with *diopside*, $CaMgSi_2O_6$, but when it is heated it is transformed into a polymorph having the quartz structure with the Li^+ ions in the interstices.

14.17 Table 14.7 gives values of the symmetric and asymmetric stretches of the heteronuclear bonds in CO_2, CS_2 and $(CN)_2$, although the molecules are indicated only by the labels I, II and III. (a) Assign an identity to each of I, II and III. (b) State whether the stretching modes listed in Table 14.7 are IR active or inactive.

Table 14.7 Data for problem 14.17.

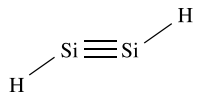
Compound	ν_1(symmetric) / cm^{-1}	ν_3(asymmetric) / cm^{-1}
I	2330	2158
II	658	1535
III	1333	2349



14.18 Account for the fact that when aqueous solution of KCN is added to a solution of aluminium sulfate, a precipitate of $Al(OH)_3$ forms.

14.19 What would you expect to be the hydrolysis products of (a) cyanic acid, (b) isocyanic acid and (c) thiocyanic acid?

14.20 For solid $Ba[CSe_3]$, the vibrational wavenumbers and assignments for the $[CSe_3]^{2-}$ ion are 802 (E', stretch), 420 (A_2''), 290 (A_1') and 185 (E', deformation) cm^{-1}. (a) Based on these assignments, deduce the shape of the $[CSe_3]^{2-}$ ion. (b) Draw diagrams to illustrate the modes of vibration of $[CSe_3]^{2-}$. (c) Which modes of vibration are IR active?



14.21 Deduce the point groups of each of the following molecular species: (a) SiF_4, (b) $[CO_3]^{2-}$, (c) CO_2, (d) SiH_2Cl_2.

14.22 By using the diagram shown below, confirm that C_{60} belongs to the I_h point group.

OVERVIEW PROBLEMS

14.23 (a) By using the description of the bonding in Sn_2R_4 as a guide (see Fig. 23.19), suggest a bonding scheme for a hypothetical HSi≡SiH molecule with the following geometry:

(b) Do you expect the $[FCO]^+$ ion to have a linear or bent structure? Give an explanation for your answer.

(c) The α-form of SnF_2 is a cyclotetramer. Give a description of the bonding in this tetramer and explain why the ring is non-planar.

14.24 Which description in the second list below can be correctly matched to each compound in the first list? There is only one match for each pair.

List 1	List 2
SiF_4	A semiconductor at 298 K with a diamond-type structure
Si	A Zintl ion
Cs_3C_{60}	Its Ca^{2+} salt is a component of cement
SnO	A water-soluble salt that is not decomposed on dissolution
$[Ge_9]^{4-}$	Gas at 298 K consisting of tetrahedral molecules
GeF_2	An acidic oxide
$[SiO_4]^{4-}$	An amphoteric oxide
PbO_2	Solid at 298 K with a sheet structure containing octahedral Sn centres
$Pb(NO_3)_2$	Becomes superconducting at 40 K
SnF_4	An analogue of a carbene

14.25 (a) $[SnF_5]^-$ has a polymeric structure consisting of chains with *cis*-bridging F atoms. Draw a repeat unit of the polymer. State the coordination environment of each Sn atom, and explain how the overall stoichiometry of Sn:F = 1:5 is retained in the polymer.

(b) Which of the salts PbI_2, $Pb(NO_3)_2$, $PbSO_4$, $PbCO_3$, $PbCl_2$ and $Pb(O_2CCH_3)_2$ are soluble in water?

(c) The IR spectrum of ClCN shows absorptions at 1917, 1060 and 230 cm^{-1}. Suggest assignments for these bands and justify your answer.

14.26 Suggest products for the following reactions; the left-hand sides of the equations are not necessarily balanced.

(a) $GeH_3Cl + NaOCH_3 \longrightarrow$

(b) $CaC_2 + N_2 \xrightarrow{\Delta}$

(c) $Mg_2Si + H_2O/H^+ \longrightarrow$

(d) $K_2SiF_6 + K \xrightarrow{\Delta}$

(e) $1,2\text{-}(OH)_2C_6H_4 + GeO_2 \xrightarrow{NaOH/MeOH}$

(f) $(H_3Si)_2O + I_2 \longrightarrow$

(g) $C_{60} \xrightarrow{O_3,\ 257\ K\ in\ xylene} \xrightarrow{296\ K}$

(h) $Sn \xrightarrow{Hot\ NaOH(aq)}$

14.27 (a) Describe the solid state structures of K_3C_{60} and of KC_8. Comment on any physical or chemical properties of the compounds that are of interest.

(b) Comment on the use of lead(II) acetate in a qualitative test for H_2S.

(c) In the $[Et_4N]^+$ salt, the $[C_2S_4]^{2-}$ ion is non-planar; the dihedral angle between the planes containing the two CS_2 groups is 90°. In contrast, in many of its salts, the $[C_2O_4]^{2-}$ ion is planar. Deduce, with reasoning, the point groups of these anions.

14.28 The reaction between a 1,2-ethanediamine solution of $K_4[Pb_9]$ and a toluene solution of $[Pt(PPh_3)_4]$ in the presence of crypt-222 leads to the formation of the platinum-centred Zintl ion $[Pt@Pb_{12}]^{2-}$, the ^{207}Pb NMR spectrum of which consists of a pseudo-triplet ($J_{^{207}Pb^{195}Pt}$ = 3440 Hz).

(a) What is the role of the crypt-222 in the reaction?

(b) Sketch the appearance of the ^{207}Pb NMR spectrum, paying attention to the relative intensities of the components of the triplet. Explain how this signal arises, and indicate on your diagram where the value of $J_{^{207}Pb^{195}Pt}$ is measured.

(c) The ^{195}Pt NMR spectrum of $[Pt@Pb_{12}]^{2-}$ is a non-binomial multiplet. Explain the origins of the coupling pattern. What is the separation (in Hz) of any pair of adjacent lines in the multiplet?

[Data: ^{207}Pb, 22.1% abundant, $I = \frac{1}{2}$; ^{195}Pt, 33.8% abundant, $I = \frac{1}{2}$]

14.29 (a) Equation 14.47 shows the reaction of Na with CCl_4. From the following data, confirm the value of $\Delta_r G^\circ = -1478\,kJ\,mol^{-1}$ at 298 K. Data: $\Delta_f G^\circ(NaCl, s) = -384\,kJ\,mol^{-1}$; $\Delta_f H^\circ(CCl_4, l) = -128.4\,kJ\,mol^{-1}$; $S^\circ(CCl_4, l) = 214\,J\,K^{-1}\,mol^{-1}$; $S^\circ(C, gr) = +5.6\,J\,K^{-1}\,mol^{-1}$; $S^\circ(Cl_2, g) = 223\,J\,K^{-1}\,mol^{-1}$.

(b) Comment on similarities and differences between the structures of β-cristobalite and a non-crystalline silica glass.

INORGANIC CHEMISTRY MATTERS

14.30 Carbon monoxide detectors are in widespread use in the workplace and home. Metal oxide (e.g. SnO_2) semiconductor and electrochemical sensors are commonly used. (a) Explain how an SnO_2 sensor for CO works. (b) An electrochemical sensor employs platinum electrodes with aqueous sulfuric acid as the electrolyte. CO is oxidized at the anode. Write half equations for the anode and cathode reactions. Outline how the cell works as a quantitative sensor for CO.

14.31 Zeolite A is used as a water softener in detergents and washing powders. Industrial production combines hydrated Al_2O_3, aqueous NaOH and Na_4SiO_4. After crystallization, the product (zeolite A) is subject to a number of washing and drying processes before use. (a) Describe the general structural characteristics of a zeolite, and comment on how an aluminosilicate differs from a silicate. (b) By representing zeolite A as Na_xA, suggest how it functions as a water softener.

14.32 The glass industry manufactures millions of tonnes of glass per year. (a) Only certain element oxides form glasses. Explain why this is, giving examples of what are termed in the glass industry as 'network-forming oxides'. Which oxide is the most important starting material in commercial glasses? Explain how a glass differs from a crystalline oxide such as α-Al_2O_3 (corundum). (b) Glass can be 'modified' by adding oxides such as Na_2O or CaO. Suggest how an O^{2-} ion might interact with the original oxide network. What role will the Na^+ or Ca^{2+} ions play in the modified glass? (c) A modified glass is treated with Al_2O_3 and the reaction is represented by the following equation:

$$2[SiO_{3/2}O]^- + 2Na^+ \xrightarrow[-2SiO_2]{Al_2O_3} 2[AlO_{4/2}]^- + 2Na^+$$

Explain the meaning of the fractional notation used in the equation and show schematically how the structure of the glass is altered when Al_2O_3 is added.

14.33 Lead-acid batteries accounted for 69% of all lead consumed in the US in 2015. (a) Complete the cell reaction given below (not balanced on the left-hand side) and show that the oxidation state changes balance in the final equation:

$$PbO_2(s) + Pb(s) + H_2SO_4(aq) \longrightarrow$$

(b) What are the two half-cell reactions in a lead–acid battery? (c) The value of E°_{cell} is 2.05 V. However, a normal automobile battery operates at about 12 V. Explain why the values differ. (d) How is a lead–acid battery recharged?

15.1 Introduction

The group 15 elements – nitrogen, phosphorus, arsenic, antimony, bismuth and muscovium – are called the ***pnictogens***.[†]

The rationalization of the properties of the group 15 elements (nitrogen, phosphorus, arsenic, antimony and bismuth) and their compounds is difficult, despite there being some general similarities in trends of the group 13, 14 and 15 elements, e.g. increase in metallic character and stabilities of lower oxidation states on descending the group. Although the 'diagonal' line (Fig. 7.8) can be drawn between As and Sb, formally separating non-metallic and metallic elements, the distinction is not well defined and should be treated with caution.

Very little of the chemistry of the group 15 elements is that of simple ions. Although metal nitrides and phosphides that react with water are usually considered to contain N^{3-} and P^{3-} ions, electrostatic considerations make it doubtful whether these ionic formulations are correct. The only definite case of a simple cation in a *chemical* environment is that of Bi^{3+}, and nearly all the chemistry of the group 15 elements involves covalently bonded compounds. The thermochemical basis of the chemistry of such species is much harder to establish than that of ionic compounds. In addition, they are much more likely to be *kinetically* inert, both to substitution reactions (e.g. NF_3 to hydrolysis, $[H_2PO_2]^-$ to deuteration), and to oxidation or reduction when these processes involve making or breaking covalent bonds, as well as the transfer of electrons. Nitrogen, for example, forms a range of oxoacids and oxoanions, and in aqueous media can exist in all oxidation states from +5 to −3, e.g. $[NO_3]^-$, N_2O_4, $[NO_2]^-$, NO, N_2O, N_2, NH_2OH, N_2H_4, NH_3. Tables of standard reduction potentials (usually calculated from thermodynamic data) or potential diagrams (see Section 8.5) are of limited use in summarizing the relationships between these species. Although they provide information about the thermodynamics of possible reactions, they say nothing about the kinetics. Much the same is true about the chemistry of phosphorus. The chemistry of the first two members of group 15 is far more extensive than that of As, Sb and Bi, and we can mention only a small fraction of the known inorganic compounds of N and P. In our discussions, we shall need to emphasize *kinetic* factors more than in earlier chapters.

Arsenic is extremely toxic (Box 15.1). Like lead(II) and mercury(II), arsenic(III) is a soft metal centre and interacts with sulfur-containing residues in proteins.

The heaviest element in group 15 is muscovium (Mc, $Z = 115$). It is an artificial element (see Section 27.5) and its discovery and name were confirmed by the IUPAC in

ENVIRONMENT

Box 15.1 Toxicity of arsenic

The toxicity of arsenic is well known, and the element features regularly in crime novels as a poison. A lethal dose is of the order of ≈130 mg. Arsenic occurs naturally in a number of minerals. Leaching of the element gradually occurs giving rise to arsenite, $[AsO_3]^{3-}$, and (predominately) arsenate, $[AsO_4]^{3-}$, salts in natural waters. In West Bengal (India) and Bangladesh, clean drinking water has been obtained from deep-bore wells since the 1970s. While this initially reduced the number of deaths from cholera and other diseases arising from bacteria, the large number of cases of chronic arsenic poisoning had become a major issue by 2000. In test bore wells, concentrations of dissolved arsenic were found to be at a maximum at a depth of about 30–40 m, and hence the depth of the wells is now known to be a key issue.

Despite the known toxicity of arsenic, it was used in agricultural pesticides until replaced by effective organic compounds in the second half of the 20th century. While this use of arsenic declined, its application in the form of chromated copper arsenate (CCA) in wood preservatives showed a general increase between 1980 and 2000 (see the graph below). Wood for a wide range of construction purposes has been treated under high pressure with CCA, resulting in a product with a higher resistance to decay caused by insect and larvae infestation. Typically, 1 m^3 of pressure-treated wood contains approximately 0.8 kg of arsenic, and therefore the total quantities used in the construction and garden landscape businesses pose a major environmental risk. Once pressure-treated wood is destroyed by burning, the residual ash contains high concentrations of arsenic. Wood left to rot releases arsenic into the ground. Added to this, the chromium waste from the wood preservative is also toxic.

The 2002 US Presidential Green Chemistry Challenge Awards (see Box 9.2) recognized the development of a copper-based 'environmentally advanced wood preservative' as a replacement for chromated copper arsenate. The new preservative contains a copper(II) complex and a quaternary ammonium salt. Its introduction into the market coincides with a change of policy within the wood-preserving industry: in 2003, US manufacturers initiated a change from arsenic-based products to alternative wood preservatives. This can be seen in the dramatic fall in CCA-containing wood preservatives in 2004 in the graph below. A number of other countries including Australia, Germany, Japan, Switzerland and Sweden have banned the use of CCA.

[Data: US Geological Survey; 'total' arsenic includes uses in wood preservatives, agricultural chemicals, glass, non-ferrous alloys and electronics.]

2015[†] and 2016, respectively. Like the other superheavy elements, Mc is radioactive and the most stable isotope ^{289}Mc has a half-life of only 220 ms. The lack of chemical data for this newly discovered element means that it is not discussed further in this chapter, and group trends are based upon N to Bi.

15.2 Occurrence, extraction and uses

Occurrence

Figure 15.1a illustrates the relative abundances of the group 15 elements in the Earth's crust. Naturally occurring N_2 makes up 78% (by volume) of the Earth's atmosphere (Fig. 15.1b) and contains ≈0.36% ^{15}N. The latter is useful for isotopic labelling and can be obtained in concentrated form by chemical exchange processes such as equilibria 15.1 and 15.2.

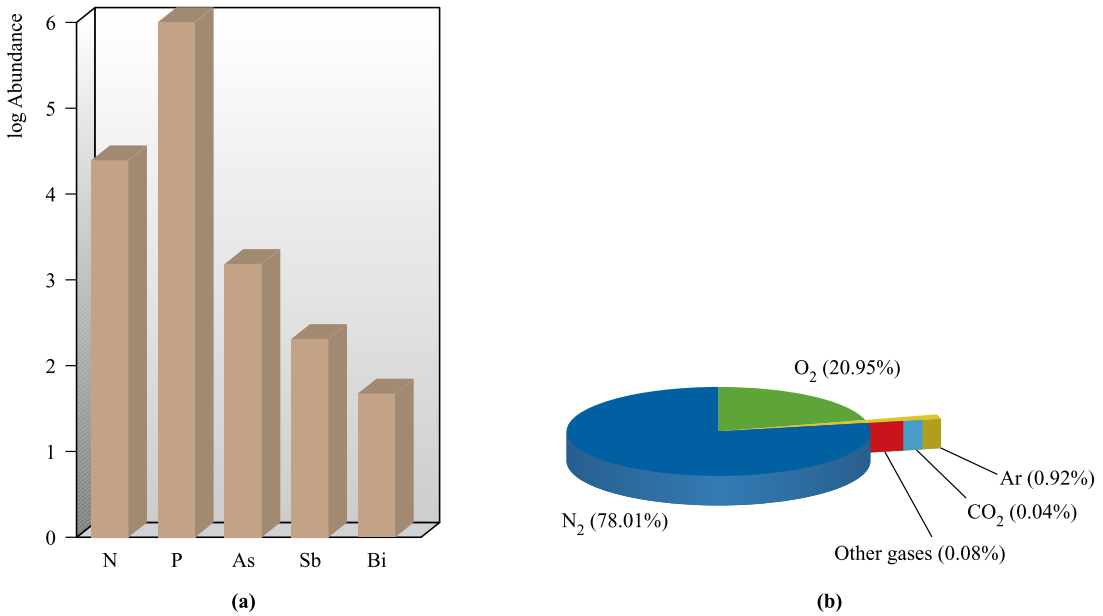

Fig. 15.1. (a) Relative abundances of the group 15 elements in the Earth's crust. Data are plotted on a logarithmic scale; units of abundance are parts per billion (1 billion = 10^9). (b) The main components (by percentage volume) of the Earth's atmosphere.

$$^{15}NH_3(g) + [^{14}NH_4]^+(aq) \rightleftharpoons [^{15}NH_4]^+(aq) + {}^{14}NH_3(g) \quad (15.1)$$

$$^{15}NO(g) + [^{14}NO_3]^-(aq) \rightleftharpoons [^{15}NO_3]^-(aq) + {}^{14}NO(g) \quad (15.2)$$

Because of the availability of N_2 in the atmosphere and its requirement by living organisms (in which N is present as proteins), the *fixing of nitrogen* in forms in which it may be assimilated by plants is of great importance. Attempts to devise synthetic nitrogen-fixation processes (see Section 29.4) that mimic the action of bacteria living in root nodules of leguminous plants have not yet been successful. However, N_2 can be fixed by other processes, e.g. its industrial conversion to NH_3 (see Section 15.5) or the conversion of metal-coordinated N_2 to NH_3 (see Section 25.4). The only natural source of nitrogen suitably 'fixed' for uptake by plants is crude $NaNO_3$ (*Chile saltpetre* or *sodanitre*) which occurs in the deserts of South America.

Phosphorus is an essential constituent of plant and animal tissue. Calcium phosphate occurs in bones and teeth, and phosphate esters of nucleotides (e.g. DNA, Fig. 10.14) are of immense biological significance (see Box 15.11). Phosphorus occurs naturally in the form of *apatites*, $Ca_5X(PO_4)_3$, the important minerals being *fluorapatite* (X = F), *chlorapatite* (X = Cl) and *hydroxyapatite* (X = OH). Major deposits of the apatite-containing ore *phosphate rock* occur in North Africa, North America, Asia and the Middle East. Although arsenic occurs in the elemental form, commercial sources of the element are *mispickel* (*arsenopyrite*, FeAsS), *realgar* (As_4S_4) and *orpiment* (As_2S_3). Native antimony is rare and the only commercial ore is *stibnite* (Sb_2S_3). Bismuth occurs as the element, and as the ores *bismuthinite* (Bi_2S_3) and *bismite* (Bi_2O_3).

Extraction

The industrial separation of N_2 is discussed in Section 15.4. Mining of phosphate rock takes place on a vast scale (in 2014, 218 Mt was mined worldwide), with the majority destined for the production of fertilizers (see Box 15.10) and animal feed supplements. Elemental phosphorus is extracted from phosphate rock (which approximates in composition to $Ca_3(PO_4)_2$) by heating with sand and coke in an electric furnace (eq. 15.3); phosphorus vapour distils out and is condensed under water to yield white phosphorus.

$$2Ca_3(PO_4)_2 + 6SiO_2 + 10C \xrightarrow{\approx 1700\,K} P_4 + 6CaSiO_3 + 10CO \quad (15.3)$$

The principal source of As is FeAsS, and the element is extracted by heating (eq. 15.4) and condensing the As sublimate. An additional method is air-oxidation of arsenic sulfide ores to give As_2O_3 which is then reduced by C. As_2O_3 is also recovered on a large scale from flue dusts in Cu and Pb smelters.

$$FeAsS \xrightarrow{\Delta(\text{in absence of air})} FeS + As \quad (15.4)$$

Antimony is obtained from stibnite by reduction using scrap iron (eq. 15.5) or by conversion to Sb_2O_3 followed by reduction with C.

$$Sb_2S_3 + 3Fe \longrightarrow 2Sb + 3FeS \quad (15.5)$$

The extraction of Bi from its sulfide or oxide ores involves reduction with carbon (via the oxide when the ore is Bi_2S_3), but the metal is also obtained as a by-product of Pb, Cu, Sn, Ag and Au refining processes.

Self-study exercises

1. Calculate $\Delta_rG^o(298\,K)$ for the following reaction, given that values of $\Delta_fG^o(298\,K)$ for $Bi_2O_3(s)$ and CO(g) are -493.7 and $-137.2\,kJ\,mol^{-1}$, respectively:

   $$Bi_2O_3(s) + 3C(gr) \longrightarrow 2Bi(s) + 3CO(g)$$

   Comment on the answer in the light of the fact that carbon is used industrially to extract Bi from Bi_2O_3.

   [*Ans.* $+82.1\,kJ\,mol^{-1}$]

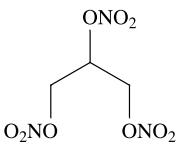
2. Bismuth melts at 544 K, and values of $\Delta_fG^o(Bi_2O_3)$ can be estimated (in $kJ\,mol^{-1}$) by using the following equations:

   $$T = 300-525\ K: \quad \Delta_fG^o(Bi_2O_3) = -580.2 + 0.410T - 0.0209T\log T$$

   $$T = 600-1125\ K: \quad \Delta_fG^o(Bi_2O_3) = -605.5 + 0.478T - 0.0244T\log T$$

   For CO(g), $\Delta_fG^o(300\,K) = -137.3\,kJ\,mol^{-1}$, and $\Delta_fG^o(1100\,K) = -209.1\,kJ\,mol^{-1}$. Use these data to construct a graph that shows the variation in Δ_fG^o of CO and Bi_2O_3 (*in kJ per half-mole of O_2*) with temperature over the range 300–1100 K. What is the significance of the graph in terms of the extraction of Bi from Bi_2O_3 using carbon as the reducing agent?

   [*Ans.* Refer to Fig. 8.6 and related discussion]



Uses

Dinitrogen ranks as one of the most important industrial chemicals, and a large proportion of N_2 is converted to NH_3 (see Box 15.3). Gaseous N_2 is widely used to provide inert atmospheres, both industrially (e.g. in the electronics industry during the production of transistors, etc.) and in laboratories. Liquid N_2 (bp 77 K) is an important coolant (Table 15.1) with applications in some freezing processes. Nitrogen-based chemicals are extremely important, and include nitrogenous fertilizers (see Box 15.3), nitric acid (see Box 15.8) and nitrate salts, explosives such as nitroglycerine (**15.1**) and trinitrotoluene (TNT, **15.2**), nitrite salts (e.g. in the curing of meat where they prevent discoloration by inhibiting oxidation of blood), cyanides and azides (e.g. in motor vehicle airbags where decomposition produces N_2 to inflate the airbag, see eq. 15.6).

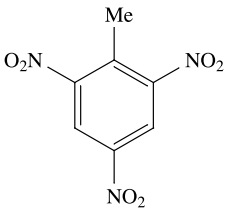


Table 15.1 Selected low-temperature baths involving liquid N_2.[†]

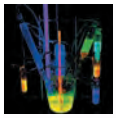
Bath contents	Temperature / K
Liquid N_2 + cyclohexane	279
Liquid N_2 + acetonitrile	232
Liquid N_2 + octane	217
Liquid N_2 + heptane	182
Liquid N_2 + hexa-1,5-diene	132

[†] To prepare a liquid N_2 *slush bath*, liquid N_2 is poured into an appropriate solvent which is constantly stirred. See also Table 14.5.

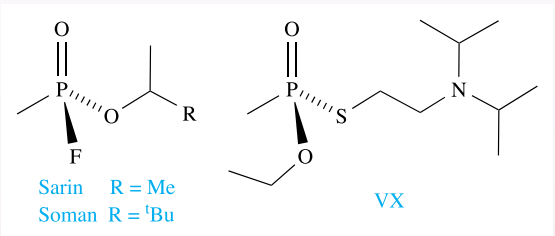
(15.1)



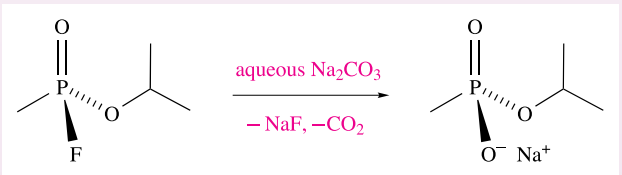
(15.2)

By far the most important application of phosphorus is in phosphate fertilizers, and in Box 15.10 we highlight this use and possible associated environmental problems. Bone ash (calcium phosphate) is used in the manufacture of bone china. Most white phosphorus is converted to H_3PO_4, or to compounds such as P_4O_{10}, P_4S_{10}, PCl_3 and $POCl_3$. Phosphoric acid is industrially very important and is used on a large scale in the production of fertilizers, detergents and food additives. It is responsible for the sharp taste of many soft drinks, and is used to remove oxide and scale from the surfaces of iron and steel. Phosphorus trichloride is also manufactured on a large scale. It is a precursor to many organophosphorus compounds, including nerve agents (see Box 15.2), flame retardants (see Box 17.1) and insecticides. Phosphorus is important in steel manufacture and phosphor bronzes. Red phosphorus (see Section 15.4) is used in safety matches and in the generation of smoke (e.g. fireworks, smoke bombs).

Arsenic salts and arsanes are extremely toxic, and uses of arsenic compounds in weedkillers, sheep- and cattle-dips, and poisons against vermin are less widespread than was once the case (see Box 15.1). Antimony compounds are less toxic, but large doses result in liver damage. Potassium antimony tartrate (*tartar emetic*) was used medicinally as an emetic and expectorant but has now been replaced by less toxic reagents. Bismuth is one of the less toxic heavy metals and compounds, such as the subcarbonate $(BiO)_2CO_3$, find use in stomach remedies including treatments for peptic ulcers.



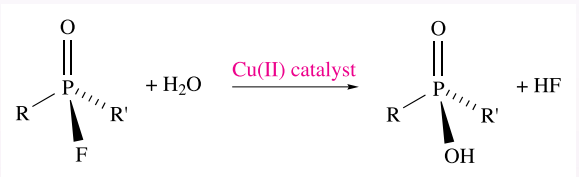
Arsenic is a doping agent in semiconductors (see Section 6.9) and GaAs has widespread uses in solid state devices and semiconductors. Other uses of As include those in alloys (e.g. it increases the strength of Pb) and in batteries. Sb_2O_3 is used in paints, adhesives and plastics, and as a flame retardant (see



APPLICATIONS

Box 15.2 Phosphorus-containing nerve agents

During the second half of the 20th century, the development of organophosphorus nerve agents became coupled not just with their actual use, but with the threat of potential use in acts of terrorism and during war. Nerve agents such as Sarin, Soman and VX tend to be called 'nerve gases' even though they are liquids at room temperature.



Each country signing the 1997 Chemical Weapons Convention agreed to ban the development, production, stockpiling and use of chemical weapons, and to destroy chemical weapons and associated production facilities by 2012. Despite this ban, in 2017, VX was implicated in the death of Kim Jong-nam, a relative of the North Korean leader. A problem for those involved in developing processes of destroying nerve agents is to ensure that the end-products are harmless. Sarin, for example, can be destroyed by room temperature hydrolysis using aqueous Na_2CO_3 to give NaF and the sodium salt of an organophosphate:

Nerve agent VX is more difficult to hydrolyse. It reacts slowly with aqueous NaOH at room temperature, so the reaction is carried out at 360 K for several hours. Hydrolysis follows the two routes shown in the scheme at the bottom of the page. The product in which the P–S bond remains intact is highly toxic. After the hydrolysis stage, the aqueous waste must be processed to render it safe.

Rapid detection of chemical warfare agents in the field is essential. However, analytical techniques such as gas or liquid chromatography are not suitable for routine use out of the laboratory. One method that has been investigated makes use of the release of HF from the hydrolysis of a fluorophosphonate compound (e.g. Sarin). The reaction is catalysed by a copper(II) complex:

The reaction is carried out over a thin film of porous silicon (which contains the copper(II) catalyst), the surface of which has been oxidized. As HF is produced, it reacts with the surface SiO_2 to give gaseous SiF_4:

$$SiO_2 + 4HF \longrightarrow SiF_4 + 2H_2O$$

Porous silicon is luminescent, and the above reaction results in changes in the emission spectrum of the porous silicon and provides a method of detecting the $R_2P(O)F$ agent. Other detection methods that have been investigated include application of carbon nanotubes as sensors for nerve agents.

Box 17.1). Uses of Sb_2S_3 include those in photoelectric devices and electrophotographic recording materials, and as a flame retardant. Major uses of bismuth are in alloys (e.g. with Sn) and as Bi-containing compounds such as BiOCl in cosmetic products (e.g. creams, hair dyes and tints). Other uses are as oxidation catalysts and in high-temperature superconductors. Bi_2O_3 has many uses in the glass and ceramics industry, and for catalysts and magnets. The move towards lead-free solders (see Box 14.3) has resulted in increased use of Bi-containing solders, e.g. Sn/Bi/Ag alloys. A number of other applications are emerging in which Bi substitutes for Pb, for example in bismuth shot for game-hunting.†

15.3 Physical properties

Table 15.2 lists selected physical properties of the group 15 elements. Some observations regarding ionization energies are that:

- they increase rather sharply after removal of the p electrons;
- they decrease only slightly between P and As (similar behaviour to that between Al and Ga, and between Si and Ge);
- for removal of the s electrons, there is an increase between Sb and Bi, just as between In and Tl, and between Sn and Pb (see Box 13.4).

Values of $\Delta_a H^\circ$ decrease steadily from N to Bi, paralleling similar trends in groups 13 and 14.

Worked example 15.1 Thermochemical data for the group 15 elements

At 298 K, the values of the enthalpy changes for the processes:

$$N(g) + e^- \longrightarrow N^-(g)$$

and

$$N(g) + 3e^- \longrightarrow N^{3-}(g)$$

are $\approx$ 0 and 2120 kJ mol^{-1}. Comment on these data.

The ground state electronic configuration of N is $1s^2 2s^2 2p^3$ and the process:

$$N(g) + e^- \longrightarrow N^-(g)$$

† Studies have indicated that bismuth may be not without toxic side-effects: R. Pamphlett *et al.* (2000) *Environ. Res. Sect. A*, vol. 82, p. 258 – 'Tissue uptake of bismuth from shotgun pellets'; N.S.C. Fahey and L.J.S. Leonard (2006) *J. Environ. Monitor.*, vol. 8, p. 1190 – 'Is there a need to re-examine the approval of bismuth shotshell as a non-toxic alternative to lead based on the precautionary principle?'

involves the addition of an electron into a 2*p* atomic orbital to create a spin-paired pair of electrons. Repulsive interactions between the valence electrons of the N atom and the incoming electron would give rise to a positive enthalpy term. This is offset by a negative enthalpy term associated with the attraction between the nucleus and the incoming electron. In the case of nitrogen, these two terms essentially compensate for one another.

The process:

$$N(g) + 3e^- \longrightarrow N^{3-}(g)$$

is highly endothermic. After the addition of the first electron, electron repulsion between the N^- ion and the incoming electron is the dominant term, making the process:

$$N^-(g) + e^- \longrightarrow N^{2-}(g)$$

endothermic. Similarly, the process:

$$N^{2-}(g) + e^- \longrightarrow N^{3-}(g)$$

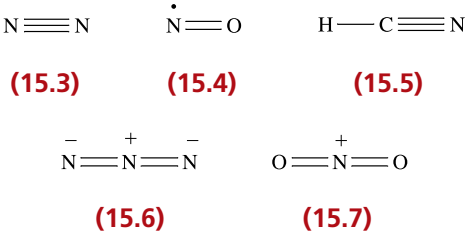
is highly endothermic.

Self-study exercises

1. Comment on reasons for the trend in the first five ionization energies for bismuth (703, 1610, 2466, 4370 and 5400 kJ mol^{-1}).
[*Ans.* Refer to Section 1.10 and Box 13.4]

2. Give an explanation for the trend in values of IE_1 down group 15 (N, 1402; P, 1012; As, 947; Sb, 831; Bi, 703 kJ mol^{-1}). [*Ans.* Refer to Section 1.10]

3. Why is there a decrease in the values of IE_1 on going from N to O, and from P to S?
[*Ans.* Refer to Section 1.10 and Box 1.6]



Bonding considerations

Analogies between groups 14 and 15 are seen if we consider certain bonding aspects. Table 15.3 lists some covalent bond enthalpy terms for group 15 elements. Data for most single bonds follow trends reminiscent of those in group 14 (Table 14.2); e.g. N forms stronger bonds with H than does P, but weaker bonds with F, Cl or O. These observations, together with the absence of stable P-containing analogues of N_2, NO, HCN, $[N_3]^-$ and $[NO_2]^+$ (**15.3–15.7**), indicate that strong $(p–p)\pi$-bonding is important only for the first member of group 15.[†] The N_2 molecule has a short and very strong bond (110 pm and 945 kJ mol^{-1}).

Table 15.3 Some covalent bond enthalpy terms (kJ mol^{-1}); the values for single bonds refer to the group 15 elements in 3-coordinate environments, and values for triple bonds are for dissociation of the appropriate diatomic molecule.

N–N 160	N=N ≈400‡	N≡N 945	N–H 391	N–F 272	N–Cl 193	N–O 201

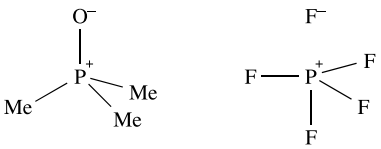
(15.3) **(15.4)** **(15.5)**

(15.6) **(15.7)**



It can be argued that differences between the chemistries of nitrogen and the heavier group 15 elements (e.g. existence of PF_5, AsF_5, SbF_5 and BiF_5, but not NF_5) arise from the fact that an N atom is simply too small to accommodate five atoms around it. Historically, the differences have been attributed to the availability of *d*-orbitals on P, As, Sb and Bi, but not on N. However, even in the presence of electronegative atoms which would lower the energy of the *d*-orbitals, it is now considered that these orbitals play no significant role in hypervalent compounds of the group 15 (and later) elements. As we saw in Chapter 5, it is possible to account for the bonding in hypervalent molecules of the *p*-block elements in terms of a valence set of *ns* and *np* orbitals, and you should be cautious about using sp^3d and sp^3d^2 hybridization schemes to describe trigonal bipyramidal and octahedral species of *p*-block elements. Although we shall show molecular structures of compounds in which P, As, Sb and Bi are in oxidation states of +5 (e.g. PCl_5, $[PO_4]^{3-}$, $[SbF_6]^-$), the representation of a line between two atoms does not necessarily mean the presence of a localized 2-centre 2-electron bond. Similarly,

[†] For an account of attempts to prepare $[PO_2]^+$ by F^- abstraction from $[PO_2F_2]^-$, see: S. Schneider *et al.* (1999) *Z. Anorg. Allg. Chem.*, vol. 627, p. 631.

the representation of a double line between two atoms does not necessarily imply that the interaction comprises covalent σ- and π-contributions. For example, while it is often convenient to draw structures for Me_3PO and PF_5 as:

it is more realistic to show the role that charge-separated species play when one is discussing the electronic distribution in ions or molecules, i.e.

Furthermore, PF_5 should really be represented by a series of resonance structures to provide a description that accounts for the equivalence of the two axial P−F bonds and the equivalence of the three equatorial P−F bonds. When we wish to focus on the *structure* of a molecule rather than on its bonding, charge-separated representations are not always the best option because they often obscure the observed geometry. This problem is readily seen by looking at the charge-separated representation of PF_5, in which the trigonal bipyramidal structure of PF_5 is not immediately apparent.

The largest *difference* between groups 14 and 15 lies in the relative strengths of the N≡N (in N_2) and N−N (in N_2H_4) bonds compared with those of C≡C and C−C bonds (Tables 15.3 and 14.2). There is some uncertainty about a value for the N=N bond enthalpy term because of difficulty in choosing a reference compound, but the approximate value given in Table 15.3 is seen to be *more* than twice that of the N−N bond, whereas the C=C bond is significantly *less* than twice as strong as the C−C bond (Table 14.2). While N_2 is thermodynamically stable with respect to oligomerization to species containing N−N bonds, HC≡CH is thermodynamically unstable with respect to species with C−C bonds, (see end-of-chapter problem 15.2). Similarly, the dimerization of P_2 to tetrahedral P_4 is thermodynamically favourable. The σ- and π-contributions that contribute to the very high strength of the N≡N bond (which makes many nitrogen compounds endothermic and most of the others only *slightly* exothermic) were discussed in Section 2.3. However, the particular weakness of the N−N single bond calls for comment. The O−O ($146\,kJ\,mol^{-1}$ in H_2O_2) and F−F ($159\,kJ\,mol^{-1}$ in F_2) bonds are also very weak, much weaker than S−S or Cl−Cl bonds. In N_2H_4, H_2O_2 and F_2,

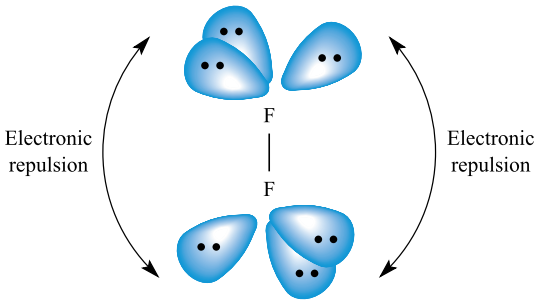


Fig. 15.2. Schematic representation of the electronic repulsion, believed to weaken the F−F bond in F_2. This represents the simplest example of a phenomenon that also occurs in N−N and O−O single bonds.

the N, O or F atoms carry lone pairs, and it is believed that the N−N, O−O and F−F bonds are weakened by repulsion between lone pairs on adjacent atoms (Fig. 15.2). Lone pairs on larger atoms (e.g. in Cl_2) are further apart and experience less mutual repulsion. Each N atom in N_2 also has a non-bonding lone pair, but they are directed away from each other. Table 15.3 illustrates that N−O, N−F and N−Cl are also rather weak and, again, interactions between lone pairs of electrons can be used to rationalize these data. However, when N is singly bonded to an atom with no lone pairs (e.g. H), the bond is strong. In pursuing such arguments, we must remember that in a heteronuclear bond, extra energy contributions may be attributed to partial ionic character (see Section 2.5).

Another important difference between N and the later group 15 elements is the ability of N to take part in strong hydrogen bonding (see Sections 10.6 and 15.5). This arises from the much higher electronegativity of N ($\chi^P = 3.0$) compared with values for the later elements (χ^P values: P, 2.2; As, 2.2; Sb, 2.1; Bi, 2.0). The ability of the first row element to participate in hydrogen bonding is also seen in group 16 (e.g. O−H····O and N−H····O interactions) and group 17 (e.g. O−H····F, N−H····F interactions). For carbon, the first member of group 14, weak hydrogen bonds (e.g. C−H····O interactions) are important in the solid state structures of molecular and biological systems.

NMR active nuclei

Nuclei that are NMR active are listed in Table 15.2. Routinely, ^{31}P NMR spectroscopy is used in characterizing P-containing species; see for example Case studies 1, 2 and 4 and end-of-chapter problem 4.40 in Chapter 4. Chemical shifts are usually reported with respect to $\delta = 0$ for 85% aqueous H_3PO_4, but other reference compounds are used, e.g. trimethylphosphite, $P(OMe)_3$. The chemical shift range for ^{31}P is large.

Self-study exercise

At 307 K, the ^{31}P NMR spectrum of a CD_2Cl_2 solution containing $[PF_5(CN)]^-$ consists of a sextet (δ –157.7 ppm, J_{PF} 744 Hz). At 178 K, the ^{19}F NMR spectrum of the same anion exhibits two signals (δ –47.6 ppm, doublet of doublets; δ –75.3 ppm, doublet of quintets) from which the following coupling constants can be measured: $J_{PF(axial)}$ 762 Hz, $J_{PF(eq)}$ 741 Hz, J_{FF} 58 Hz. (a) Rationalize these observations. (b) Draw a diagram to show the ^{19}F NMR spectrum and mark on it where the values of the coupling constants may be measured.

[*Ans.* 307 K, fluxional; 178 K, static; see Section 4.8]

Radioactive isotopes

Although the only naturally occurring isotope of phosphorus is ^{31}P, 16 man-made radioactive isotopes are known. Of these, ^{32}P is the most important with its half-life of 14.3 days making it suitable as a tracer.

15.4 The elements

Nitrogen

Dinitrogen is obtained industrially by fractional distillation of liquid air, and the product contains some Ar and traces of O_2. Dioxygen can be removed by addition of a small amount of H_2 and passage over a Pt catalyst. The separation of N_2 and O_2 using gas-permeable membranes[†] is growing in importance and is a cheaper alternative to purifying N_2 by the fractional distillation of liquid air. Compared with the latter, N_2 produced by membrane separation is less pure (typically it contains 0.5–5% O_2), and the technology is suited to the production of lower volumes of gas. Nonetheless, the use of gas-permeable membranes is well suited for applications such as the production of inert atmospheres for the storage and transport of fruit and vegetables, or for generating small volumes or low flow-rates of N_2 for laboratory applications. Membranes are made from polymeric materials, the gas permeability of which is selective. The factors which determine this are the solubility of a given gas in the membrane and its rate of diffusion across the membrane. When the N_2/O_2 mixture passes across the surface of the membrane, O_2 permeates through the membrane, leaving the initial stream of gas enriched in the less permeable gas (N_2). Small amounts of N_2 can be prepared by thermal decomposition of sodium azide (eq. 15.6) or by reaction 15.7 or 15.8. The latter should be carried out cautiously because of the risk of explosion. Ammonium nitrite (NH_4NO_2) is potentially explosive, as is ammonium nitrate which is a powerful oxidant and a component of dynamite. In car airbags, the decomposition of NaN_3 is initiated by an electrical impulse.[‡]

$$2NaN_3(s) \xrightarrow{\Delta} 2Na + 3N_2 \qquad (15.6)$$

$$NH_4NO_2(aq) \xrightarrow{\Delta} N_2 + 2H_2O \qquad (15.7)$$

$$2NH_4NO_3(s) \xrightarrow{>570\,K} 2N_2 + O_2 + 4H_2O \qquad (15.8)$$

Dinitrogen is generally unreactive. It combines slowly with Li at ambient temperatures (eq. 11.6), and, when heated, with the group 2 metals, Al, Si, Ge (Section 14.5) and many *d*-block metals. The reaction between CaC_2 and N_2 is used industrially for manufacturing the nitrogenous fertilizer calcium cyanamide (eqs. 14.32 and 14.33). Many elements (e.g. Na, Hg, S) which are inert towards N_2 do react with atomic nitrogen, produced by passing N_2 through an electric discharge. At ambient temperatures, N_2 is reduced to hydrazine (N_2H_4) by vanadium(II) and magnesium hydroxides. The reaction of N_2 with H_2 is discussed later in the chapter.

A large number of *d*-block metal complexes containing coordinated N_2 are known (see Fig. 15.10 and eqs. 22.98 and 22.99 and discussion). N_2 is isoelectronic with CO and the bonding in complexes containing the N_2 ligand can be described in a similar manner to that in metal carbonyl complexes (see Chapter 24).

Phosphorus

Phosphorus exhibits complicated allotropy; 12 forms have been reported, and these include both crystalline and amorphous forms. Crystalline white phosphorus contains tetrahedral P_4 molecules (Fig. 15.3a) in which the P–P distances (221 pm) are used to define $r_{cov} = 110$ pm for a single bond. White phosphorus is *defined* as the standard state of the element, but is actually metastable (eq. 15.9). The lower stability of the white form probably originates in strain associated with the 60° bond angles.

$$\underset{\text{black}}{P} \xleftarrow{\Delta_f H^\circ = -39.3\ kJ\ mol^{-1}} \underset{\text{white}}{\tfrac{1}{4}P_4} \xrightarrow{\Delta_f H^\circ = -17.6\ kJ\ mol^{-1}} \underset{\text{red}}{P} \qquad (15.9)$$

White phosphorus is manufactured by reaction 15.3, and heating this allotrope in an inert atmosphere at ≈540 K

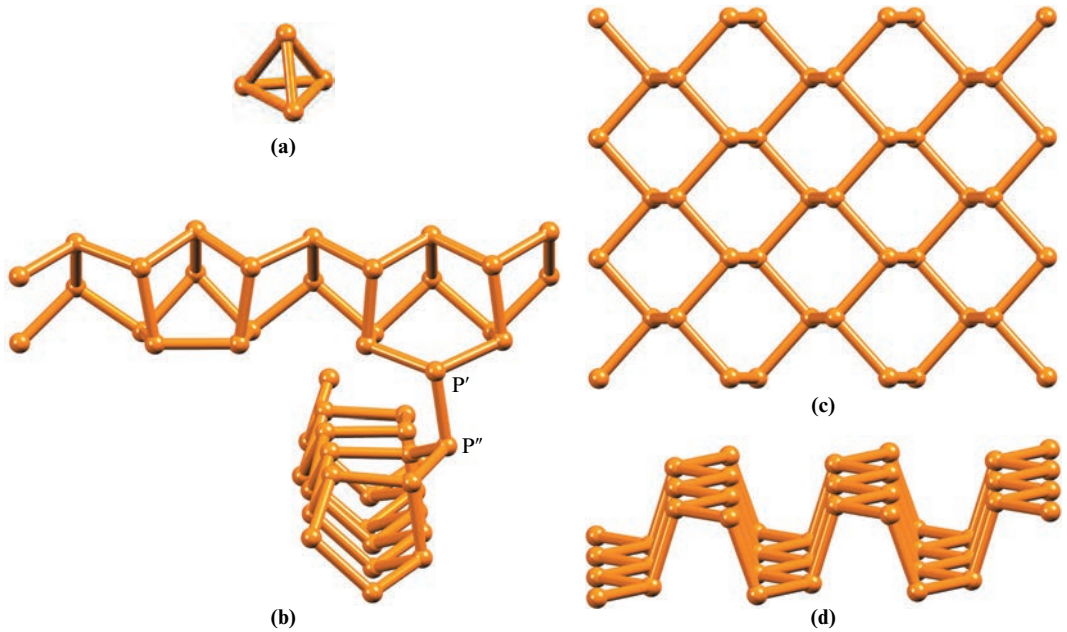

Fig. 15.3. (a) The tetrahedral P_4 molecule found in white phosphorus. (b) Part of two chains present in the infinite lattice of Hittorf's phosphorus; the repeat unit contains 21 atoms, and atoms P' and P" are equivalent atoms in adjacent chains, with chains connected through P'–P" bonds. (c) and (d) Two views of part of one sheet in the layered structure of black phosphorus; the view in (c) shows the 6-membered rings which have a chair conformation and the side view in (d) shows the puckered nature of each layer.

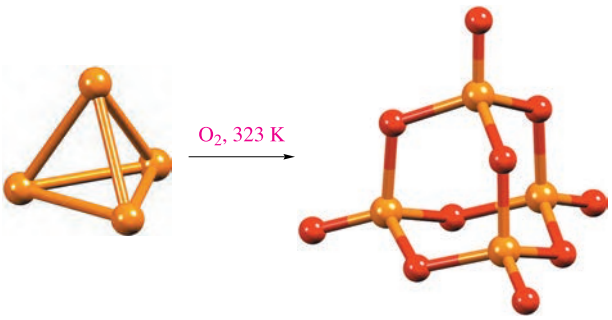
produces red phosphorus. Several crystalline forms of red phosphorus exist.[†] Hittorf's phosphorus (also called violet phosphorus) is a well-characterized form of the red allotrope and its complicated structure is best described in terms of interlocking chains (Fig. 15.3b). Non-bonded chains lie parallel to each other to give layers, and the chains in one layer lie at right-angles to the chains in the next layer, being connected by the P'–P" bonds shown in Fig. 15.3b. All P–P bond distances are ≈222 pm, indicating covalent single bonds. One method of obtaining crystals of Hittorf's phosphorus is to sublime commercially available amorphous red phosphorus under vacuum in the presence of an I_2 catalyst. Under these conditions, another allotrope, fibrous red phosphorus, also crystallizes. Both Hittorf's and fibrous red phosphorus consist of the chains shown in Fig. 15.3b. Whereas in Hittorf's phosphorus pairs of these chains are linked in a mutually perpendicular orientation (Fig. 15.3b), in fibrous phosphorus they lie parallel to one another. Black phosphorus is the most stable allotrope and is obtained by heating white phosphorus under high pressure. Its appearance and electrical conductivity resemble those of graphite, and it possesses a layered structure. Each layer consists of 6-membered rings (Fig. 15.3c) which are organized so as to generate a puckered sheet (Fig. 15.3d). The P–P distances within a layer in black phosphorus are 220 pm and the shortest interlayer P–P distance is 390 pm. On melting, all allotropes give a liquid containing P_4 molecules, and these are also present in the vapour. Above 1070 K or at high pressures, P_4 is in equilibrium with P_2 (**15.8**).

(15.8)



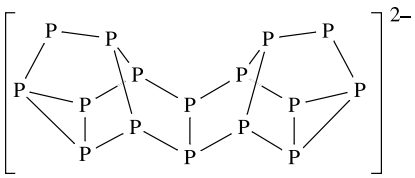
Most of the chemical differences between the allotropes of phosphorus are due to differences in activation energies for reactions. Black phosphorus is kinetically inert and does not ignite in air even at 670 K. Red phosphorus is intermediate in reactivity between the white and black allotropes. It is not poisonous, is insoluble in organic solvents, does not react with aqueous alkali, and ignites in air above 520 K. There is growing interest in the semiconducting properties of red phosphorus and its applications as a photocatalyst; fibrous red phosphorus has a band gap of ≈1.5 eV.[‡] Red phosphorus reacts with halogens, sulfur and metals, but less vigorously than does white phosphorus. The latter is a soft, waxy solid which becomes yellow on exposure to light; it is very poisonous, being readily absorbed into the blood and liver.

[†] For details, see: H. Hartl (1995) *Angew. Chem. Int. Ed.*, vol. 34, p. 2637 – 'New evidence concerning the structure of amorphous red phosphorus'; M. Ruck *et al.* (2005) *Angew. Chem. Int. Ed.*, vol. 44, p. 7616 – 'Fibrous red phosphorus'; A. Pfitzner (2006) *Angew. Chem. Int. Ed.*, vol. 45, p. 699 – 'Phosphorus remains exciting!'

[‡] Semiconducting and photocatalytic properties of red phosphorus: G. Schusteritsch *et al.* (2016) *Nano Lett.*, vol. 16, p. 2975; S.A. Ansari *et al.* (2016) *RSC Adv.*, vol. 6, p. 44616; Z. Hu *et al.* (2016) *Angew. Chem. Int. Ed.*, vol. 55, p. 9580; Z. Shen *et al.* (2014) *Nanoscale*, vol. 6, p. 14163.

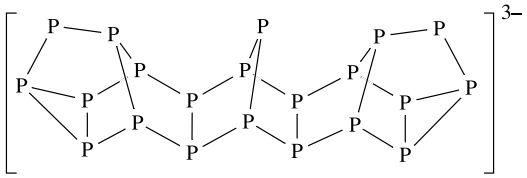
White phosphorus is soluble in benzene, PCl_3 and CS_2 but is virtually insoluble in water, and is stored under water to prevent oxidation. In moist air, it undergoes *chemiluminescent* oxidation, emitting a green glow and slowly forming P_4O_8 (see Section 15.10) and some O_3; the chain reaction involved is extremely complicated.

A ***chemiluminescent*** reaction is one that is accompanied by the emission of light.



(15.10)

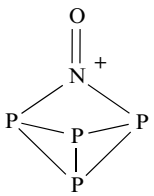
Above 323 K, white phosphorus inflames, yielding phosphorus(V) oxide (eq. 15.10); in a limited supply of air, P_4O_6 may form. White phosphorus combines violently with all of the halogens, giving PX_3 (X = F, Cl, Br, I) or PX_5 (X = F, Cl, Br) depending on the relative amounts of P_4 and X_2. Concentrated HNO_3 oxidizes P_4 to H_3PO_4, and with hot aqueous NaOH, reaction 15.11 occurs, some H_2 and P_2H_4 also being formed.



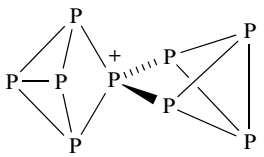
$$P_4 + 3NaOH + 3H_2O \longrightarrow 3NaH_2PO_2 + PH_3 \qquad (15.11)$$

$$23P_4 + 12LiPH_2 \longrightarrow 6Li_2P_{16} + 8PH_3 \qquad (15.12)$$

Reaction 15.12 yields Li_2P_{16}, while Li_3P_{21} and Li_4P_{26} can be obtained by altering the ratio of P_4 : $LiPH_2$. The structures of the phosphide ions $[P_{16}]^{2-}$, **15.9**, $[P_{21}]^{3-}$, **15.10**, and $[P_{26}]^{4-}$ are related to one chain in Hittorf's and fibrous red phosphorus (Fig. 15.3b).



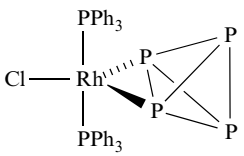
(15.9)



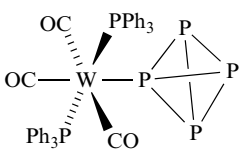
(15.10)

Many $[P_x]^{n-}$ anions are known, but only in 2012 was the first $[P_x]^{n+}$ cation isolated. Oxidation of P_4 with $[NO]^+[Al(OC(CF_3)_3)_4]^-$ first gives $[P_4NO]^+$ (**15.11**) and then, under broad band UV-VIS irradiation in the presence of an excess of P_4, yields $[P_9]^+$ (**15.12**). The use of the sterically demanding and weakly coordinating $[Al(OC(CF_3)_3)_4]^-$ counter-ion is key to stabilizing $[P_9]^+$.

(15.11)



(15.12)



Self-study exercise

Structure **15.11** shows one possible resonance structure for $[P_4NO]^+$; draw a further two resonance structures which allow the outer P atoms to bear the positive charge.
[*Ans.* See: T. Köchner *et al.* (2010) *Angew. Chem. Int. Ed.*, vol. 49, p. 8139]

Like N_2, P_4 can act as a ligand in *d*-block metal complexes. Examples of different coordination modes of P_4 are shown in structures **15.13–15.14**.

(15.13)

(15.14)

Arsenic, antimony and bismuth

Arsenic vapour contains As_4 molecules, and the unstable yellow form of solid As probably also contains these units. At relatively low temperatures, Sb vapour contains molecular Sb_4. At room temperature and pressure, As, Sb and Bi are grey solids with layered structures; each layer is composed of 6-membered rings (Fig. 15.4a). The layers pack as shown in Fig. 15.4b, and on going from As to Sb to Bi, the atom···atom contacts between layers become more important (Table 15.4). By comparing Fig. 15.4a with Fig. 15.3c, and Fig. 15.4b with Fig. 15.3d, it is possible to see how the different arrangement of the 6-membered rings (all with chair-conformations) leads to the 'planar' sheets in As, Sb and Bi, but to puckered sheets in black P.

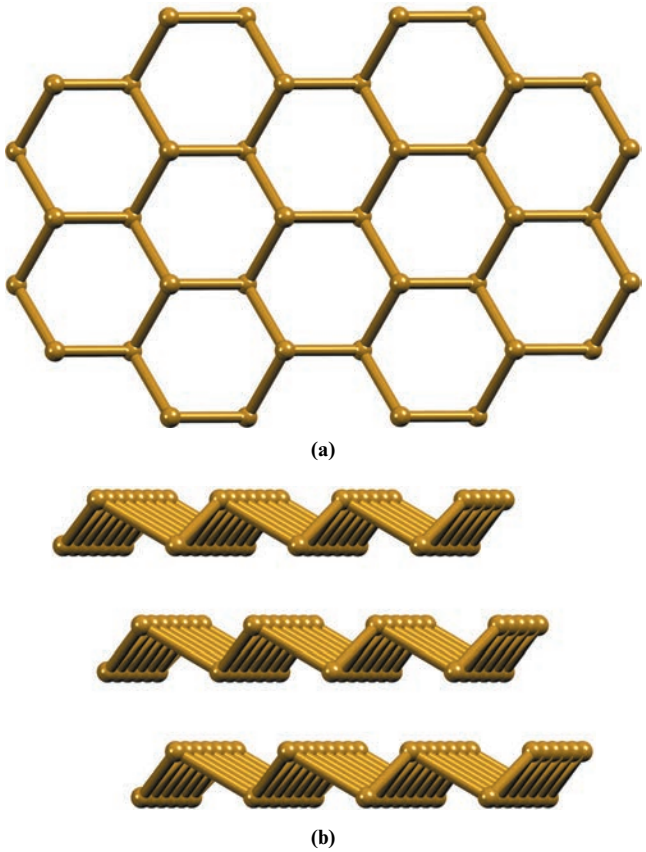


Fig. 15.4. The layered structure of As, Sb and Bi. (a) Part of one layer showing 6-membered rings (chair conformation) and (b) stacking of adjacent layers.

Table 15.4 Distances between adjacent atoms within and between layers in the structures of As, Sb and Bi (Fig. 15.4) at room temperature and pressure.

Group 15 element, E	E–E distance within a layer / pm	Closest E...E distance between adjacent layers / pm
As	252	312
Sb	291	336
Bi	307	353

Although there are reports of an allotrope of As with a black P structure-type, it is likely that 'black As' is metastable and that the structure is only stabilized by the presence of impurities.[†]

Arsenic, antimony and bismuth burn in air (eq. 15.13) and combine with halogens (see Section 15.7).

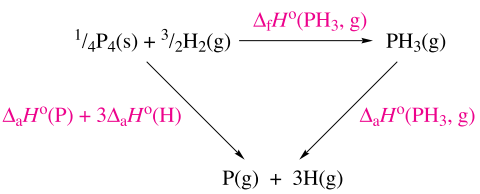
[†] See: O. Osters *et al.* (2012) *Angew. Chem. Int. Ed.*, vol. 51, p. 2994 – 'Synthesis and identification of metastable compounds: Black arsenic – science or fiction?'.

$$4M + 3O_2 \xrightarrow{\Delta} 2M_2O_3 \qquad M = As,\ Sb \text{ or } Bi \qquad (15.13)$$

The elements are not attacked by non-oxidizing acids but react with concentrated HNO_3 to give H_3AsO_4 (hydrated As_2O_5), hydrated Sb_2O_5 and $Bi(NO_3)_3$ respectively, and with concentrated H_2SO_4 to produce As_4O_6, $Sb_2(SO_4)_3$ and $Bi_2(SO_4)_3$ respectively. None of the elements reacts with aqueous alkali, but As is attacked by fused NaOH (eq. 15.14).

$$2As + 6NaOH \longrightarrow \underset{\text{sodium arsenite}}{2Na_3AsO_3} + 3H_2 \qquad (15.14)$$

15.5 Hydrides



Trihydrides, EH_3 (E = N, P, As, Sb and Bi)

Each group 15 element forms a trihydride, selected properties of which are given in Table 15.5; the lack of data for BiH_3 stems from its instability. The variation in boiling points (Fig. 10.7b, Table 15.5) is one of the strongest pieces of evidence for hydrogen bond formation by nitrogen. Further evidence comes from the fact that NH_3 has a greater value of $\Delta_{vap}H^o$ and a higher surface tension than the later trihydrides. Thermal stabilities of these compounds decrease down the group (BiH_3 decomposes above 228 K), and this trend is reflected in the bond enthalpy terms (Table 15.3). Ammonia is the only trihydride to possess a negative value of Δ_fH^o (Table 15.5).

Worked example 15.2
Bond enthalpies in group 15 hydrides

Given that $\Delta_fH^o(298\,K)$ for $PH_3(g)$ is $+5.4\,kJ\,mol^{-1}$, calculate a value for the P–H bond enthalpy term in PH_3. [Other data: see Appendix 10.]

Construct an appropriate Hess cycle, bearing in mind that the P–H bond enthalpy term can be determined from the standard enthalpy of atomization of $PH_3(g)$.

$$\Delta_fH^o(PH_3, g) + \Delta_aH^o(PH_3, g) = \Delta_aH^o(P, g) + 3\Delta_aH^o(H, g)$$

Standard enthalpies of atomization of the elements are listed in Appendix 10.

Table 15.5 Selected data for the group 15 trihydrides, EH_3.

	NH_3	PH_3	AsH_3	SbH_3	BiH_3
Name[†]	Ammonia (azane)	Phosphane (phosphine)	Arsane (arsine)	Stibane (stibine)	Bismuthane
Melting point / K	195.5	140	157	185	206
Boiling point / K	240	185.5	210.5	256	290[‡]
$\Delta_{vap}H^o$(bp) / kJ mol^{-1}	23.3	14.6	16.7	21.3	–
$\Delta_f H^o$(298 K) / kJ mol^{-1}	−45.9	5.4	66.4	145.1	277[‡]
Dipole moment / D	1.47	0.57	0.20	0.12	–
E−H bond distance / pm	101.2	142.0	151.1	170.4	–
∠H−E−H / deg	106.7	93.3	92.1	91.6	–

[†] Ammonia is the accepted trivial name for NH_3. Azane is the IUPAC parent name for NH_3 and is used for naming derivatives. Phosphane, arsane and stibane are the IUPAC systematic names for PH_3, AsH_3 and SbH_3. Phosphine, arsine and stibine are still in use but are no longer accepted by the IUPAC.
[‡] Estimated value.

$$\begin{aligned}\Delta_a H^o(PH_3, g) &= \Delta_a H^o(P, g) + 3\Delta_a H^o(H, g) - \Delta_f H^o(PH_3, g)\\ &= 315 + 3(218) - 5.4\\ &= 963.6 = 964\,\text{kJ mol}^{-1}\ \text{(to 3 sig. fig.)}\end{aligned}$$

$$\text{P−H bond enthalpy term} = \frac{964}{3} = 321\,\text{kJ mol}^{-1}$$

Self-study exercises

1. Using data from Table 15.3 and Appendix 10, calculate a value for $\Delta_f H^o(NH_3, g)$. [*Ans.* −46 kJ mol^{-1}]
2. Calculate a value for the Bi−H bond enthalpy term in BiH_3 using data from Table 15.5 and Appendix 10. [*Ans.* 196 kJ mol^{-1}]
3. Use data in Table 15.5 and Appendix 10 to calculate the As−H bond enthalpy term in AsH_3. [*Ans.* 297 kJ mol^{-1}]

Ammonia is obtained by the action of H_2O on the nitrides of Li or Mg (eq. 15.15), by heating $[NH_4]^+$ salts with base (e.g. reaction 15.16), or by reducing a nitrate or nitrite in alkaline solution with Zn or Al (e.g. reaction 15.17).

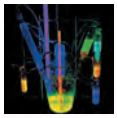
$$Li_3N + 3H_2O \longrightarrow NH_3 + 3LiOH \qquad (15.15)$$

$$2NH_4Cl + Ca(OH)_2 \longrightarrow 2NH_3 + CaCl_2 + 2H_2O \qquad (15.16)$$

$$[NO_3]^- + 4Zn + 6H_2O + 7[OH]^- \longrightarrow NH_3 + 4[Zn(OH)_4]^{2-} \qquad (15.17)$$

Trihydrides of the later elements are best made by method 15.18, or by acid hydrolysis of phosphides, arsenides, antimonides or bismuthides (e.g. reaction 15.19). Phosphane can also be made by reaction 15.20, $[PH_4]I$ being prepared from P_2I_4 (see Section 15.7).

$$ECl_3 \xrightarrow{Li[AlH_4]\text{ in }Et_2O} EH_3 \qquad E = P,\ As,\ Sb,\ Bi \qquad (15.18)$$

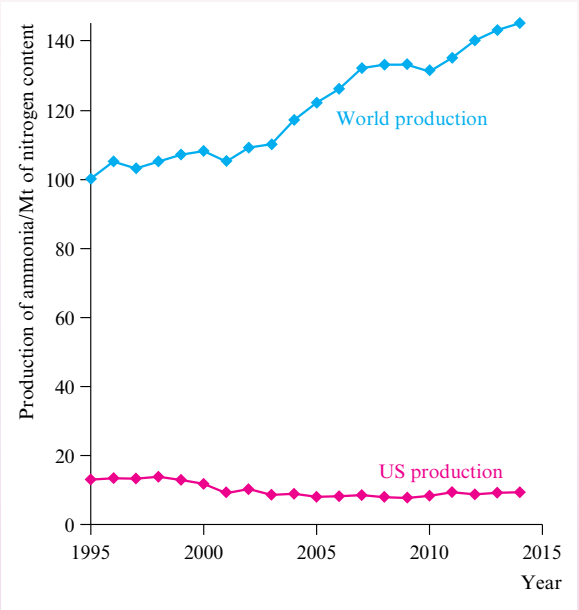


$$Ca_3P_2 + 6H_2O \longrightarrow 2PH_3 + 3Ca(OH)_2 \qquad (15.19)$$

$$[PH_4]I + KOH \longrightarrow PH_3 + KI + H_2O \qquad (15.20)$$

The industrial manufacture of NH_3 (Box 15.3) involves the Haber–Bosch process (also known as the Haber process) (reaction 15.21), and the manufacture of the H_2 (see Section 10.4) required contributes significantly to the overall cost of the process.

$$N_2 + 3H_2 \rightleftharpoons 2NH_3 \qquad \begin{cases}\Delta_r H^o(298\,K) = -92\,\text{kJ mol}^{-1}\\ \Delta_r G^o(298\,K) = -33\,\text{kJ mol}^{-1}\end{cases} \qquad (15.21)$$



The Haber–Bosch process is a classic application of physicochemical principles to a system in equilibrium. The decrease in number of moles of gas means that $\Delta_r S^o(298\,K)$ is negative. For industrial viability, NH_3 must be formed in optimum yield *and* at a reasonable rate. Increasing the temperature increases the rate of reaction, but decreases the yield since the forward reaction is exothermic. At a given temperature, both the equilibrium yield and the reaction rate are increased by working at high pressures. The presence of a suitable

APPLICATIONS

Box 15.3 Ammonia: an industrial giant

Ammonia is manufactured on a huge scale, the major producers being China, the US, India and Russia; China now produces around one-third of the world's supply of ammonia. The graph below shows the trends in world and US production of NH_3 between 1995 and 2014.

[Data: US Geological Survey]

Agriculture demands vast quantities of fertilizers to supplement soil nutrients; this is critical when the same land is used year after year for crop production. Essential nutrients are N, P, K (the three required in largest amounts), Ca, Mg and S plus trace elements. In 2015, in the US, direct use and its conversion into other nitrogenous fertilizers accounted for ≈90% of all NH_3 produced. In addition to NH_3 itself, the nitrogen-rich compound $CO(NH_2)_2$ (urea) is of prime importance, along with $[NH_4][NO_3]$ and $[NH_4]_2[HPO_4]$ (which has the benefit of supplying both N and P nutrients); $[NH_4]_2[SO_4]$ accounts for a smaller portion of the market. The remaining 10% of NH_3 produced in the US was used in the synthetic fibre industry (e.g. nylon-6, nylon-66 and rayon), manufacture of explosives (see structures **15.1** and **15.2**), resins and miscellaneous chemicals.

Phosphorus-containing fertilizers are highlighted in Box 15.10.

Application of anhydrous NH_3 as a fertilizer. Gaseous NH_3 is released from a tank via a nozzle alongside a blade that cuts through the soil.

catalyst (see Section 25.8) also increases the rate. The rate-determining step is the dissociation of N_2 into N atoms chemisorbed onto the catalyst. The optimum reaction conditions are $T = 723\,K$, $P = 20\,260\,kPa$, and Fe_3O_4 mixed with K_2O, SiO_2 and Al_2O_3 as the heterogeneous catalyst. The Fe_3O_4 is reduced to give the catalytically active α-Fe. The NH_3 formed is either liquefied or dissolved in H_2O to form a saturated solution of specific gravity 0.880.

Worked example 15.3 Thermodynamics of NH_3 formation

For the equilibrium:

$\frac{1}{2}N_2(g) + \frac{3}{2}H_2(g) \rightleftharpoons NH_3(g)$

values of $\Delta_r H^o(298\,K)$ and $\Delta_r G^o(298\,K)$ are -45.9 and $-16.4\,kJ\,mol^{-1}$, respectively. Calculate $\Delta_r S^o(298\,K)$ and comment on the value.

$$\Delta_r G^o = \Delta_r H^o - T\Delta_r S^o$$

$$\Delta_r S^o = \frac{\Delta_r H^o - \Delta_r G^o}{T}$$

$$= \frac{-45.9 - (-16.4)}{298}$$

$$= -0.0990\,kJ\,K^{-1}\,mol^{-1}$$

$$= -99.0\,J\,K^{-1}\,mol^{-1}$$

The negative value is consistent with a decrease in the number of moles of gas in going from the left- to right-hand side of the equilibrium.

Self-study exercises

These exercises all refer to the equilibrium given in the worked example.

1. Determine $\ln K$ at 298 K. [*Ans.* 6.62]

2. At 700 K, $\Delta_r H^o$ and $\Delta_r G^o$ are −52.7 and +27.2 kJ mol^{-1}, respectively. Determine a value for $\Delta_r S^o$ under these conditions. [*Ans.* −114 J K^{-1} mol^{-1}]

3. Determine ln K at 700 K. [*Ans.* −4.67]

4. Comment on your answer to question 3, given that the optimum temperature for the industrial synthesis of NH_3 is 723 K.

Ammonia is a colourless gas with a pungent odour. Table 15.5 lists selected properties and structural data for the trigonal pyramidal molecule **15.15**, the barrier to inversion for which is very low (24 kJ mol^{-1}). Oxidation products of NH_3 depend on conditions. Reaction 15.22 occurs on combustion in O_2, but at ≈1200 K in the presence of a Pt/Rh catalyst and a contact time of ≈1 ms, the less exothermic reaction 15.23 takes place. This reaction forms part of the manufacturing process for HNO_3 (see Section 15.9).

(15.15)

$$4NH_3 + 3O_2 \longrightarrow 2N_2 + 6H_2O \qquad (15.22)$$

$$4NH_3 + 5O_2 \xrightarrow{Pt/Rh} 4NO + 6H_2O \qquad (15.23)$$

The solubility of NH_3 in water is greater than that of any other gas, doubtless because of hydrogen bond formation between NH_3 and H_2O. The equilibrium constant (at 298 K) for reaction 15.24 shows that nearly all the dissolved NH_3 is *non-ionized*, consistent with the fact that even dilute solutions retain the characteristic smell of NH_3. Since $K_w = 10^{-14}$, it follows that the aqueous solutions of $[NH_4]^+$ salts of strong acids (e.g. NH_4Cl) are slightly acidic (eq. 15.25). (See worked example 7.2 for calculations relating to equilibria 15.24 and 15.25, and worked example 7.3 for the relationship between pK_a and pK_b.)

$$NH_3(aq) + H_2O(l) \rightleftharpoons [NH_4]^+(aq) + [OH]^-(aq) \qquad K_b = 1.8 \times 10^{-5} \qquad (15.24)$$

$$[NH_4]^+(aq) + H_2O(l) \rightleftharpoons [H_3O]^+(aq) + NH_3(aq) \qquad K_a = 5.6 \times 10^{-10} \qquad (15.25)$$

Ammonium salts are easily prepared by neutralization reactions, e.g. eq. 15.26. Industrial syntheses are carried out using the Solvay process (Fig. 11.7), or reactions 15.27 and 15.28. Both ammonium sulfate and ammonium nitrate are important fertilizers, and NH_4NO_3 is a component of some explosives (see eq. 15.8).

$$NH_3 + HBr \longrightarrow NH_4Br \qquad (15.26)$$

$$CaSO_4 + 2NH_3 + CO_2 + H_2O \longrightarrow CaCO_3 + [NH_4]_2[SO_4] \qquad (15.27)$$

$$NH_3 + HNO_3 \longrightarrow NH_4NO_3 \qquad (15.28)$$

Detonation of NH_4NO_3 may be initiated by another explosion, and ammonium perchlorate is similarly metastable with respect to oxidation of the $[NH_4]^+$ cation by the anion; NH_4ClO_4 is used in solid rocket propellants, e.g. in the booster rockets of the space shuttle.

All perchlorate salts are potentially explosive and must be treated with extreme caution.

'Technical ammonium carbonate' (used in smelling salts) is actually a mixture of $[NH_4][HCO_3]$ and $[NH_4][NH_2CO_2]$ (ammonium carbamate). The latter is prepared by reacting NH_3 and CO_2 under pressure. It smells strongly of NH_3 because carbamic acid is an extremely weak acid (scheme 15.29). Pure carbamic acid (H_2NCO_2H) has not been isolated; the compound dissociates completely at 332 K.

$$\underbrace{[NH_4]^+(aq) + [H_2NCO_2]^-(aq)}_{\text{salt of a strong base and a weak acid}} \rightleftharpoons NH_3(aq) + \{H_2NCO_2H(aq)\} \rightleftarrows NH_3(aq) + CO_2(aq) \qquad (15.29)$$

Ammonium salts often crystallize with structures similar to those of the corresponding K^+, Rb^+ or Cs^+ salts. The $[NH_4]^+$ ion can be approximated to a sphere (Fig. 6.20) with $r_{ion} = 150$ pm, a value similar to that of Rb^+. However, if, in the solid state, there is potential for hydrogen bonding involving the $[NH_4]^+$ ions, ammonium salts adopt structures unlike those of their alkali metal analogues, e.g. NH_4F possesses a wurtzite rather than an NaCl-type structure. The majority of $[NH_4]^+$ salts are soluble in water, with hydrogen bonding between $[NH_4]^+$ and H_2O being a contributing factor. An exception is $[NH_4]_2[PtCl_6]$.

Phosphane (Table 15.5) is an extremely toxic, colourless gas which is much less soluble in water than is NH_3. The P−H bond is not polar enough to form hydrogen bonds with H_2O. In contrast to NH_3, aqueous solutions of PH_3 are neutral, but in liquid NH_3, PH_3 acts as an acid (e.g. eq. 15.30).

$$K + PH_3 \xrightarrow{\text{liquid } NH_3} K^+ + [PH_2]^- + \tfrac{1}{2}H_2 \qquad (15.30)$$

The spontaneous flammability associated with PH_3 is due to the presence of P_2H_4 (see later). Phosphonium halides, PH_4X, are formed by treating PH_3 with HX but only the iodide is stable under ambient conditions. The chloride is unstable above 243 K and the bromide decomposes at 273 K. The $[PH_4]^+$ ion is decomposed by water (eq. 15.31). Phosphane acts as a Lewis base and a range of

adducts (including those with low oxidation state *d*-block metal centres) are known. Examples include $H_3B{\cdot}PH_3$, $Cl_3B{\cdot}PH_3$, $Ni(PH_3)_4$ (decomposes above 243 K) and $Ni(CO)_2(PH_3)_2$. Combustion of PH_3 yields H_3PO_4.

$$[PH_4]^+ + H_2O \longrightarrow PH_3 + [H_3O]^+ \qquad (15.31)$$

The hydrides AsH_3 and SbH_3 resemble those of PH_3 (Table 15.5), but they are less stable with respect to decomposition into their elements. The thermal instability of AsH_3 and SbH_3 was the basis for the Marsh test which was a classic analytical technique used in forensic science; arsenic- or antimony-containing materials were first converted to AsH_3 or SbH_3, and the latter were then thermally decomposed (eq. 15.32). Treatment of the brown-black residue with aqueous NaOCl was used to distinguish between As (which reacted, eq. 15.33) and Sb (which did not react).

$$2EH_3(g) \xrightarrow{\Delta} 2E(s) + 3H_2(g) \qquad E = As, Sb \qquad (15.32)$$

$$5NaOCl + 2As + 3H_2O \longrightarrow 2H_3AsO_4 + 5NaCl \qquad (15.33)$$

Both AsH_3 and SbH_3 are extremely toxic gases, and SbH_3 is liable to explode. They are less basic than PH_3, but can be protonated with HF in the presence of AsF_5 or SbF_5 (eq. 15.34). The salts $[AsH_4][AsF_6]$, $[AsH_4][SbF_6]$ and $[SbH_4][SbF_6]$ form air- and moisture-sensitive crystals which decompose well below 298 K.

$$AsH_3 + HF + AsF_5 \longrightarrow [AsH_4]^+ + [AsF_6]^- \qquad (15.34)$$

Hydrides E_2H_4 (E = N, P, As)

Hydrazine, N_2H_4, is a colourless liquid (mp 275 K, bp 386 K), miscible with water and with a range of organic solvents, and is corrosive and toxic. Its vapour forms explosive mixtures with air. Although $\Delta_f H^o(N_2H_4, 298\,K) = +50.6\,kJ\,mol^{-1}$, N_2H_4 at ambient temperatures is *kinetically* stable with respect to N_2 and H_2. Alkyl derivatives of hydrazine (see eq. 15.44) have been used as rocket fuels, e.g. combined with N_2O_4 in the *Apollo* missions.[†] N_2H_4 has uses in the agricultural and plastics industries, and in the removal of O_2 from industrial water boilers to minimize corrosion (eq. 15.35).

$$N_2H_4 + O_2 \longrightarrow N_2 + 2H_2O \qquad (15.35)$$

Hydrazine is obtained by the Raschig reaction (the basis for the industrial synthesis, see below) which involves the partial oxidation of NH_3 (eq. 15.36). Glue or gelatine is added to inhibit side-reaction 15.37 which otherwise consumes the N_2H_4 as it is formed; the additive removes traces of metal ions that catalyse reaction 15.37.

$$\left.\begin{aligned} NH_3 + NaOCl &\longrightarrow NH_2Cl + NaOH \quad \textit{fast} \\ NH_3 + NH_2Cl + NaOH &\longrightarrow N_2H_4 + NaCl + H_2O \quad \textit{slow} \end{aligned}\right\} \qquad (15.36)$$

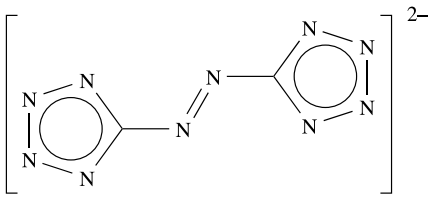
$$2NH_2Cl + N_2H_4 \longrightarrow N_2 + 2NH_4Cl \qquad (15.37)$$

Hydrazine is obtained commercially from the Raschig process as the monohydrate and is used in this form for many purposes. Dehydration is difficult, and direct methods to produce anhydrous N_2H_4 include reaction 15.38.

$$2NH_3 + [N_2H_5][HSO_4] \longrightarrow N_2H_4 + [NH_4]_2[SO_4] \qquad (15.38)$$

In aqueous solution, N_2H_4 usually forms $[N_2H_5]^+$ (hydrazinium) salts, but some salts of $[N_2H_6]^{2+}$ have been isolated, e.g. $[N_2H_6][SO_4]$. The pK_b values for hydrazine are given in eqs. 15.39 and 15.40, and the first step shows N_2H_4 to be a weaker base than NH_3 (eq. 15.24).

$$N_2H_4(aq) + H_2O(l) \rightleftharpoons [N_2H_5]^+(aq) + [OH]^-(aq) \qquad K_b(1) = 8.9 \times 10^{-7} \qquad (15.39)$$



$$[N_2H_5]^+(aq) + H_2O(l) \rightleftharpoons [N_2H_6]^{2+}(aq) + [OH]^-(aq) \qquad K_b(2) \approx 10^{-14} \qquad (15.40)$$

Both N_2H_4 and $[N_2H_5]^+$ are reducing agents, and reaction 15.41 is used for the determination of hydrazine.

$$N_2H_4 + KIO_3 + 2HCl \longrightarrow N_2 + KCl + ICl + 3H_2O \qquad (15.41)$$

The use of N_2H_4 in rocket fuels was described above. The stored energy in explosives and propellants ('high-energy density materials') usually arises either from oxidation of an organic framework, or from an inherent high positive enthalpy of formation. For the hydrazinium salt $[N_2H_5]_2$[**15.16**] (prepared by reaction 15.42), $\Delta_f H^o(s, 298\,K) = +858\,kJ\,mol^{-1}$ (or $3.7\,kJ\,g^{-1}$), making $[N_2H_5]_2$[**15.16**] a spectacular example of a high-energy density material.

$$Ba[\mathbf{15.15}] + [N_2H_5]_2[SO_4] \longrightarrow [N_2H_5]_2[\mathbf{15.16}]{\cdot}2H_2O \xrightarrow{373\,K,\ \textit{in vacuo}} [N_2H_5]_2[\mathbf{15.16}] \qquad (15.42)$$

5,5'-Azotetrazolate dianion

(15.16)

[†]O. de Bonn *et al.* (2001) *Z. Anorg. Allg. Chem.*, vol. 627, p. 2011 – 'Plume deposits from bipropellant rocket engines: Methylhydrazinium nitrate and *N*,*N*-dimethylhydrazinium nitrate'.

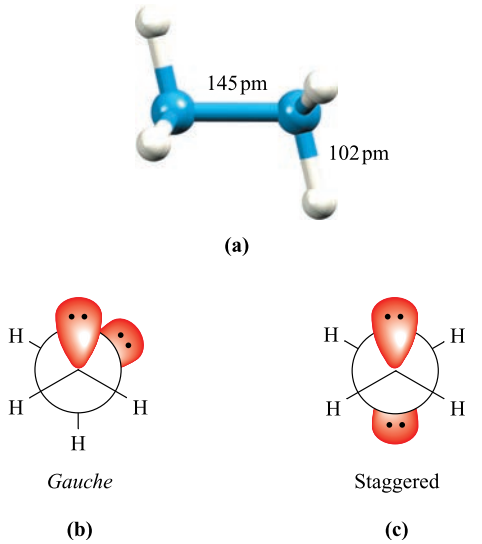


Fig. 15.5. (a) The structure of N_2H_4, and Newman projections showing (b) the observed *gauche* conformation, and (c) the possible staggered conformation. An eclipsed conformation is also possible.

Figure 15.5a shows the structure of N_2H_4. Of the conformations possible for N_2H_4, electron diffraction and IR spectroscopic data confirm that the *gauche*-form is favoured in the gas phase. The *gauche* conformation (Figs. 15.5a and 15.5b) is also adopted by P_2H_4 in the gas phase. In the solid state, P_2H_4 has a staggered conformation (Fig. 15.5c) while the related N_2F_4 exhibits both conformers. The eclipsed conformation (which would maximize lone pair–lone pair repulsions) is not observed.

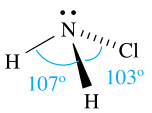
Diphosphane, P_2H_4, is a colourless liquid (mp 174 K, bp 329 K), and is toxic and spontaneously inflammable. When heated, it forms higher phosphanes. Diphosphane is formed as a minor product in several reactions in which PH_3 is prepared (e.g. reaction 15.11) and may be separated from PH_3 by condensation in a freezing mixture. It exhibits no basic properties.

Fig. 15.6. The solid state structure (X-ray diffraction at 123 K) of the anion in $[Na(NH_3)_5]^+[Na(NH_3)_3(P_3H_3)]^-$ [N. Korber *et al.* (2001) *J. Chem. Soc., Dalton Trans.*, p. 1165]. Two of the three P atoms coordinate to the sodium centre (Na–P = 308 pm). Colour code: P, orange; Na, purple; N, blue; H, white.

The $[P_3H_3]^{2-}$ ion is formed in reaction 15.43 and is stabilized by coordination to the sodium centre in $[Na(NH_3)_3(P_3H_3)]^-$. In the solid state, the H atoms in $[P_3H_3]^{2-}$ are in an all-*trans* configuration (Fig. 15.6).

$$5Na + 0.75P_4 + 11NH_3 \xrightarrow{\text{Na in liquid } NH_3,\ 238\ K} [Na(NH_3)_5]^+[Na(NH_3)_3(P_3H_3)]^- + 3NaNH_2 \quad (15.43)$$

Self-study exercise



The single crystal structure of $K_3[P_3H_2] \cdot 2.3NH_3$ shows that the $[P_3H_2]^{3-}$ ion has C_2 symmetry. The P–P–P bond angle is 115.5°.

(a) Draw a structure for $[P_3H_2]^{3-}$ and explain how the relative positions of the H atoms follow from the point group.

(b) Suggest what inter-ion and intermolecular interactions are likely to be important in the lattice of $K_3[P_3H_2] \cdot 2.3NH_3$.

[*Ans.* See: F. Kraus *et al.* (2009) *Inorg. Chem.*, vol. 48, p. 1911]

Chloramine and hydroxylamine

(15.17)

The reactions of NH_3 and Cl_2 (diluted with N_2) or aqueous NaOCl (the first step in reaction 15.36) yield chloramine, **15.17**, the compound responsible for the odour of water containing nitrogenous matter that has been sterilized with Cl_2. Chloramine is unstable, and violently explosive, and is usually handled in dilute solutions (e.g. in H_2O or Et_2O). Its reaction with Me_2NH (eq. 15.44) yields the rocket fuel 1,1-dimethylhydrazine.

$$NH_2Cl + 2Me_2NH \longrightarrow Me_2NNH_2 + [Me_2NH_2]Cl \quad (15.44)$$

Although dilute aqueous solutions of NH_2Cl can conveniently be handled, it is not practical to work with neat NH_2Cl because of its instability and the risk of explosion. Thus, apparently simple reactions such as the preparation and isolation of salts containing $[NH_3Cl]^+$ are not trivial. Use of pure NH_2Cl can be avoided by reaction of $(Me_3Si)_2NCl$ with HF in the presence of a strong Lewis base. As soon as NH_2Cl forms, it immediately forms $[NH_3Cl]^+$ (scheme 15.45).

$$(Me_3Si)_2NCl + 2HF \longrightarrow 2Me_3SiF + \{NH_2Cl\}$$
$$\downarrow \text{Immediate reaction with HF and } SbF_5 \qquad (15.45)$$
$$[NH_3Cl]^+[SbF_6]^-$$

Reaction 15.46 is one of several routes to hydroxylamine, NH_2OH, which is usually handled as a salt (e.g. the sulfate) or in aqueous solution. The free base can be obtained from its salts by treatment with NaOMe in MeOH.

$$2NO + 3H_2 + H_2SO_4 \xrightarrow{\text{platinized charcoal catalyst}} [NH_3OH]_2[SO_4] \qquad (15.46)$$

Pure NH_2OH forms white, hygroscopic crystals which melt at 306 K and explode at higher temperatures. It is a weaker base than NH_3 or N_2H_4. Many of its reactions arise from the great variety of redox reactions in which it takes part in aqueous solution, e.g. it reduces Fe(III) in acidic solution (eq. 15.47) but oxidizes Fe(II) in the presence of alkali (eq. 15.48).

$$2NH_2OH + 4Fe^{3+} \longrightarrow N_2O + 4Fe^{2+} + H_2O + 4H^+ \qquad (15.47)$$

$$NH_2OH + 2Fe(OH)_2 + H_2O \longrightarrow NH_3 + 2Fe(OH)_3 \qquad (15.48)$$

More powerful oxidizing agents (e.g. $[BrO_3]^-$) oxidize NH_2OH to HNO_3. The formation of N_2O in most oxidations of NH_2OH exemplifies dominance of kinetic over thermodynamic factors. Consideration of the potential diagram (see Section 8.5) in Fig. 15.7 shows that, on thermodynamic grounds, the expected product from the action of weak oxidizing agents on $[NH_3OH]^+$ (i.e. NH_2OH in acidic solution) would be N_2, but it seems that the reaction occurs by the steps in eq. 15.49.

$$\left.\begin{aligned} NH_2OH &\longrightarrow NOH + 2H^+ + 2e^- \\ 2NOH &\longrightarrow HON{=}NOH \\ HON{=}NOH &\longrightarrow N_2O + H_2O \end{aligned}\right\} \qquad (15.49)$$

Figure 15.7 also shows that, at pH = 0, $[NH_3OH]^+$ is unstable with respect to disproportionation into N_2 and $[NH_4]^+$ or $[N_2H_5]^+$. In fact, hydroxylamine does slowly decompose to N_2 and NH_3.

Worked example 15.4 Using potential and Frost–Ebsworth diagrams

(a) Use the data in Fig. 15.7 to calculate $\Delta G^o(298\,K)$ for the following reduction process.

$$\mathbf{2[NH_3OH]^+(aq) + H^+(aq) + 2e^- \longrightarrow [N_2H_5]^+(aq) + 2H_2O(l)}$$

(b) Estimate $\Delta G^o(298\,K)$ for the same process using the Frost–Ebsworth diagram in Fig. 8.4c.

(a) From the potential diagram, E^o for this half-reaction is +1.41 V.

$$\Delta G^o = -zFE^o$$
$$= -2 \times (96\,485 \times 10^{-3}) \times 1.41$$
$$= -272\,kJ\,mol^{-1}$$

(b) The gradient of the line joining the points for $[NH_3OH]^+$ and $[N_2H_5]^+ \approx \dfrac{1.9 - 0.5}{1} = 1.4\,V$

$$E^o = \frac{\text{Gradient of line}}{\text{Number of electrons transferred per mole of N}}$$
$$= \frac{1.4}{1} = 1.4\,V$$

$$\Delta G^o = -zFE^o$$
$$= -2 \times (96\,485 \times 10^{-3}) \times 1.4$$
$$= -270\,kJ\,mol^{-1}$$

Self-study exercises

1. Explain how the Frost–Ebsworth diagram for nitrogen (Fig. 8.4c) illustrates that $[NH_3OH]^+$ (at pH 0) is unstable with respect to disproportionation.
[*Ans.* See the bullet-point list in Section 8.6]

2. Use the data in Fig. 15.7 to calculate E^o for the reduction process:
$$[NO_3]^-(aq) + 4H^+(aq) + 3e^- \longrightarrow NO(g) + 2H_2O(l)$$
[*Ans.* +0.95 V]

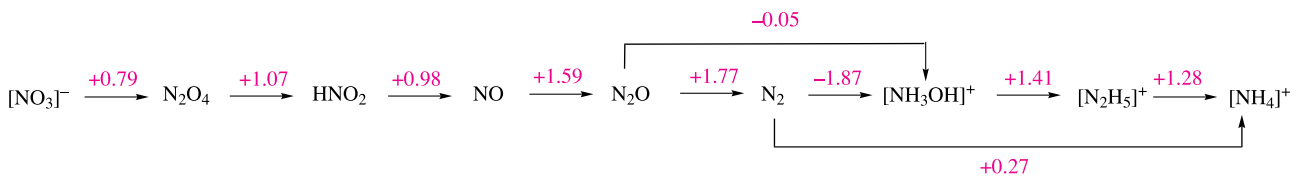


Fig. 15.7. Potential diagram for nitrogen at pH = 0. A Frost–Ebsworth diagram for nitrogen is given in Fig. 8.4c.

3. In basic solution (pH = 14), $E^{o}_{[OH^-]=1}$ for the following process is +0.15 V. Calculate ΔG^{o}(298 K) for the reduction process.

$$2[NO_2]^-(aq) + 3H_2O(l) + 4e^- \rightleftharpoons N_2O(g) + 6[OH]^-(aq)$$

[*Ans.* −58 kJ mol^{-1}]

Further relevant problems can be found after worked example 8.8.

Hydrogen azide and azide salts

Sodium azide, NaN_3, is obtained from molten sodium amide by reaction 15.50 (or by reacting $NaNH_2$ with $NaNO_3$ at 450 K), and treatment of NaN_3 with H_2SO_4 yields hydrogen azide, HN_3.

$$2NaNH_2 + N_2O \xrightarrow{460\ K} NaN_3 + NaOH + NH_3 \qquad (15.50)$$

Hydrogen azide (hydrazoic acid) is a colourless liquid (mp 193 K, bp 309 K). It is dangerously explosive ($\Delta_f H^o$(l, 298 K) = +264 kJ mol^{-1}) and highly poisonous. Aqueous solutions of HN_3 are weakly acidic (eq. 15.51).

$$HN_3 + H_2O \rightleftharpoons [H_3O]^+ + [N_3]^- \quad pK_a = 4.75 \qquad (15.51)$$

The structure of HN_3 is shown in Fig. 15.8a, and a consideration of the resonance structures in Fig. 15.8b provides an explanation for the asymmetry of the NNN-unit. The azide ion is isoelectronic with CO_2, and the symmetrical structure of $[N_3]^-$ (Fig. 15.8c) is consistent with the bonding description in Fig. 15.8d. A range of azide salts is known; Ag(I), Cu(II) and Pb(II) azides, which are insoluble in water, are explosive, and $Pb(N_3)_2$ is used as an initiator for less sensitive explosives. On the other hand, group 1 metal azides decompose less violently when heated (eqs. 11.2 and 15.6). The reaction between NaN_3 and Me_3SiCl yields the covalent compound Me_3SiN_3 which is a useful reagent in organic synthesis. Reaction 15.52 occurs when Me_3SiN_3 is treated with $[PPh_4]^+[N_3]^-$ in the presence of ethanol. The $[N_3HN_3]^-$ anion in the product is stabilized by hydrogen bonding (compare with $[FHF]^-$, see Fig. 10.10). Although the position of the H atom in the anion is not known with great accuracy, structural parameters for the solid state structure of $[PPh_4][N_3HN_3]$ (Fig. 15.9) are sufficiently accurate to confirm an asymmetrical N−H···N interaction (N···N = 272 pm).

$$[PPh_4][N_3] + Me_3SiN_3 + EtOH \longrightarrow [PPh_4][N_3HN_3] + Me_3SiOEt \qquad (15.52)$$

The azide group, like $CN^{\bullet}$ (though to a lesser extent), shows similarities to a halogen and is another example of a pseudo-halogen (see Section 14.12). However, no N_6 molecule (i.e. a dimer of $N_3^{\bullet}$ and so an analogue of an X_2 halogen) has yet been prepared.[†] Like halide ions, the azide ion acts as a ligand in a wide variety of complexes of both metals and non-metals, e.g. $[Au(N_3)_4]^-$, *trans*-$[TiCl_4(N_3)_2]^{2-}$, *cis*-$[Co(en)_2(N_3)_2]^+$, *trans*-$[Ru(en)_2(N_2)(N_3)]^+$ (which is also an example of a dinitrogen complex, Fig. 15.10a), $[Sn(N_3)_6]^{2-}$ (Fig. 15.10b), $[Si(N_3)_6]^{2-}$, $[Sb(N_3)_6]$, $[W(N_3)_6]$, $[W(N_3)_7]^-$ and $[U(N_3)_7]^{3-}$.

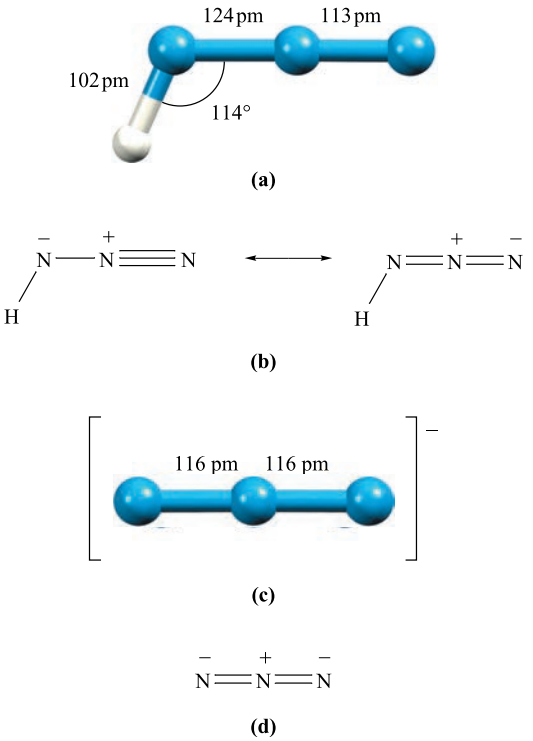

Fig. 15.8. (a) Structure of HN_3, (b) the major contributing resonance forms of HN_3, (c) the structure of the azide ion (the ion is symmetrical but bond distances vary slightly in different salts), and (d) the principal resonance structure of $[N_3]^-$. Colour code: N, blue; H, white.

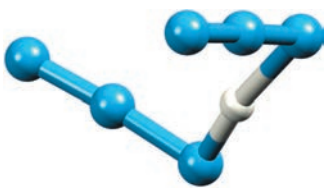

Fig. 15.9. The solid state structure (X-ray diffraction at 203 K) of the anion in $[PPh_4]^+[N_3HN_3]^-$ [B. Neumüller *et al.* (1999) *Z. Anorg. Allg. Chem.*, vol. 625, p. 1243]. Colour code: N, blue; H, white.

[†]For theoretical data on N_6, see: T.M. Klapötke (2000) *J. Mol. Struct.*, vol. 499, p. 99; L.J. Wang, P. Warburton and P.G. Mezey (2002) *J. Phys. Chem. A*, vol. 106, p. 2748; M.J. Greschner *et al.* (2016) *J. Phys. Chem. A*, vol. 120, p. 2920.

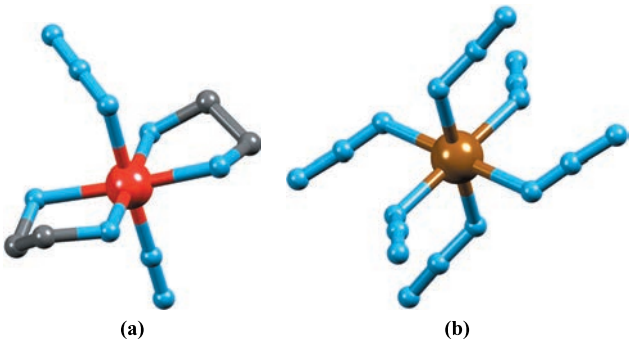

Fig. 15.10. The structures (X-ray diffraction) of (a) *trans*-$[Ru(en)_2(N_2)(N_3)]^+$ in the $[PF_6]^-$ salt (H atoms omitted) [B.R. Davis *et al.* (1970) *Inorg. Chem.*, vol. 9, p. 2768] and (b) $[Sn(N_3)_6]^{2-}$ structurally characterized as the $[Ph_4P]^+$ salt [D. Fenske *et al.* (1983) *Z. Naturforsch., Teil B*, vol. 38, p. 1301]. Colour code: N, blue; Ru, red; Sn, brown; C, grey.

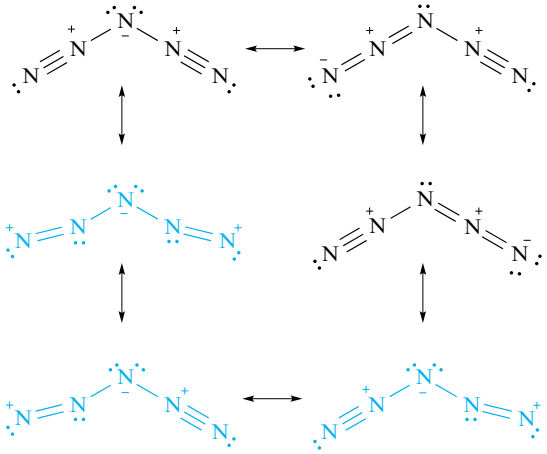
The reaction of HN_3 with $[N_2F][AsF_6]$ (prepared by reaction 15.69) in HF at 195 K results in the formation of $[N_5][AsF_6]$. Designing the synthesis of $[N_5]^+$ was not trivial. Precursors in which the N≡N and N=N bonds are preformed are critical, but should not involve gaseous N_2 since this is too inert. The HF solvent provides a heat sink for the exothermic reaction, the product being potentially explosive. Although $[N_5][AsF_6]$ was the first example of a salt of $[N_5]^+$ and is therefore of significant interest, it is not very stable and tends to explode. In contrast, $[N_5][SbF_6]$ (eq. 15.53) is stable at 298 K and is relatively resistant to impact. Solid $[N_5][SbF_6]$ oxidizes NO, NO_2 and Br_2 (scheme 15.54), but not Cl_2 or O_2.

$$[N_2F]^+[SbF_6]^- + HN_3 \xrightarrow[\text{(ii) warm to 298 K}]{\text{(i) liquid HF, 195 K}} [N_5]^+[SbF_6]^- + HF \quad (15.53)$$

$$[N_5]^+[SbF_6]^- \xrightarrow{NO} [NO]^+[SbF_6]^- + 2.5N_2$$
$$[N_5]^+[SbF_6]^- \xrightarrow{NO_2} [NO_2]^+[SbF_6]^- + 2.5N_2$$
$$[N_5]^+[SbF_6]^- \xrightarrow{Br_2} [Br_2]^+[SbF_6]^- + 2.5N_2 \quad (15.54)$$

The reaction of $[N_5][SbF_6]$ with SbF_5 in liquid HF yields $[N_5][Sb_2F_{11}]$, the solid state structure of which has been determined, confirming a V-shaped $[N_5]^+$ ion (central N–N–N angle = 111°). The N–N bond lengths are 111 pm (almost the same as in N_2) and 130 pm (slightly more than in MeN=NMe), respectively, for the terminal and central bonds. Resonance stabilization (Fig. 15.11) provides a degree of multiple-bond character to all the N–N bonds. The three resonance structures shown in blue contain one or two terminal sextet N atoms. Their inclusion helps to account for the observed $N_{terminal}$–N–$N_{central}$ bond angles of 168°.



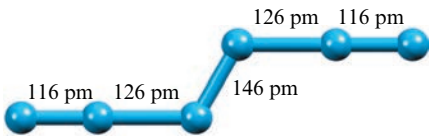


Fig. 15.11. Resonance structures for the $[N_5]^+$ ion.

Self-study exercise

A theoretical study has concluded that N_6 might be produced under conditions of high temperature and high pressure. The predicted structure and bond distances are shown below. Use the information to draw a Lewis structure for N_6.

[*Ans.* See: M.J. Greschner *et al.* (2016) *J. Phys. Chem. A*, vol. 120, p. 2920]

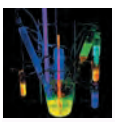
15.6 Nitrides, phosphides, arsenides, antimonides and bismuthides

Nitrides

Classifying nitrides is not simple, but nearly all nitrides fall into one of the following groups, although, as we have seen for the borides and carbides, some care is needed in attempting to generalize:

- saline nitrides of the group 1 and 2 metals, and aluminium;
- covalently bonded nitrides of the *p*-block elements (see Sections 13.8, 14.12 and 16.10 for BN, C_2N_2, Si_3N_4, Sn_3N_4 and S_4N_4);
- interstitial nitrides of *d*-block metals;
- pernitrides of the group 2 metals.

The classification of 'saline nitride' implies the presence of the N^{3-} ion, but this is unlikely (see Section 15.1). However, it is usual to consider Li_3N, Na_3N (see Section 11.4), Be_3N_2,



Mg_3N_2, Ca_3N_2, Ba_3N_2 and AlN in terms of ionic formulations. Hydrolysis of saline nitrides liberates NH_3. Sodium nitride is very hygroscopic, and samples are often contaminated with NaOH (reaction 15.55).

$$Na_3N + 3H_2O \longrightarrow 3NaOH + NH_3 \qquad (15.55)$$

Among the nitrides of the *p*-block elements, Sn_3N_4 and the γ-phase of Si_3N_4 represent the first examples of spinel nitrides (see Section 14.12).

Nitrides of the *d*-block metals are hard, inert solids which resemble metals in appearance, and have high melting points and electrical conductivities (see Box 15.4). They can be prepared from the metal or metal hydride with N_2 or NH_3 at high temperatures. Most possess structures in which the nitrogen atoms occupy octahedral holes in a close-packed metal lattice. Full occupancy of these holes leads to the stoichiometry MN (e.g. TiN, ZrN, HfN, VN, NbN). Cubic close-packing of the metal atoms with an NaCl-type structure for the nitride MN is favoured for metals in the earliest groups of the *d*-block.

Pernitrides contain the $[N_2]^{2-}$ ion and are known for barium, strontium and platinum. BaN_2 is prepared from the elements under a 5600 bar pressure of N_2 at 920 K. It is structurally related to the carbide ThC_2 (see Section 14.7), and contains isolated $[N_2]^{2-}$ ions with an N−N distance of 122 pm, consistent with an N=N bond. The strontium nitrides SrN_2 and SrN are made from Sr_2N at 920 K under N_2 pressures of 400 and 5500 bar, respectively. The structure of SrN_2 is derived from the layered structure of Sr_2N by having half of the octahedral holes between the layers occupied by $[N_2]^{2-}$ ions. Its formation can be considered in terms of N_2 (at high pressure) oxidizing Sr from a formal oxidation state of +1.5 to +2, and concomitant reduction of N_2 to $[N_2]^{2-}$. At higher pressures of N_2, all the octahedral holes in the structure become occupied by $[N_2]^{2-}$ ions, and the final product, SrN, is better formulated as $(Sr^{2+})_4(N^{3-})_2(N_2^{2-})$.

APPLICATIONS

Box 15.4 Materials chemistry: metal and non-metal nitrides

Nitrides of the *d*-block metals are hard, are resistant to wear and chemical attack including oxidation, and have very high melting points. These properties render nitrides such as TiN, ZrN and HfN invaluable for protecting high-speed cutting tools. The applied coatings are extremely thin (typically ≤10 μm), but nonetheless significantly prolong the lifetimes of tools that operate under the toughest of work conditions. Nitride coatings can be applied using the technique of chemical vapour deposition (see Section 28.6), or by forming a surface layer of Fe_3N or Fe_4N by reacting the prefabricated steel tool with N_2.

Ceramic cutting-tool materials include alumina (α-Al_2O_3) and silicon nitride. Of these two refractory materials, Si_3N_4 has greater strength at higher temperatures, higher thermal stability, lower thermal coefficient of expansion, and higher thermal conductivity. Other properties include extremely high thermal shock resistance, and resistance to attack by oxidizing agents. Despite these advantages, Si_3N_4 is difficult to fabricate in a dense form, and additives (e.g. MgO, Y_2O_3) are required to aid the conversion of powdered Si_3N_4 to the final material (i.e. the *sintering* process). The powdered Si_3N_4 comprises mainly the α-phase which is metastable with respect to the β-form. Conversion of α- to β-Si_3N_4 occurs during sintering, and gives rise to elongated grains. These grains grow within a fine-grained matrix, giving the material a reinforced microstructure. Silicon nitride is used extensively in cutting tools (e.g. for machining cast iron), and in bearings such as in machine-tool spindles. The thermal properties of Si_3N_4 have resulted in its use in ceramic heating devices. Since the mid-1980s, silicon nitride glow plugs in diesel engines have found widespread application. 'Glow plugs' are used to heat the combustion chamber of a diesel engine, aiding ignition on a cold-start. Si_3N_4 heaters can achieve a rise in temperature from ambient to around 600°C (≈900 K) in a few seconds. Silicon nitride heating devices are also employed for household appliances, e.g. for heating water.

Titanium nitride coated 10 mm drill bits.

Layers of TiN, ZrN, HfN or TaN are applied as diffusion barriers in semiconducting devices. The barrier layer (≈100 nm thick) is fabricated between the semiconducting material (e.g. GaAs or Si) and the protective metallic (e.g. Au or Ni) coating, and prevents diffusion of metal atoms into the GaAs or Si device.

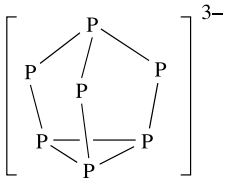
For related information: see the discussions on boron nitride, silicon nitride and ceramic coatings in Section 28.6.

The pernitrides RuN_2, OsN_2, RhN_2, IrN_2, PdN_2, PtN_2 and TiN_2 contain the $[N_2]^{4-}$ ion. They are prepared by reacting the metal and N_2 (e.g. for M = Pt, Ir or Os) or TiN and N_2 under extreme conditions of temperature and pressure in a diamond anvil cell[†] (Box 14.4) and are stable only under pressure. The $[N_4]^{2-}$ ions reside in the cavities in the metal lattice, and in PtN_2, OsN_2 and TiN_2, the N–N bond distance is 141, 143 and ≈138 pm, respectively.

Self-study exercise

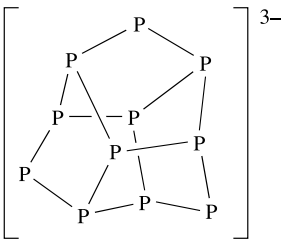
Raman spectroscopy has been used to investigate metal pernitrides. For PtN_2, TiN_2 and BaN_2, values of $\nu(N_2)$ are 860, ≈1150 and 1466 cm^{-1}, respectively.

(a) Why is Raman and not IR spectroscopy used?



(b) Comment on the consistency between the values of $\nu(N_2)$ and the N−N bond lengths (141, ≈138, 122 pm).

(c) What are the formal bond orders in N_2, $[N_2]^{2-}$ and $[N_2]^{4-}$? Are your answers consistent with the N–N bond lengths (110, 122, 141 pm)? Draw a Lewis structure for each species.



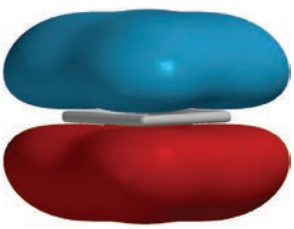
Phosphides

Most elements combine with phosphorus to give solid state binary phosphides; exceptions are Hg, Pb, Sb and Te. A solid of composition BiP has been reported, but the formation of a phosphide as opposed to a mixture of elemental bismuth and phosphorus has not been confirmed.[‡] Types of solid state phosphides are very varied, and simple classification is not possible. Phosphides of the *d*-block metals tend to be inert, metallic-looking compounds with high melting points and electrical conductivities. Their formulae are often deceptive in terms of the oxidation state of the metal and their structures may contain isolated P centres, P_2 groups, or rings, chains or layers of P atoms.

The group 1 and 2 metals form compounds M_3P and M_3P_2 respectively, which are hydrolysed by water and can be considered to be ionic. The alkali metals also form phosphides which contain groups of P atoms forming chains or cages, the cages being either $[P_7]^{3-}$ (**15.18**) or $[P_{11}]^{3-}$ (**15.19**). Lithium phosphide of stoichiometry LiP consists of helical chains and is better formulated as $Li_n[P_n]$, the $[P_n]^{n-}$ chains being isoelectronic with S_n (see Box 1.1). The P–P distances in the chains are 221 ppm, consistent with single bonds (r_{cov} = 110 pm). K_4P_3 contains $[P_3]^{4-}$ chains, Rb_4P_6 has planar $[P_6]^{4-}$ rings, Cs_3P_7 contains $[P_7]^{3-}$ cages, and Na_3P_{11} features $[P_{11}]^{3-}$ cages. Ba_3P_{14} and Sr_3P_{14} also contain $[P_7]^{3-}$ cages. The phosphides BaP_{10}, CuP_7, Ag_3P_{11}, MP_4 (e.g. M = Mn, Tc, Re, Fe, Ru, Os) and TlP_5 contain more extended arrays of P atoms, two examples (**15.9** and **15.10**) of which have already been mentioned.

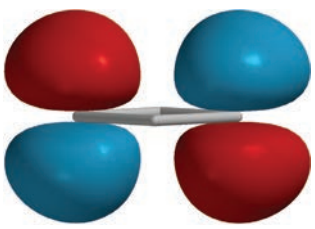
(15.18)

(15.19)



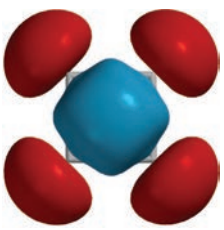
For the preparation of metal phosphides, the most general method is to heat the metal with red phosphorus. Alkali metal phosphides may be prepared using, for example, $LiPH_2$ (eq. 15.12) or P_2H_4. The reaction of Cs with P_2H_4 (eq. 15.56) followed by recrystallization from liquid NH_3 gives $Cs_2P_4{\cdot}2NH_3$ which contains planar $[P_4]^{2-}$ rings.

$$6P_2H_4 + 10Cs \longrightarrow Cs_2P_4 + 8CsPH_2 + 4H_2 \qquad (15.56)$$



The P–P bond distances of 215 pm are shorter than a typical single bond (220 pm) but longer than a double bond (see Section 23.6). Cyclic $[P_4]^{2-}$ is a 6π-aromatic system, and the bonding is explored in the exercise below.

Self-study exercise



Three of the occupied MOs of $[P_4]^{2-}$ are shown below. The e_g orbitals are the highest lying occupied MOs. Assume that the P_4-ring is oriented in the *xy*-plane.

a_{2u}

one MO of an e_g set

a_{1g}

(a) Assuming that $[P_4]^{2-}$ is a perfect square, use Fig. 3.10 to confirm that $[P_4]^{2-}$ belongs to the D_{4h} point group.

[†] See: K. Niwa *et al.* (2014) *Chem. Eur. J.*, vol. 20, p. 13885 and references cited therein; V.S. Bhadram *et al.* (2016) *Chem. Mater.*, vol. 28, p. 1616.

[‡] G.C. Allen *et al.* (1997) *Chem. Mater.*, vol. 9, p. 1385 – 'Material of composition BiP'.

(b) By using the appropriate character table in Appendix 3, confirm that the symmetries of the MOs labelled a_{1g} and a_{2u} are consistent with the labels given.

(c) How many occupied MOs does $[P_4]^{2-}$ possess? (Consider only the valence electrons.)

(d) Explain why the a_{1g} orbital is classed as a σ-bonding MO.

(e) The π-orbitals of $[P_4]^{2-}$ are derived from combinations of the phosphorus $3p_z$ orbitals. How many π-MOs are there? Draw diagrams to represent these π-MOs. Draw an energy level diagram to show the relative energies of these MOs.

[*Ans.* (c) 11; (e) $[P_4]^{2-}$ is isoelectronic with $[C_4H_4]^{2-}$, see Fig. 24.32]

Arsenides, antimonides and bismuthides

Metal arsenides, antimonides and bismuthides can be prepared by direct combination of the metal and group 15 element. Like the phosphides, classification is not simple, and structure types vary. The coverage here is, therefore, selective.

Gallium arsenide, GaAs, is an important III–V semiconductor (see Section 28.6) and crystallizes with a zinc blende-type structure (see Fig. 6.21b). Slow hydrolysis occurs in moist air and protection of semiconductor devices from the air is essential; N_2 is often used as a 'blanket gas'. At 298 K, GaAs has a band gap of 1.42 eV, and can be used to make devices that emit light in the infrared region. Gallium arsenide exhibits a high electron mobility (8500 $cm^2\,V^{-1}\,s^{-1}$, compared with a value of 1500 $cm^2\,V^{-1}\,s^{-1}$ for silicon). While this property, coupled with the highly desirable optical properties of GaAs, provides advantages for GaAs over Si, there are a number of disadvantages for use in devices: (i) GaAs is more expensive than Si, (ii) GaAs wafers are more brittle than those fabricated from Si, and (iii) GaAs has a lower thermal conductivity than Si, resulting in heat-sinks in GaAs devices.

Nickel arsenide, NiAs, gives its name to a prototype structure which is adopted by a number of *d*-block metal arsenides, antimonides, sulfides, selenides and tellurides. The structure can be described as a hexagonal close-packed (hcp) array of As atoms with Ni atoms occupying octahedral holes. Although such a description might give the idea of an *ionic* lattice, the bonding in NiAs is certainly *not* purely ionic. Figure 15.12 shows a unit cell of NiAs. The placement of the Ni atoms in *octahedral* holes in the hcp arrangement of As atoms means that the coordination environment of the As centres is *trigonal prismatic*. Although each Ni atom has six As neighbours at 243 pm, there are two Ni neighbours at a distance of only 252 pm (compare $r_{metal}(Ni) = 125$ pm) and there is almost certainly Ni–Ni bonding running through the structure. This is consistent with the observation that NiAs conducts electricity.

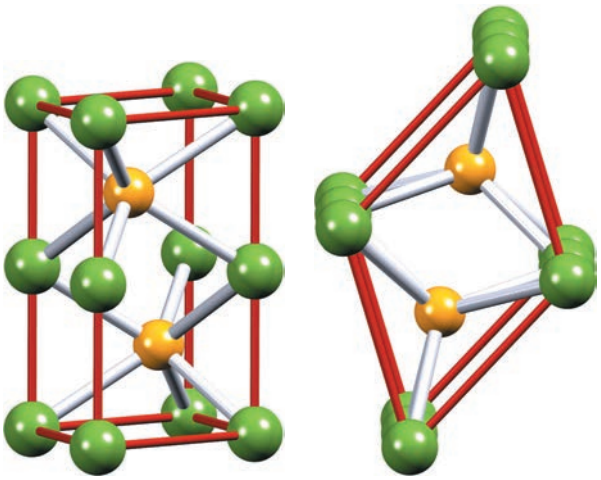


Fig. 15.12. Two views of the unit cell (defined by the red lines) of the nickel arsenide (NiAs) lattice; colour code: Ni, green; As, yellow. View (a) shows the trigonal prismatic coordination environment of the As centres, while (b) (which views (a) from above) illustrates more clearly that the unit cell is not a cuboid.

Arsenides and antimonides containing the $[As_7]^{3-}$ and $[Sb_7]^{3-}$ ions can be prepared by, for example, reactions 15.57 and 15.58. These Zintl ions are structurally related to $[P_7]^{3-}$ (**15.18**) and their bonding can be described in terms of localized 2-centre 2-electron interactions.

$$3Ba + 14As \xrightarrow{1070\ K} Ba_3[As_7]_2 \qquad (15.57)$$

$$Na/Sb\ alloy \xrightarrow[crypt\text{-}222]{1,2\text{-ethanediamine,}} [Na(crypt\text{-}222)]_3[Sb_7] \qquad (15.58)$$

Heteroatomic Zintl ions incorporating group 15 elements are present in the compounds $[K(crypt\text{-}222)]_2[Pb_2Sb_2]$, $[K(crypt\text{-}222)]_2[GaBi_3]$, $[K(crypt\text{-}222)]_2[InBi_3]$ and $[Na(crypt\text{-}222)]_3[In_4Bi_5]$, all of which are prepared (mostly as solvates with 1,2-ethanediamine) in a similar way to reaction 15.58. The $[Pb_2Sb_2]^{2-}$, $[GaBi_3]^{2-}$ and $[InBi_3]^{2-}$ ions are tetrahedral in shape. The $[In_4Bi_5]^{3-}$ ion adopts a monocapped square-antiprismatic structure in which the Bi atoms occupy the unique capping site and the four open-face sites. These structures are consistent with Wade's rules (see Section 13.11).[†] Examples of non-cluster $[E_n]^{x-}$ species are provided by $[Bi_2]^{2-}$, $[As_4]^{4-}$, $[Sb_4]^{4-}$ and $[Bi_4]^{4-}$. The $[Bi_2]^{2-}$ ion forms as a minor component in a 1,2-ethanediamine solution of the phase $K_5In_2Bi_4$ (made by heating a stoichiometric mixture of K, In and Bi) and may be crystallized as the salt

[†]For examples of related clusters that violate Wade's rules, see: L. Xu and S.C. Sevov (2000) *Inorg. Chem.*, vol. 39, 5383.

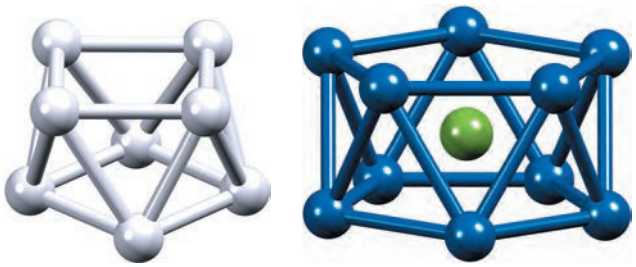

Fig. 15.13. (a) The square antiprismatic structure of $[Sb_8]^{2+}$ and $[Bi_8]^{2+}$. (b) The Pd-centred pentagonal antiprismatic structure of $[Pd@Bi_{10}]^{4+}$.

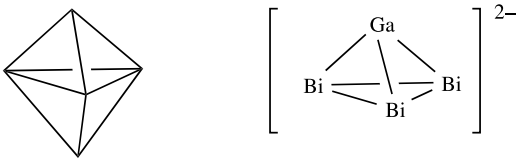
$[K(crypt\text{-}222)]_2[Bi_2]$. The short Bi–Bi distance of 284 pm is consistent with a double bond. The $[Bi_2]^{2-}$ ion is also present in the salt $[Cs(18\text{-crown-}6)]_2[Bi_2]$. The phases M_5E_4 (M = K, Rb, Cs; E = As, Sb, Bi) are formed by heating the respective elements under vacuum and slowly cooling the mixtures. They are noteworthy because they contain $[E_4]^{4-}$ chains and 'extra' electrons, i.e. they are formulated as $[M^+]_5[E_4^{4-}][e^-]$ with the additional electron being delocalized over the structure.

The syntheses of cationic bismuth clusters were described in Section 9.12. The $[Bi_5]^{3+}$ ion may also be obtained by oxidation of Bi using $GaCl_3$ in benzene, or using AsF_5. Although $[Bi_5]^{3+}$, $[Bi_8]^{2+}$ and $[Bi_9]^{5+}$ have been known for many years, no well-characterized example of a homopolyatomic antimony cation was reported until 2004. The salt $[Sb_8][GaCl_3]_2$ is formed by reducing $SbCl_3$ using $Ga^+[GaCl_4]^-$ in $GaCl_3$/benzene solution. The $[Sb_8]^{2+}$ cation is isostructural with $[Bi_8]^{2+}$ and possesses a square antiprismatic structure (Fig. 15.13a), consistent with Wade's rules (i.e. a 22 cluster-electron *arachno*-cage). Figure 15.13b shows the Pd-centred pentagonal antiprismatic cluster adopted by $[Pd@Bi_{10}]^{4+}$. This cluster is related to the endohedral Zintl ions shown in Fig. 14.16. Assuming that the palladium is a Pd(0) centre and contributes no electrons to cluster bonding, then $[Pd@Bi_{10}]^{4+}$ is a 26 cluster-electron *arachno*-cage.

Worked example 15.5 Electron counting in heteroatomic Zintl ions



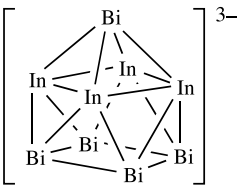
Explain how Wade's rules rationalize the tetrahedral shape of $[GaBi_3]^{2-}$.

Assume that each main group element in the cluster retains a lone pair of electrons, localized outside the cluster (i.e. not involved in cluster bonding).

Electrons available for cluster bonding are as follows:

Ga (group 13) provides one electron.
Bi (group 15) provides three electrons.
The overall 2− charge provides two electrons.
Total cluster electron count = $1 + (3 \times 3) + 2$
= 12 electrons.

The $[GaBi_3]^{2-}$ ion has six pairs of electrons with which to bond four atoms. $[GaBi_3]^{2-}$ is therefore classed as a *nido*-cluster, based on a 5-vertex trigonal bipyramid with one vertex missing. This is consistent with the observed tetrahedral shape:



closo-trigonal bipyramid

Self-study exercises

1. Explain how Wade's rules rationalize why $[Pb_2Sb_2]^{2-}$ has a tetrahedral shape. What class of cluster is $[Pb_2Sb_2]^{2-}$?
[*Ans.* 6 cluster electron pairs; *nido*]

2. Explain why the monocapped square-antiprismatic structure for $[In_4Bi_5]^{3-}$ shown below is consistent with Wade's rules. What class of cluster is $[In_4Bi_5]^{3-}$?

[*Ans.* 11 cluster electron pairs; *nido*]

3. In theory, would isomers be possible for tetrahedral $[Pb_2Sb_2]^{2-}$ and for tetrahedral $[InBi_3]^{2-}$?
[*Ans.* No isomers possible]

15.7 Halides, oxohalides and complex halides

Nitrogen halides

The highest molecular halides of nitrogen are of formula NX_3. Nitrogen pentahalides are not known and this has been attributed to the steric crowding of five halogen atoms around the small N atom. Important nitrogen halides are NX_3 (X = F, Cl), N_2F_4 and N_2F_2, selected properties for which are listed in Table 15.6. NBr_3 and NI_3 exist but are less well characterized than NF_3 and NCl_3.

Nitrogen trifluoride is made either by reaction 15.59 which must be carried out in a controlled manner, or by electrolysis of anhydrous NH_4F/HF mixtures.

Table 15.6 Selected data for nitrogen fluorides and trichloride.

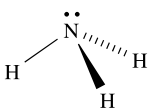
	NF_3	NCl_3	N_2F_4	*cis*-N_2F_2	*trans*-N_2F_2
Melting point / K	66	<233	108.5	<78	101
Boiling point / K	144	<344; explodes at 368	199	167	162
$\Delta_f H^o(298\,K)$ / kJ mol^{-1}	−132.1	230.0	−8.4	69.5	82.0
Dipole moment / D	0.24	0.39	0.26†	0.16	0
N–N bond distance / pm	–	–	149	121	122
N–X bond distance / pm	137	176	137	141	140
Bond angles / deg	∠F–N–F 102.5	∠Cl–N–Cl 107	∠F–N–F 103 ∠N–N–F 101	∠N–N–F 114	∠N–N–F 106

† *Gauche* conformation (see Fig. 15.5).

$$4NH_3 + 3F_2 \xrightarrow{\text{Cu catalyst}} NF_3 + 3NH_4F \qquad (15.59)$$

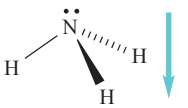
NF_3 is the most stable of the trihalides of nitrogen, being the only one to have a negative value of $\Delta_f H^o$ (Table 15.6). It is a colourless gas which is resistant to attack by acids and alkalis, but is decomposed by sparking with H_2 (eq. 15.60). The resistance towards hydrolysis parallels that observed for the carbon tetrahalides (Section 14.8).

$$2NF_3 + 3H_2 \longrightarrow N_2 + 6HF \qquad (15.60)$$



(15.20)

The gas-phase structure of NF_3 is trigonal pyramidal (**15.20**), and the molecular dipole moment is very small (Table 15.6). In contrast to NH_3 and PF_3, NF_3 shows no donor properties.



Worked example 15.6 Dipole moments in NX_3 molecules

Explain why NH_3 is polar. In which direction does the dipole moment act?

NH_3 is a trigonal pyramidal molecule with a lone pair of electrons on the N atom:

The Pauling electronegativity values of N and H are 3.0 and 2.2, respectively (see Appendix 7) and, therefore, each N–H bond is polar in the sense $N^{\delta-}-H^{\delta+}$. The resultant molecular dipole moment is reinforced by the lone pair of electrons:

(By SI convention, the arrow representing the dipole moment points from δ^- to δ^+: see Section 2.6.)

Self-study exercises

1. Rationalize why there is a significant difference between the dipole moments of the gas-phase molecules NH_3 ($\mu = 1.47$ D) and NF_3 ($\mu = 0.24$ D).
[*Ans.* See Example 3 in Section 2.6]
2. Account for the fact that the dipole moment of NHF_2 (1.92 D) is greater than that of NF_3 (0.24 D).
3. Suggest how the directionalities of the resulting dipole moments in NH_3 and NHF_2 differ. Give reasons for your answer.

Nitrogen trichloride is an oily, yellow liquid at 289 K, but it is highly endothermic and dangerously explosive (Table 15.6). The difference in stabilities of NF_3 and NCl_3 lies in the relative bond strengths of N–F over N–Cl, and of Cl_2 over F_2. Nitrogen trichloride can be prepared by reaction 15.61, with the equilibrium being drawn to the right-hand side by extracting NCl_3 into a suitable organic solvent. Diluted with air, NCl_3 is used for bleaching flour since hydrolysis by moisture forms HOCl (see Section 17.9). Alkalis hydrolyse NCl_3 according to eq. 15.62.

$$NH_4Cl + 3Cl_2 \rightleftharpoons NCl_3 + 4HCl \qquad (15.61)$$

$$2NCl_3 + 6[OH]^- \longrightarrow N_2 + 3[OCl]^- + 3Cl^- + 3H_2O \quad (15.62)$$

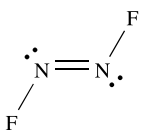
Nitrogen tribromide is more reactive than NCl_3, and explodes at temperatures as low as 175 K. It can be prepared by reaction 15.63, attempts to make it by treating NCl_3 with Br_2 being unsuccessful.

$$(Me_3Si)_2NBr + 2BrCl \xrightarrow{\text{in pentane, 186 K}} NBr_3 + 2Me_3SiCl \quad (15.63)$$

Nitrogen triiodide has been made by reacting IF with boron nitride in $CFCl_3$. Although NI_3 is stable at 77 K and has been characterized by IR, Raman and ^{15}N NMR spectroscopies, it is highly explosive at higher temperatures ($\Delta_f H^o(NI_3, g) = +287\,kJ\,mol^{-1}$). The reaction between concentrated aqueous NH_3 and $[I_3]^-$ yields $NH_3{\cdot}NI_3$, black crystals of which are dangerously explosive ($\Delta_f H^o(NH_3{\cdot}NI_3, s) = +146\,kJ\,mol^{-1}$) as the compound decomposes to NH_3, N_2 and I_2.

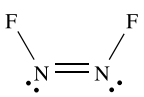
The nitrogen fluorides N_2F_4 and N_2F_2 can be obtained from reactions 15.64 and 15.65. Properties of these fluorides are listed in Table 15.6, and both compounds are explosive.

$$2NF_3 \xrightarrow{\text{Cu, 670 K}} N_2F_4 + CuF_2 \quad (15.64)$$



$$2N_2F_4 + 2AlCl_3 \xrightarrow{\text{203 K}} \textit{trans}\text{-}N_2F_2 + 3Cl_2 + N_2 + 2AlF_3$$
$$\textit{trans}\text{-}N_2F_2 \xrightarrow{\text{373 K}} \textit{cis}\text{-}N_2F_2 \quad (15.65)$$

The structure of N_2F_4 resembles that of hydrazine, except that both the *gauche* and *trans* (staggered) conformers (Fig. 15.5) are present in the liquid and gas phases. At temperatures above 298 K, N_2F_4 reversibly dissociates into blue $NF_2^{\bullet}$ radicals which undergo a wide range of reactions (e.g. eqs 15.66–15.68).



$$2NF_2 + S_2F_{10} \longrightarrow 2F_2NSF_5 \quad (15.66)$$

$$2NF_2 + Cl_2 \longrightarrow 2NClF_2 \quad (15.67)$$

$$NF_2 + NO \longrightarrow F_2NNO \quad (15.68)$$

(15.21)

(15.22)

Dinitrogen difluoride, N_2F_2, exists in both the *trans*- and *cis*-forms (**15.21** and **15.22**), with the *cis*-isomer being thermodynamically the more stable of the two but also the more reactive. Reaction 15.65 gives a selective method of preparing *trans*-N_2F_2. Isomerization by heating gives a mixture of isomers from which *cis*-N_2F_2 can be isolated by treatment with AsF_5 (reaction 15.69).

Mixture of isomers:

$$\begin{cases} \textit{cis}\text{-}N_2F_2 \xrightarrow{AsF_5} [N_2F]^+[AsF_6]^- \xrightarrow{NaF/HF} \textit{cis}\text{-}N_2F_2 \\ \textit{trans}\text{-}N_2F_2 \xrightarrow{AsF_5} \text{No reaction} \end{cases} \quad (15.69)$$

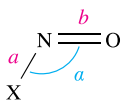
Reaction 15.69 illustrates the ability of N_2F_2 to donate F^- to *strong* acceptors such as AsF_5 and SbF_5, a reaction type shared by N_2F_4 (eqs. 15.70 and 15.71). The cation $[NF_4]^+$ is formed in reaction 15.72. We return to the properties of AsF_5 and SbF_5 later.

$$N_2F_4 + AsF_5 \longrightarrow [N_2F_3]^+[AsF_6]^- \quad (15.70)$$

$$N_2F_4 + 2SbF_5 \longrightarrow [N_2F_3]^+[Sb_2F_{11}]^- \quad (15.71)$$

$$NF_3 + F_2 + SbF_5 \longrightarrow [NF_4]^+[SbF_6]^- \quad (15.72)$$

Self-study exercise



Use the data below to determine $\Delta_r H^o(298\,K)$ for the following reaction, and comment on why the endothermic compound $NI_3{\cdot}NH_3$ forms.

$$3I_2(s) + 5NH_3(aq) \longrightarrow NI_3{\cdot}NH_3(s) + 3NH_4I(aq)$$

Data: $\Delta_f H^o(298\,K)$: $NH_3(aq)$, –80; $NH_4I(aq)$, –188; $NI_3{\cdot}NH_3(s)$, +146 kJ mol^{-1}.

[*Ans.* See: D. Tudela (2002) *J. Chem. Educ.*, vol. 79, p. 558]

Oxofluorides and oxochlorides of nitrogen

	X		
	F	Cl	Br
a / pm	152	198	214
b / pm	113	114	115
a / °	110	113	117

(15.23)

Several oxofluorides and oxochlorides of nitrogen are known, but all are unstable gases or volatile liquids which are rapidly hydrolysed. Nitrosyl halides FNO, ClNO and BrNO are formed in reactions of NO with F_2, Cl_2 and Br_2 respectively. Structural details for gas-phase molecules are shown in **15.23**. The short N–O bond lengths indicate triple rather than double bond character and a contribution from the left-hand resonance structure in the resonance pair **15.24** is clearly important. Crystals of FNO and ClNO have been grown from condensed samples of the compounds, and their solid state structures have been determined at 128 and

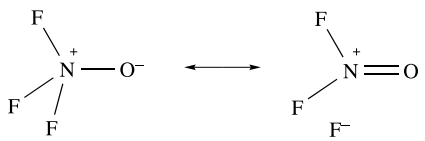
153 K, respectively. Compared with those in the gas phase, FNO molecules in the crystal have shorter (108 pm) N–O and longer (165 pm) N–F bonds. A similar trend is seen for ClNO (solid: N–O = 105 pm, N–Cl = 219 pm). These data suggest that the $[NO]^+X^-$ form in resonance pair **15.24** becomes more dominant on going from gaseous to solid XNO.

(15.24)

Nitryl fluoride, FNO_2, and nitryl chloride, $ClNO_2$, are prepared, respectively, by fluorination of N_2O_4 (reaction 15.73) and oxidation of ClNO (using e.g. Cl_2O or O_3). Both are planar molecules; FNO_2 is isoelectronic with $[NO_3]^-$.

$$N_2O_4 + 2CoF_3 \xrightarrow{570\ K} 2FNO_2 + 2CoF_2 \qquad (15.73)$$

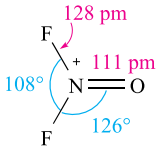
The oxohalides FNO, ClNO, FNO_2 and $ClNO_2$ combine with suitable fluorides or chlorides to give salts containing $[NO]^+$ or $[NO_2]^+$, e.g. reactions 15.74–15.76.



$$FNO + \underset{\text{halide acceptor}}{AsF_5} \longrightarrow [NO]^+[AsF_6]^- \qquad (15.74)$$

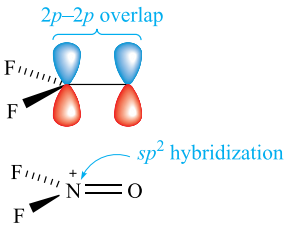
$$ClNO + SbCl_5 \longrightarrow [NO]^+[SbCl_6]^- \qquad (15.75)$$

$$FNO_2 + BF_3 \longrightarrow [NO_2]^+[BF_4]^- \qquad (15.76)$$



The main factor involved in the change from covalent to ionic halide is believed to be the enthalpy change accompanying the attachment of the halide ion to the halide acceptor.

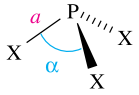
The reaction of FNO with the powerful fluorinating agent IrF_6 results in the formation of the nitrogen(V) oxofluoride F_3NO. Above 520 K, F_3NO is in equilibrium with FNO and F_2. Resonance structures **15.25** and **15.26** can be written to depict the bonding, and the short N–O bond (116 pm) and long N–F bonds (143 pm) suggest that contributions from **15.26** (and similar structures) are important.



(15.25) **(15.26)**

Reactions of F_3NO with strong F^- acceptors such as BF_3 and AsF_5 yield the salts $[F_2NO]^+[BF_4]^-$ and $[F_2NO]^+[AsF_6]^-$. In the $[AsF_6]^-$ salt (see Box 15.5), the $[F_2NO]^+$ ion is planar (structure **15.27**), consistent with the formation of an N(2*p*)–O(2*p*) π-bond (diagram **15.28**).

(15.27)



(15.28)

Phosphorus halides

Phosphorus forms the halides PX_3 (X = F, Cl, Br and I) and PX_5 (X = F, Cl and Br); PI_5 is unknown. Most of these compounds are made by direct combination of the elements with the product determined by which element is in excess. PF_3, however, must be made by reaction 15.77 and a convenient synthesis of PF_5 is from KPF_6 (see below). The halides are all hydrolysed by water (e.g. eq. 15.78), although PF_3 reacts only slowly.

$$PCl_3 + AsF_3 \longrightarrow PF_3 + AsCl_3 \qquad (15.77)$$

$$PCl_3 + 3H_2O \longrightarrow H_3PO_3 + 3HCl \qquad (15.78)$$

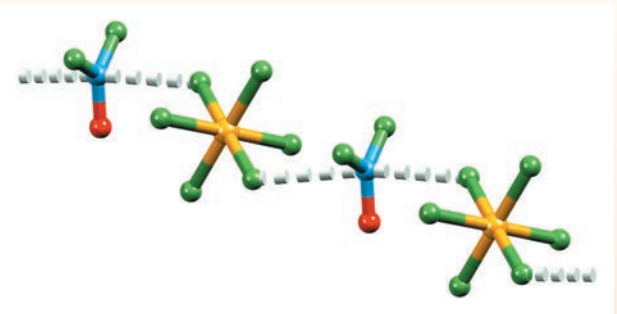
X	*a* / pm	α / °
F	156	96.5
Cl	204	100
Br	222	101
I	243	102

(15.29)

Each of the trihalides has a trigonal pyramidal structure, **15.29**. Phosphorus trifluoride is a very poisonous, colourless and odourless gas. It has the ability (like CO, see Section 24.2) to form complexes with metals and Lewis acids such as BH_3, and its toxicity arises from complex formation with haemoglobin. Protonation of PF_3 can be achieved when HF/SbF_5 is used as the acid (eq. 15.79), although an analogous reaction does not occur with AsF_3. $[HPF_3][SbF_6]\cdot HF$ is thermally unstable, but low-temperature structural data show that the tetrahedral $[HPF_3]^+$ ion has bond lengths of P–H = 122 and P–F = 149 pm.[†]

$$PF_3 + HF + SbF_5(\text{excess}) \xrightarrow[\text{crystallize at 213 K}]{\text{anhydrous HF, 77 K;}} [HPF_3][SbF_6]\cdot HF \qquad (15.79)$$

The reaction of PF_3 with Me_4NF in MeCN gives $[Me_4N][PF_4]$. The $[PF_4]^-$ ion has a see-saw shape, consistent



[†] For theoretical insight, see: M. Giordani and F. Grandinetti (2009) *J. Fluorine Chem.*, vol. 130, p. 557 – 'Protonated MF_3 (M = N–Bi): Structure, stability, and thermochemistry of the $H–MF_3^+$ and $HF–MF_2^+$ isomers'.

THEORY

Box 15.5 Crystal structure disorders: disorders involving F and O atoms

The technique of X-ray diffraction was introduced in Section 4.11, and throughout this book we make use of the results of single-crystal structure determinations. Not all structure solutions are straightforward. Some involve disordering of atomic positions, a problem that, for example, made the elucidation of the structure of C_{60} difficult (see Section 14.4). Examples of disordered structures occur commonly in oxofluorides because the O and F atoms are similar in size and possess similar electronic properties. Thus, in a crystal containing molecules of an oxofluoride XF_xO_y, a given atomic position might be occupied by O in one molecule and by F in another molecule. The overall result is modelled by *fractional occupation* of each site by O and F. Fractional occupancies can lead to difficulties in determining true X–F and X–O bond lengths and true bond angles. The compound $[F_2NO]^+[AsF_6]^-$ represents a classic example of the problem. Although first prepared and characterized in 1969, its structure was not reported until 2001. The $[F_2NO]^+$ ions in crystalline $[F_2NO][AsF_6]$ are disordered such that the fluorine occupancy of each 'F' position is 78% and 77% respectively (rather than being 100%), and the fluorine occupancy of the 'O' position is 45% (rather than being 0%). The paper cited in the further reading below illustrates how the structural data can be treated so that meaningful N–O and N–F bond lengths and F–N–F and F–N–O bond angles are obtained. Crystalline $[F_2NO][AsF_6]$ is composed of infinite chains of alternating cations and anions. There are close contacts between the N atom of each cation and the F atoms of adjacent $[AsF_6]^-$ ions as shown in the figure:

Colour code: N, blue; O, red; F, green; As, yellow.

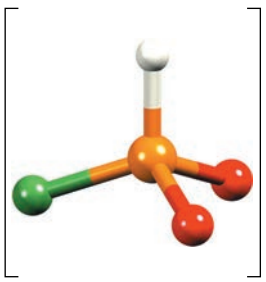
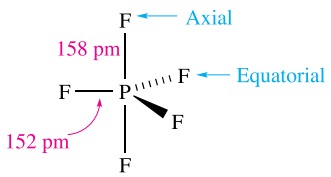
A. Vij, X. Zhang and K.O. Christe (2001) *Inorg. Chem.*, vol. 40, p. 416 – 'Crystal structure of $F_2NO^+AsF_6^-$ and method for extracting meaningful geometries from oxygen/fluorine disordered crystal structures'.



For other examples of crystallographic disorders, see: Section 14.4, C_{60}; Section 14.9, C_3O_2; Section 15.13, $(NPF_2)_4$; Section 16.10, $Se_2S_2N_4$; Box 16.2, $[O_2]^-$; Fig. 23.4, Cp_2Be; Section 24.14, $(\eta^5\text{-Cp})_2Fe$.

with the VSEPR model, i.e. the structure is derived from a trigonal bipyramid with a lone pair of electrons occupying one equatorial position. In solution, $[PF_4]^-$ is stereochemically non-rigid and the mechanism of F atom exchange is probably by Berry pseudo-rotation (see Fig. 4.25). When treated with an equimolar amount of water, $[PF_4]^-$ hydrolyses (eq. 15.80). With an excess of water, $[HPF_5]^-$ (**15.30**) hydrolyses to $[HPO_2F]^-$ (**15.31**). Further hydrolysis of $[HPO_2F]^-$ is not observed.

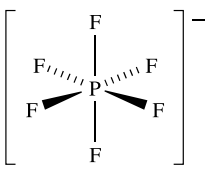
$$2[PF_4]^- + 2H_2O \xrightarrow{\text{MeCN, 293 K}} [HPF_5]^- + [HPO_2F]^- + 2HF \qquad (15.80)$$



(15.30)

(15.31)

Phosphorus trichloride is a colourless liquid (mp 179.5 K, bp 349 K) which fumes in moist air (eq. 15.78) and is toxic. Its reactions include those in scheme 15.81.



$$PCl_3 \begin{cases} \xrightarrow{O_2} POCl_3 \\ \xrightarrow{X_2\ (X=\text{halogen})} PCl_3X_2 \\ \xrightarrow{NH_3} P(NH_2)_3 \end{cases} \qquad (15.81)$$

(15.32)

Single-crystal X-ray diffraction (at 109 K) data show that PF_5 has a trigonal bipyramidal structure, **15.32**. In solution, the molecule is fluxional on the NMR spectroscopic timescale and one doublet is observed in the ^{19}F NMR spectrum, i.e. all ^{19}F environments are equivalent and couple with the ^{31}P nucleus. This stereochemical non-rigidity is another

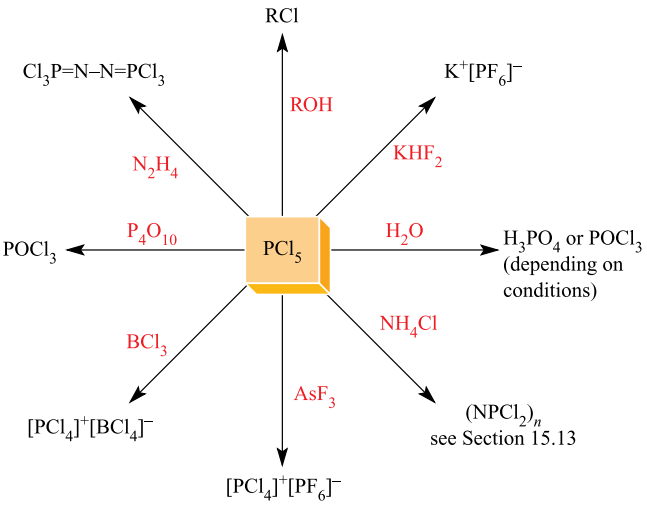
example of Berry pseudo-rotation (see Fig. 4.25). Electron diffraction data show that in the gas phase, PCl_5 has a molecular, trigonal bipyramidal structure ($P-Cl_{ax} = 214$, $P-Cl_{eq} = 202$ pm), provided that thermal dissociation into PCl_3 and Cl_2 is prevented by the presence of an excess of Cl_2. In the solid state, however, tetrahedral $[PCl_4]^+$ ($P-Cl = 197$ pm) and octahedral $[PCl_6]^-$ ($P-Cl = 208$ pm) ions are present, and the compound crystallizes with a CsCl-type structure (Fig. 6.19). In contrast, PBr_5 (which dissociates in the gas phase to PBr_3 and Br_2) crystallizes as $[PBr_4]^+Br^-$. The mixed halide PF_3Cl_2 is obtained as a gas (bp 280 K) from the reaction of PF_3 and Cl_2 and has a molecular structure with equatorial Cl atoms. However, when PCl_5 reacts with AsF_3 in $AsCl_3$ solution, the solid product $[PCl_4]^+[PF_6]^-$ (mp $\approx$ 403 K) is isolated. Solid PI_5 has not been isolated,[†] but the isolation of the salts $[PI_4]^+[AsF_6]^-$ (from the reaction of PI_3 and $[I_3]^+[AsF_6]^-$) and $[PI_4]^+[AlCl_4]^-$ (from the reaction between PI_3, ICl and $AlCl_3$) confirms the existence of the tetrahedral $[PI_4]^+$ ion. The reaction of PBr_3 with $[I_3][AsF_6]$ leads to a mixture of $[PBr_4][AsF_6]$, $[PBr_3I][AsF_6]$ and small amounts of $[PBr_2I_2][AsF_6]$. Selective formation of $[PBr_4][AsF_6]$ can be achieved by treating PBr_3 with $[Br_3]^+[AsF_6]^-$.

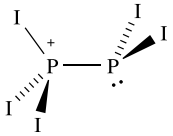
(15.33)

Phosphorus pentafluoride is a strong Lewis acid and forms stable complexes with amines and ethers. The hexafluoridophosphate ion, $[PF_6]^-$, **15.33**, is made in aqueous solution by reacting H_3PO_4 with concentrated HF. $[PF_6]^-$ is isoelectronic and isostructural with $[SiF_6]^{2-}$ (see Fig. 14.17b). Salts such as $[NH_4][PF_6]$ are commercially available, and $[PF_6]^-$ is used to precipitate salts containing large organic or complex cations. Solid KPF_6 (prepared as in Fig. 15.14) decomposes on heating to give PF_5 and this route is a useful means of preparing PF_5. Phosphorus pentachloride is an important reagent, and is made industrially by the reaction of PCl_3 and Cl_2. Selected reactions are given in Fig. 15.14.

Of the lower halides P_2X_4, the most important is the red, crystalline P_2I_4 (mp 398 K), made by reacting white phosphorus with I_2 in CS_2. In the solid state, molecules of P_2I_4 adopt a *trans* (staggered) conformation (see Fig. 15.5). In many of its reactions, P_2I_4 undergoes P–P bond fission, e.g. hydrolysis of P_2I_4 leads to a mixture of mononuclear products including PH_3, H_3PO_4, H_3PO_3 and H_3PO_2.

[†] An estimate of $\Delta_f H^o([PI_4]^+I^-, s) = +180\,kJ\,mol^{-1}$ has been made: see I. Tornieporth-Oetting *et al.* (1990) *J. Chem. Soc., Chem. Comm.*, p. 132.





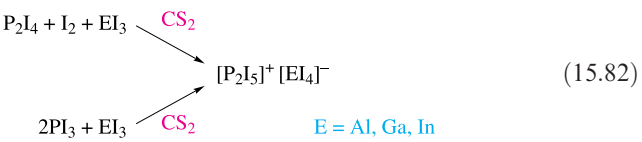


Fig. 15.14. Selected reactions of PCl_5.

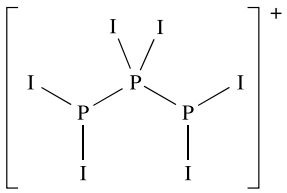
(15.34)

Salts of $[P_2I_5]^+$ (**15.34**) can be obtained according to scheme 15.82. However, the $[P_2I_5]^+$ ion exists only in the solid state. The ^{31}P NMR spectra of CS_2 solutions of dissolved samples show a singlet at δ +178 ppm, consistent with the presence of PI_3 rather than $[P_2I_5]^+$. In contrast, solution ^{31}P NMR spectra have been obtained for $[P_2I_5]^+$ in the presence of the $[Al\{OC(CF_3)_3\}_4]^-$ anion (see exercise 1 after worked example 15.7).



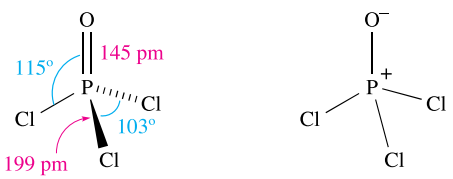
(15.82)

Worked example 15.7 ^{31}P NMR spectroscopy of phosphorus halides

The $[P_3I_6]^+$ ion is formed in the reaction of P_2I_4 with PI_3 and $Ag[Al\{OC(CF_3)_3\}_4]\cdot CH_2Cl_2$. The solution ^{31}P NMR spectrum shows a triplet and a doublet with relative integrals 1 : 2 ($J = 385$ Hz). Suggest a structure for $[P_3I_6]^+$ that is consistent with the NMR spectroscopic data.

First look up the spin quantum number and natural abundance of ^{31}P (Tables 4.3 or 15.2): $I = \frac{1}{2}$, 100%.

Adjacent ^{31}P nuclei will couple, and the presence of a triplet and doublet in the spectrum is consistent with a P–P–P backbone in $[P_3I_6]^+$. The terminal P atoms must be equivalent and therefore the following structure can be proposed:



Self-study exercises

1. Rationalize why the ^{31}P NMR spectrum of $[P_2I_5]^+$ contains two, equal-intensity doublets ($J = 320$ Hz).
2. Prolonged reaction between PI_3, $PSCl_3$ and powdered Zn results in the formation of P_3I_5 as one of the products. The solution ^{31}P NMR spectrum of P_3I_5 shows a doublet at δ +98 ppm and a triplet at δ +102 ppm. These values compare with δ +106 ppm for P_2I_4. Suggest a structure for P_3I_5 and give reasoning for your answer.
   [*Ans.* See K.B. Dillon *et al.* (2001) *Inorg. Chim. Acta*, vol. 320, p. 172]
3. The solution ^{31}P NMR spectrum of $[HPF_5]^-$ consists of a 20-line multiplet from which three coupling constants can be obtained. Explain the origins of these spin–spin coupling constants in terms of the structure of $[HPF_5]^-$.

See also end-of-chapter problems 4.40, 15.32a and 15.35a.

Phosphoryl trichloride, $POCl_3$

Of the phosphorus oxohalides, the most important is $POCl_3$, prepared by reaction of PCl_3 with O_2. Phosphoryl trichloride is a colourless, fuming liquid (mp 275 K, bp 378 K), which is readily hydrolysed by water, liberating HCl. The vapour contains discrete molecules (**15.35**). Some of the many uses of $POCl_3$ are as a phosphorylating and chlorinating agent, and as a reagent in the preparation of phosphate esters. An example of its use is the basis for end-of-chapter problem 15.39b.

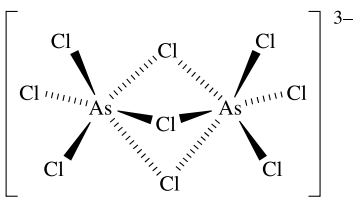
(15.35)

Arsenic and antimony halides

Arsenic forms the halides AsX_3 (X = F, Cl, Br, I) and AsX_5 (X = F, Cl). The trihalides $AsCl_3$, $AsBr_3$ and AsI_3 can be made by direct combination of the elements, and reaction 15.83 is another route to $AsCl_3$. Reaction 15.84 is used to prepare AsF_3 (mp 267 K, bp 330 K) despite the fact that AsF_3 (like the other trihalides) is hydrolysed by water; the H_2O formed in the reaction is removed with excess H_2SO_4. Glass containers are not practical for AsF_3 as it reacts with silica in the presence of moisture.

$$As_2O_3 + 6HCl \xrightarrow{\text{conc}} 2AsCl_3 + 3H_2O \qquad (15.83)$$

$$As_2O_3 + 3H_2SO_4 + 3CaF_2 \xrightarrow{\text{conc}} 2AsF_3 + 3CaSO_4 + 3H_2O \qquad (15.84)$$



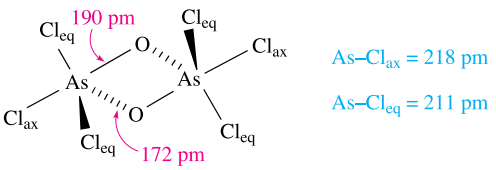
In the solid, liquid and gas states, AsF_3 and $AsCl_3$ have molecular, trigonal pyramidal structures. With an appropriate reagent, AsF_3 may act as either an F^- donor or acceptor (eqs. 15.85 and 15.86). Compare this with the behaviours of BrF_3 (Section 9.10) and $AsCl_3$ (eq. 15.87) which finds some use as a non-aqueous solvent.

$$AsF_3 + KF \longrightarrow K^+[AsF_4]^- \qquad (15.85)$$

$$AsF_3 + SbF_5 \longrightarrow [AsF_2]^+[SbF_6]^- \qquad (15.86)$$

$$2AsCl_3 \rightleftharpoons [AsCl_2]^+ + [AsCl_4]^- \qquad (15.87)$$

The reaction of $AsCl_3$ with Me_2NH and excess HCl in aqueous solution gives $[Me_2NH_2]_3[As_2Cl_9]$ containing anion **15.36**.†



(15.36)

Salts containing the $[AsX_4]^+$ (X = F, Cl, Br, I) ions include $[AsF_4][PtF_6]$ and $[AsCl_4][AsF_6]$ which are stable compounds, and $[AsBr_4][AsF_6]$ and $[AsI_4][AlCl_4]$, both of which are unstable. By using the weakly coordinating anions $[AsF(OTeF_5)_5]^-$ and $[As(OTeF_5)_6]^-$ (for example, in redox reaction 15.88), it is possible to stabilize $[AsBr_4]^+$ in the solid state.

$$AsBr_3 + BrOTeF_5 + As(OTeF_5)_5 \xrightarrow[[OTeF_5]^- \text{ acceptor}]{} [AsBr_4]^+[As(OTeF_5)_6]^- \qquad (15.88)$$

†For comments on the effect that cation size may have on the solid state structure of $[E_2X_9]^{3-}$ (E = As, Sb, Bi; X = Cl, Br), see: M. Wojtaś *et al.* (2002) *Z. Anorg. Allg. Chem.*, vol. 628, p. 516.

The only stable pentahalide of arsenic is AsF_5 (prepared by reaction 15.89), although $AsCl_5$ can be made at 173 K by treating $AsCl_3$ with Cl_2 under UV radiation. X-ray diffraction data for $AsCl_5$ at 150 K confirm the presence of discrete, trigonal bipyramidal molecules in the solid state ($As-Cl_{ax} = 221$ pm, $As-Cl_{eq} = 211$ pm). If, during the preparation of $AsCl_5$, H_2O and HCl are present, the isolated, crystalline products are $[H_5O_2]_5[AsCl_6]Cl_4$ and $[H_5O_2][AsCl_6]{\cdot}AsOCl_3$. These are stable below 253 K and contain hydrogen-bonded $[H_5O_2]^+$ and $[AsCl_6]^-$ ions. $[H_5O_2][AsCl_6]{\cdot}AsOCl_3$ is the result of cocrystallization of $[H_5O_2][AsCl_6]$ and $AsOCl_3$. This provides an example of *monomeric*, tetrahedral $AsOCl_3$, whereas solid $AsOCl_3$ (made by reacting $AsCl_3$ and O_3 at 195 K) contains the dimers **15.37**; each As atom is in a trigonal bipyramidal environment.

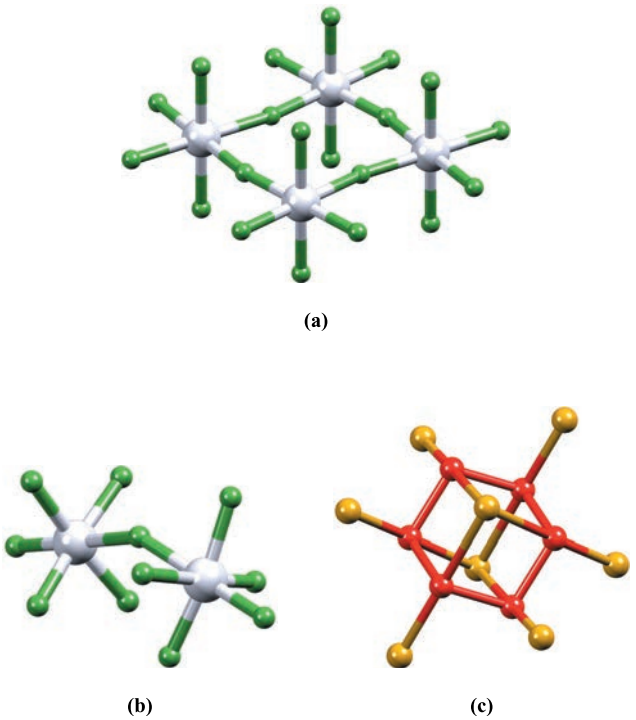
(15.37)

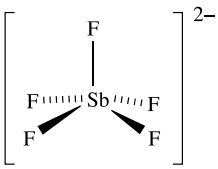
At 298 K, AsF_5 is a colourless gas and has a molecular structure similar to **15.32**.

$$AsF_3 + 2SbF_5 + Br_2 \longrightarrow AsF_5 + 2SbBrF_4 \qquad (15.89)$$

AsF_5 is a strong F^- acceptor (e.g. reactions 15.69, 15.70 and 15.74) and many complexes containing the octahedral $[AsF_6]^-$ ion are known. One interesting reaction of AsF_5 is with metallic Bi to give $[Bi_5][AsF_6]_3$ which contains the trigonal bipyramidal cluster $[Bi_5]^{3+}$. Although $[AsF_6]^-$ is the usual species formed when AsF_5 accepts F^-, the $[As_2F_{11}]^-$ adduct has also been isolated. X-ray diffraction data for $[(MeS)_2CSH]^+[As_2F_{11}]^-$ (formed from $(MeS)_2CS$, HF and AsF_5) confirm that $[As_2F_{11}]^-$ is structurally like $[Sb_2F_{11}]^-$ (Fig. 15.15b).

Antimony trihalides are low melting solids, and although these contain trigonal pyramidal molecules, each Sb centre has additional, longer range, intermolecular Sb····X interactions. The trifluoride and trichloride are prepared by reacting Sb_2O_3 with concentrated HF and HCl, respectively. SbF_3 is a widely used fluorinating agent, e.g. converting B_2Cl_4 to B_2F_4 (Section 13.6), $CHCl_3$ to CHF_2Cl (eq. 14.45), $COCl_2$ to COClF and COF_2 (Section 14.8), $SiCl_4$ to SiF_4 (Section 14.8) and $SOCl_2$ to SOF_2 (Section 16.7). However, reactions may be complicated by SbF_3 acting as an oxidizing agent (eq. 15.90). Reactions between SbF_3 and MF (M = alkali metal) give salts which include K_2SbF_5 (containing $[SbF_5]^{2-}$, **15.38**), KSb_2F_7 (with discrete SbF_3 and $[SbF_4]^-$, **15.39**), $KSbF_4$ (in which the anion is $[Sb_4F_{16}]^{4-}$, **15.40**) and $CsSb_2F_7$ (containing $[Sb_2F_7]^-$, **15.41**).





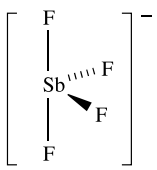


Fig. 15.15. The solid state structures of (a) $\{SbF_5\}_4$, (b) $[Sb_2F_{11}]^-$ (X-ray diffraction) in the *tert*-butyl salt [S. Hollenstein *et al.* (1993) *J. Am. Chem. Soc.*, vol. 115, p. 7240] and (c) $[As_6I_8]^{2-}$ (X-ray diffraction) in $[\{MeC(CH_2PPh_2)_3\}NiI]_2[As_6I_8]$ [P. Zanello *et al.* (1990) *J. Chem. Soc., Dalton Trans.*, p. 3761]. The bridge Sb–F bonds in $\{SbF_5\}_4$ and $[Sb_2F_{11}]^-$ are ≈15 pm longer than the terminal bonds. Colour code: Sb, silver; As, red; F, green; I, gold.

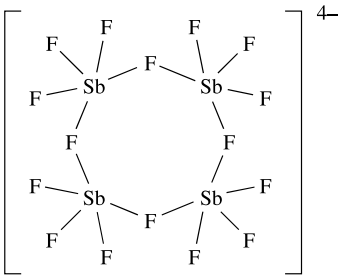
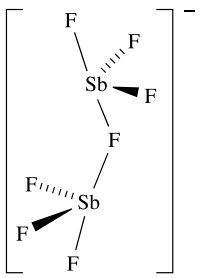
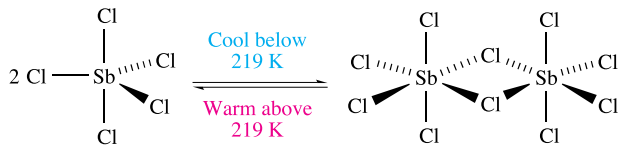


$$3C_6H_5PCl_2 + 4SbF_3 \longrightarrow 3C_6H_5PF_4 + 2SbCl_3 + 2Sb \qquad (15.90)$$



(15.38)

(15.39)



(15.40)

(15.41)

Antimony pentafluoride (mp 280 K, bp 422 K) is prepared from SbF_3 and F_2, or by reaction 15.91. In the

solid state, SbF_5 is tetrameric (Fig. 15.15a) and the presence of Sb−F−Sb bridges accounts for the very high viscosity of the liquid. Antimony pentachloride (mp 276 K, bp 352 K) is prepared from the elements, or by reaction of Cl_2 with $SbCl_3$. Liquid $SbCl_5$ contains discrete trigonal bipyramidal molecules, and these are also present in the solid between 219 K and the melting point. Like PCl_5 and $AsCl_5$, the axial bonds in $SbCl_5$ are longer than the equatorial bonds (233 and 227 pm for the solid at 243 K). Below 219 K, the solid undergoes a reversible change involving dimerization of the $SbCl_5$ molecules (diagram **15.42**).

(15.42)

$$SbCl_5 + 5HF \longrightarrow SbF_5 + 5HCl \qquad (15.91)$$

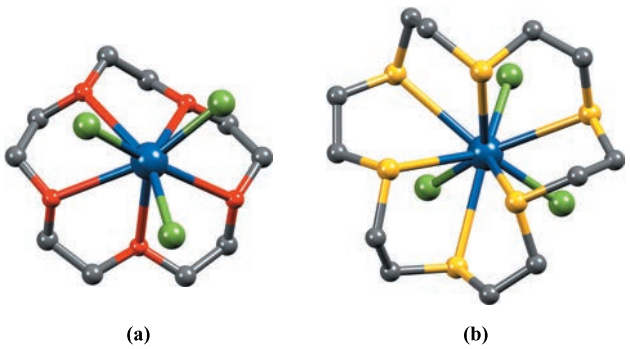
We have already illustrated the role of SbF_5 as an extremely powerful fluoride acceptor (e.g. reactions 9.44, 9.67, 15.71, 15.72 and 15.86). Similarly, $SbCl_5$ is one of the strongest chloride acceptors known (e.g. reactions 15.75 and 15.92). Reactions of SbF_5 and $SbCl_5$ with alkali metal fluorides and chlorides yield compounds of the type $M[SbF_6]$ and $M[SbCl_6]$.

$$SbCl_5 + AlCl_3 \longrightarrow [AlCl_2]^+[SbCl_6]^- \qquad (15.92)$$

Whereas the addition of Cl^- to $SbCl_5$ invariably gives $[SbCl_6]^-$, acceptance of F^- by SbF_5 may be accompanied by further association by the formation of Sb−F−Sb bridges. Thus, products may contain $[SbF_6]^-$, $[Sb_2F_{11}]^-$ (Fig. 15.15b) or $[Sb_3F_{16}]^-$ in which each Sb centre is octahedrally sited. The strength with which SbF_5 can accept F^- has led to the isolation of salts of some unusual cations, including $[O_2]^+$, $[XeF]^+$, $[Br_2]^+$, $[ClF_2]^+$ and $[NF_4]^+$. Heating $Cs[SbF_6]$ and CsF (molar ratio 1:2) at 573 K for 45 h produces $Cs_2[SbF_7]$. Vibrational spectroscopic and theoretical results are consistent with the $[SbF_7]^{2-}$ ion having a pentagonal bipyramidal structure.

When $SbCl_3$ reacts with Cl_2 in the presence of CsCl, dark blue Cs_2SbCl_6 precipitates. Black $[NH_4]_2[SbBr_6]$ can be similarly obtained. Since these compounds are diamagnetic, they cannot contain Sb(IV) and are, in fact, mixed oxidation state species containing $[SbX_6]^{3-}$ and $[SbX_6]^-$. The dark colours of the compounds arise from absorption of light associated with electron transfer between the two anions. The solid state structures of Cs_2SbCl_6 and $[NH_4]_2[SbBr_6]$ show similar characteristics to one another, e.g. in $[NH_4]_2[SbBr_6]$, two distinct octahedral anions are present, $[SbBr_6]^-$ (Sb−Br = 256 pm) and $[SbBr_6]^{3-}$ (Sb−Br = 279 pm); the lone pair in the Sb(III) species is stereochemically inactive.

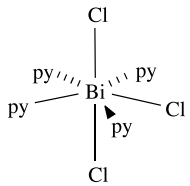
A number of high nuclearity halo-anions of As and Sb are known which contain doubly and triply bridging X^-, e.g. $[As_6I_8]^{2-}$ (Fig. 15.15c), $[As_8I_{28}]^{4-}$, $[Sb_5I_{18}]^{3-}$ and $[Sb_6I_{22}]^{4-}$.



Self-study exercise

To what point group do the $[SbBr_6]^-$ and $[SbBr_6]^{3-}$ ions belong if they possess regular octahedral structures? Explain why one of these ions possesses a stereochemically inactive lone pair of electrons, while the other ion has no Sb-centred lone pair.

Bismuth halides



The trihalides BiF_3, $BiCl_3$, $BiBr_3$ and BiI_3 are all well characterized, but BiF_5 is the only Bi(V) halide known. All are solids at 298 K. In the vapour phase, the trihalides have molecular (trigonal pyramidal) structures. In the solid state, β-BiF_3 contains 9-coordinate Bi(III) centres. Solid $BiCl_3$ and $BiBr_3$ have molecular structures but with an additional five long Bi···X contacts, and in BiI_3, the Bi atoms occupy octahedral sites in an hcp array of I atoms. The trihalides can be formed by combination of the elements at high temperature. Each trihalide is hydrolysed by water to give BiOX, which are insoluble compounds with layer structures. The reaction of BiF_3 with F_2 at 880 K yields BiF_5 which is a powerful fluorinating agent. Heating BiF_5 with an excess of MF (M = Na, K, Rb or Cs) at 503–583 K for four days produces $M_2[BiF_7]$; the reactions are carried out under a low pressure of F_2 to prevent reduction of Bi(V) to Bi(III). Treatment of BiF_5 with an excess of FNO at 195 K yields $[NO]_2[BiF_7]$, but this is thermally unstable and forms $[NO][BiF_6]$ when warmed to room temperature. The $[BiF_7]^{2-}$ ion has been assigned a pentagonal bipyramidal structure on the basis of vibrational spectroscopic and theoretical data.

The trihalides are Lewis acids and form donor–acceptor complexes with a number of ethers, e.g. *fac*-$[BiCl_3(THF)_3]$, *mer*-$[BiI_3(py)_3]$ (py = pyridine), *cis*-$[BiI_4(py)_2]^-$, $[BiCl_3(py)_4]$ (**15.43**) and the macrocyclic ligand complexes shown in Fig. 15.16. Reactions with halide ions give species such as $[BiCl_5]^{2-}$ (square pyramidal), $[BiBr_6]^{3-}$ (octahedral), $[Bi_2Cl_8]^{2-}$ (**15.44**), $[Bi_2I_8]^{2-}$ (structurally similar to **15.44**), and $[Bi_2I_9]^{3-}$ (**15.45**). Bismuth(III) also forms some higher nuclearity halide complexes, e.g. $[Bi_4Cl_{16}]^{4-}$, as well as the polymeric species $[\{BiX_4\}_n]^{n-}$ and $[\{BiX_5\}_n]^{2n-}$. In each case, the Bi atoms are octahedrally sited.

(15.45)

Worked example 15.8 Redox chemistry of group 15 metal halides

In reaction 15.88, which species undergo oxidation and which reduction? Confirm that the equation balances in terms of changes in oxidation states.

The reaction to be considered is:

$$AsBr_3 + BrOTeF_5 + As(OTeF_5)_5 \longrightarrow [AsBr_4]^+[As(OTeF_5)_6]^-$$

Oxidation states:		
	$AsBr_3$	As, +3; Br, −1
	$BrOTeF_5$	Br, +1; Te, +6
	$As(OTeF_5)_5$	As, +5; Te, +6
	$[AsBr_4]^+$	As, +5; Br, −1
	$[As(OTeF_5)_6]^-$	As, +5; Te, +6

The redox chemistry involves As and Br. The As in $AsBr_3$ is oxidized on going to $[AsBr_4]^+$, while Br in $BrOTeF_5$ is reduced on going to $[AsBr_4]^+$.

Oxidation: As(+3) to As(+5) Change in oxidation state = +2

Reduction: Br(+1) to Br(−1) Change in oxidation state = −2

Therefore the equation balances in terms of oxidation state changes.

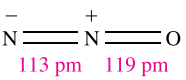
Self-study exercises

1. In reaction 15.59, which elements are oxidized and which reduced? Confirm that the reaction balances in terms of changes in oxidation states.
[*Ans.* N, oxidized; F, reduced]
2. Which elements undergo redox changes in reaction 15.62? Confirm that the equation balances in terms of the oxidation state changes.
[*Ans.* N, reduced; half of the Cl, oxidized]
3. Are reactions 15.74, 15.75 and 15.76 redox reactions? Confirm your answer by determining the oxidation states of the N atoms in the reactants and products in each equation. [*Ans.* Non-redox]
4. Confirm that reaction 15.90 is a redox process, and that the equation balances with respect to changes in oxidation states for the appropriate elements.

15.8 Oxides of nitrogen

As in group 14, the first element of group 15 stands apart in forming oxides in which (p–p)π-bonding is important. Table 15.7 lists selected properties of nitrogen oxides, excluding NO_3 which is an unstable radical. NO_2 exists in equilibrium with N_2O_4.

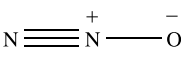
Dinitrogen monoxide, N_2O



Dinitrogen monoxide (Table 15.7) is usually prepared by decomposition of solid ammonium nitrate (eq. 15.93, compare reaction 15.8) but the aqueous solution reaction 15.94 is useful for obtaining a purer product. For further detail on the oxidation of NH_2OH to N_2O, see Section 15.5.

$$NH_4NO_3 \xrightarrow{450-520\,K} N_2O + 2H_2O \qquad (15.93)$$

$$NH_2OH + HNO_2 \longrightarrow N_2O + 2H_2O \qquad (15.94)$$



Dinitrogen monoxide has a faint, sweet odour. It dissolves in water to give a neutral solution, but does not react to any significant extent. The position of equilibrium 15.95 is far to the left.

$$N_2O + H_2O \rightleftharpoons H_2N_2O_2 \qquad (15.95)$$

113 pm 119 pm

† N_2O and NO are commonly called nitrous oxide and nitric oxide, respectively.

Dinitrogen monoxide is a non-toxic gas which is fairly unreactive at 298 K. The N_2O molecule is linear, and the bonding can be represented as in structure **15.46**, although the bond lengths suggest some contribution from resonance structure **15.47**. In the past, N_2O ('laughing gas') was widely used as an anaesthetic, but possible side-effects coupled with the availability of a range of alternative anaesthetics have led to a significant decline in its use.† Nitrous oxide remains in use as a propellant in whipped cream dispensers. Its reactivity is higher at elevated temperatures; N_2O supports combustion, and reacts with $NaNH_2$ at 460 K (eq. 15.50). This reaction is used commercially to prepare NaN_3, a precursor to other azides such as $Pb(N_3)_2$ which is used as a detonator.

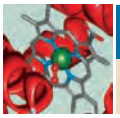
Nitrogen monoxide, NO

Nitrogen monoxide (Table 15.7 and Box 15.6) is made industrially from NH_3 (eq. 15.96), and on a laboratory scale by reducing HNO_3 or nitrites (e.g. KNO_2) in the presence of H_2SO_4 in aqueous solution (reaction 15.97 or 15.98).

$$4NH_3 + 5O_2 \xrightarrow{1300\,K,\ Pt\ catalyst} 4NO + 6H_2O \qquad (15.96)$$

$$[NO_3]^- + 3Fe^{2+} + 4H^+ \longrightarrow NO + 3Fe^{3+} + 2H_2O \qquad (15.97)$$

$$[NO_2]^- + I^- + 2H^+ \longrightarrow NO + H_2O + \tfrac{1}{2}I_2 \qquad (15.98)$$



Reaction 15.97 is the basis of the brown ring test for $[NO_3]^-$. After the addition of an equal volume of aqueous $FeSO_4$ to the test solution, cold concentrated H_2SO_4 is added slowly to form a separate, lower layer. If $[NO_3]^-$ is present, NO is liberated, and a brown ring forms between the two layers. The brown colour is due to the formation of $[Fe(NO)(OH_2)_5]^{2+}$, an example of one of many *nitrosyl complexes* in which NO acts as a ligand (see Sections 20.4 and 24.2). The IR spectrum of $[Fe(NO)(OH_2)_5]^{2+}$ shows an absorption at 1810 cm^{-1} assigned to ν(NO) and is consistent with the formulation of an $[NO]^-$ ligand bound to Fe(III) rather than $[NO]^+$ coordinated to Fe(I). The presence of Fe(III) is also supported by Mössbauer spectroscopic data. The reaction between $[Fe(OH_2)_6]^{2+}$ and NO is discussed again in Box 26.1. The compound $[Et_4N]_5[NO][V_{12}O_{32}]$ is unusual because it contains a non-coordinated $[NO]^-$ ion. The $[V_{12}O_{32}]^{4-}$ ion (see Section 21.6) has a 'bowl-shaped' structure and acts as a 'host', trapping the $[NO]^-$ ion as a 'guest' within the cage. There are only weak van der Waals interactions between the host and guest.

(15.48)

Structure **15.48** shows that NO is a radical. Unlike NO_2, it does not dimerize unless cooled to low temperature under high pressure. In the diamagnetic solid, a dimer with a long

BIOLOGY AND MEDICINE

Box 15.6 Nitrogen monoxide in biology

Research into the role played by NO in biological systems is an active area, and in 1992, *Science* named NO 'Molecule of the Year'. The 1998 Nobel Prize in Physiology or Medicine was awarded to Robert F. Furchgott, Louis J. Ignarro and Ferid Murad for 'their discoveries concerning nitric oxide as a signalling molecule in the cardiovascular system' (www.nobel.se/medicine/laureates/1998/press.html).

Nitrogen monoxide is synthesized *in vivo* from the amino acid L-arginine, and the reaction is catalysed by the haem-containing NO synthase (NOS) enzymes which are related to cytochromes P450 (see Section 29.3). There are three forms of NO synthases: neuronal (nNOS), inducible (iNOS) and endothelial (eNOS). nNOS and eNOS are classed as low-output enzymes and their activities are regulated by Ca^{2+} ions in the presence of the calcium-binding protein, calmodulin. In contrast, iNOS is a high-output enzyme and its activity does not depend on the presence of Ca^{2+} ions. L-Arginine is converted to NO and L-citrulline (see below) in a two-step reaction. This involves a 5-electron oxidation process, and requires O_2 in addition to the cofactor NADPH (nicotinamide adenine dinucleotide phosphate).

L-Arginine L-Citrulline

The enzymic receptor for NO in the body (*guanylyl cyclase*) also contains a haem unit. In addition to these haem groups, NO may coordinate to the haem iron atom in myoglobin and haemoglobin (see Section 29.3). The structure of iron(II) horse heart myoglobin with NO bound to the haem-iron centre has been determined by single crystal X-ray diffraction. The structure is illustrated in the left-hand figure below, with the protein shown in a ribbon representation and the haem-unit in a stick representation. The secondary structure of the protein is colour-coded, with α-helices shown in red, turns in green, and coils in silver-grey. The right-hand figure below is an enlargement of the active site. The iron(II) centre is octahedrally coordinated. The NO molecule is bound *trans* to the histidine residue (see Table 29.2) that connects the active site to the protein backbone. The structural data confirm that the Fe–N–O unit is non-linear (angle Fe–N–O = 147°).

The small molecular dimensions of NO mean that it readily diffuses through cell walls. It acts as a messenger molecule in biological systems, and appears to have an active role in mammalian functions such as the regulation of blood pressure, muscle relaxation and neuro-transmission. A remarkable property exhibited by NO is that it appears to be cytotoxic (i.e. it is able to specifically destroy particular cells) and it affects the ability of the body's immune system to kill tumour cells.

N−N bond (218 pm) is present. It is probable that a dimer is an intermediate in reactions 15.99, for which reaction rates decrease with increasing temperature.

$$\left.\begin{aligned} 2NO + Cl_2 &\longrightarrow 2ClNO \quad \text{Rate} \propto (P_{NO})^2(P_{Cl_2}) \\ 2NO + O_2 &\longrightarrow 2NO_2 \quad \text{Rate} \propto (P_{NO})^2(P_{O_2}) \end{aligned}\right\} \quad (15.99)$$

The reaction of NO with O_2 is important in the manufacture of nitric acid (Section 15.9), but NO can also be oxidized directly to HNO_3 by acidified $[MnO_4]^-$. The reduction of NO depends on the reducing agent, e.g. with SO_2, the product is N_2O, but reduction with tin and acid gives NH_2OH. Although NO is thermodynamically unstable with respect to its elements (Table 15.7), it does not decompose at an appreciable rate below 1270 K, and so does not support combustion well. The positive value of $\Delta_f H^o$ means that at high temperatures, the formation of NO is favoured, and this is significant during combustion of motor and aircraft fuels where NO is one of several oxides formed. These oxides are collectively described by NO_x (see Box 15.7) and contribute to the formation of smogs over large cities.

A reaction of NO that has been known since the early 1800s is that with sulfite ion to form $[O_3SNONO]^{2-}$. One resonance structure for this ion is shown in diagram **15.49**. The bond lengths for the K^+ salt are consistent with an S−N single bond, and double bond character for the N−N bond, but they also suggest some degree of multiple bond character for the N−O bonds. It is proposed that $[O_3SNONO]^{2-}$ forms by sequential addition of NO to $[SO_3]^{2-}$, rather than the single-step addition of the transient dimer, ONNO.

For the K^+ salt:

S–N = 175 pm

N–N = 128 pm

N–O = 129, 132 pm

(15.49)

Reactions 15.74 and 15.75 showed the formation of salts containing the $[NO]^+$ (nitrosyl) cation. Many salts are known and X-ray diffraction data confirm an N−O distance of 106 pm, i.e. less than in NO (115 pm). A molecular orbital treatment of the bonding (see end-of-chapter problem 15.20) is consistent with this observation. In going from NO to $[NO]^+$ there is an increase in the NO vibrational frequency (from 1876 to ≈2300 cm^{-1}), in keeping with an increase in bond strength. All nitrosyl salts are decomposed by water (eq. 15.100).

$$[NO]^+ + H_2O \longrightarrow HNO_2 + H^+ \quad (15.100)$$

Dinitrogen trioxide, N_2O_3

Dinitrogen trioxide (Table 15.7 and Fig. 15.17) is obtained as a dark blue liquid in reaction 15.101 at low temperatures, but even at 195 K, extensive dissociation back to NO and N_2O_4 occurs.

$$2NO + N_2O_4 \rightleftharpoons 2N_2O_3 \quad (15.101)$$

Dinitrogen trioxide is water-soluble and is the *acid anhydride* of HNO_2, nitrous acid (eq. 15.102).

$$N_2O_3 + H_2O \longrightarrow 2HNO_2 \quad (15.102)$$

An ***acid anhydride*** is formed when one or more molecules of acid lose one or more molecules of water.

Dinitrogen tetraoxide, N_2O_4, and nitrogen dioxide, NO_2

Dinitrogen tetraoxide and nitrogen dioxide (Table 15.7 and Fig. 15.17) exist in equilibrium 15.103, and must be discussed together.

$$N_2O_4 \rightleftharpoons 2NO_2 \quad (15.103)$$

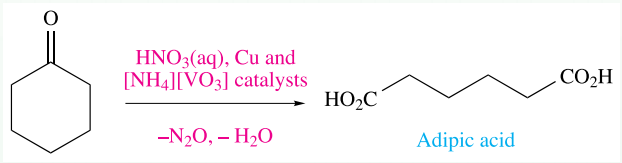
The solid is colourless and is diamagnetic, consistent with the presence of only N_2O_4. Dissociation of this dimer gives the brown NO_2 radical. Solid N_2O_4 melts to give a yellow liquid, the colour arising from the presence of a little NO_2. At 294 K (bp), the brown vapour contains 15% NO_2. The colour of the vapour darkens as the temperature is raised, and at 413 K dissociation of N_2O_4 is almost complete. Above 413 K, the colour lightens again as NO_2 dissociates to NO and O_2. Laboratory-scale preparations of NO_2 or N_2O_4 are usually by thermal decomposition of *dry* lead(II) nitrate (eq. 15.104). If the brown gaseous NO_2 is cooled to ≈273 K, N_2O_4 condenses as a yellow liquid.

$$2Pb(NO_3)_2(s) \xrightarrow{\Delta} 2PbO(s) + 4NO_2(g) + O_2(g) \quad (15.104)$$

Dinitrogen tetraoxide is a powerful oxidizing agent (e.g. see Box 9.1) which attacks many metals, including Hg, at 298 K. The reaction of NO_2 or N_2O_4 with water gives a 1:1 mixture of nitrous and nitric acids (eq. 15.105), although nitrous acid disproportionates (see below). Because of the formation of these acids, atmospheric NO_2 is corrosive and contributes to 'acid rain' (see Box 16.5). In concentrated H_2SO_4, N_2O_4 yields the nitrosyl and nitryl cations (eq. 15.106). The reactions of N_2O_4 with halogens and uses of N_2O_4 as a non-aqueous solvent were outlined in Sections 15.7 and 9.11, respectively.

$$2NO_2 + H_2O \longrightarrow HNO_2 + HNO_3 \quad (15.105)$$

$$N_2O_4 + 3H_2SO_4 \longrightarrow [NO]^+ + [NO_2]^+ + [H_3O]^+ + 3[HSO_4]^- \quad (15.106)$$



The nitryl cation **15.50** is linear, compared with the bent structures of NO_2 (Fig. 15.17) and of $[NO_2]^-$ ($\angle O-N-O = 115^\circ$).

ENVIRONMENT

Box 15.7 NO_x: tropospheric pollutant

'NO_x' (pronounced 'NOX') is a combination of nitrogen oxides arising from both natural (soil emissions and lightning) and man-made sources. The major man-made culprits are vehicle and aircraft exhausts and large industrial power (e.g. electricity-generating) plants (see Fig. 25.16). The term NO_x usually refers to a combination of NO and NO_2, and excludes N_2O which is naturally produced by denitrifying bacteria (see Box 15.9) and is formed in the manufacture of adipic acid. Adipic acid is one of the reagents in the industrial synthesis of Nylon-66, and is produced by the oxidation of cyclohexanol and cyclohexanone using nitric acid:

Because of the large scale of adipic acid manufacture, emissions of N_2O from this source are significant. Since the 1990s, measures have been put in place to prevent N_2O reaching the atmosphere. Both thermal destruction and catalytic (e.g. CuO/Al_2O_3) decomposition convert N_2O to N_2 and O_2.

In the closing years of the 20th century, a better awareness of our environment led to the regulation of exhaust emissions. Regulated emissions are CO, hydrocarbons and NO_x, as well as particulate matter. Catalytic converters (see Section 25.8) are now routinely used to reduce the emissions of CO, hydrocarbons and NO_x from the combustion of transport fuels. A combination of Rh, Pt and Pd metals is required in a catalytic converter to catalyse the oxidation of CO and hydrocarbons, and the reduction of NO_x, thereby producing acceptable emissions of CO_2, H_2O and N_2. Rhodium metal catalyses the following reactions:

$$2NO + 2CO \longrightarrow 2CO_2 + N_2$$

$$2NO + 2H_2 \longrightarrow N_2 + 2H_2O$$

The troposphere is the region immediately above the Earth's surface and varies in depth from around 10 to 15 km. The region that follows the troposphere is the stratosphere (up to 50 km above the Earth's surface). Of the nitrogen oxides NO, NO_2 and N_2O, dinitrogen oxide is moderately unreactive and has a relatively long lifetime in the troposphere. Once N_2O crosses into the stratosphere, it undergoes photolytic decomposition to N_2 and O_2. The effects of NO_x (i.e. NO and NO_2) in the troposphere are to increase $HO^{\bullet}$ and O_3 concentrations. While O_3 in the upper atmosphere acts as a barrier against UV radiation, increased levels at lower altitudes are detrimental to human lung tissue. Photochemical smog which forms over large cities consists mainly of O_3 and is associated with volatile organic compounds (VOCs) and with NO_x emissions from motor vehicle exhausts. Ozone formation in the troposphere usually begins with a reaction between CO or a VOC with an $HO^{\bullet}$ radical and atmospheric O_2, for example:

$$CO + HO^{\bullet} + O_2 \longrightarrow HO_2^{\bullet} + CO_2$$

This is followed by a sequence of radical reactions (in which we explicitly show NO and NO_2 as radicals) resulting in the production of O_3.

$$HO_2^{\bullet} + ON^{\bullet} \longrightarrow HO^{\bullet} + NO_2^{\bullet}$$

$$NO_2^{\bullet} \xrightarrow{h\nu} ON^{\bullet} + O$$

$$O_2 + O \longrightarrow O_3$$

Notice that overall, neither NO nor $HO^{\bullet}$ is destroyed, and therefore each radical can re-enter the reaction chain. The photograph below shows the detrimental effects of these reactions in the production of photochemical smog over Santiago, Chile. Santiago, Mexico City and Sao Paulo are the most polluted cities in Latin America.

Air pollution over Santiago, Chile.

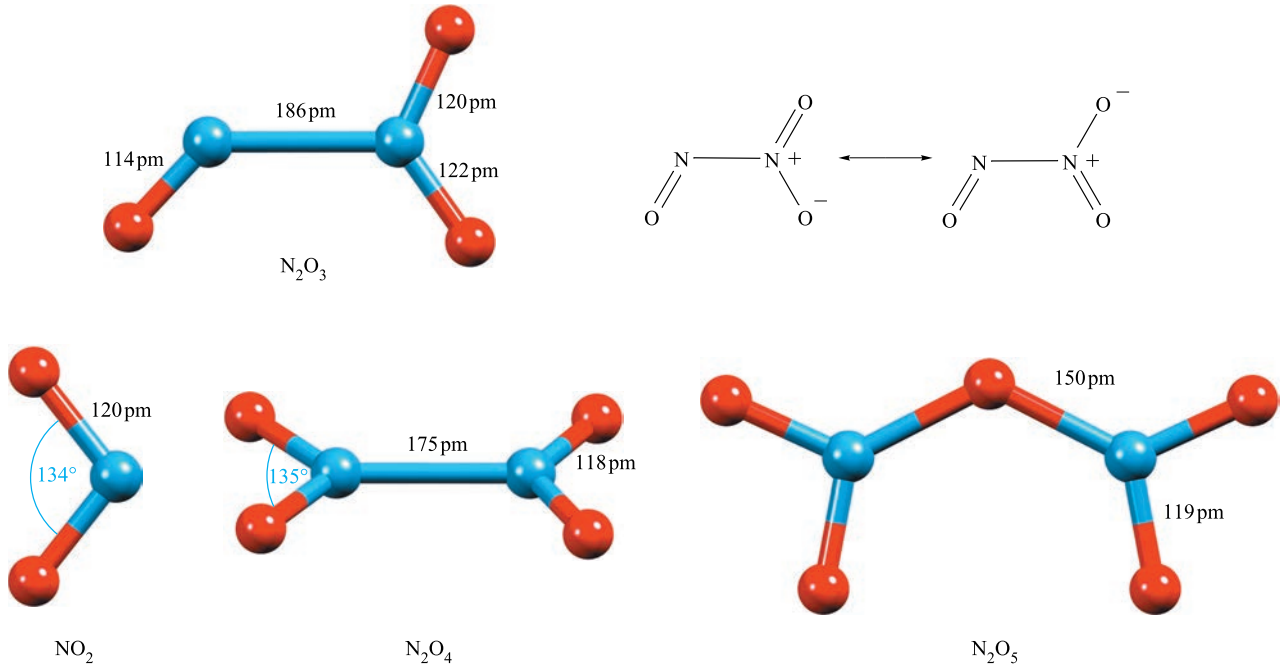

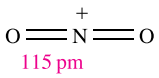

Fig. 15.17. The molecular structures of N_2O_3 (with resonance structures), NO_2, N_2O_4 and N_2O_5; molecules of N_2O_3, N_2O_4 and N_2O_5 are planar. The N–N bonds in N_2O_3 and N_2O_4 are particularly long (compare with N_2H_4, Fig. 15.5). Colour code: N, blue; O, red.

(15.50)

Dinitrogen pentaoxide, N_2O_5

Dinitrogen pentaoxide (Table 15.7 and Fig. 15.17) is the acid anhydride of HNO_3 and is prepared by reaction 15.107.

$$2HNO_3 \xrightarrow[\text{(dehydrating agent)}]{P_2O_5} N_2O_5 + H_2O \qquad (15.107)$$

It forms colourless deliquescent crystals but slowly decomposes above 273 K to give N_2O_4 and O_2. In the solid state, N_2O_5 consists of $[NO_2]^+$ and $[NO_3]^-$ ions, but the vapour contains planar molecules (Fig. 15.17). A molecular form of the solid can be formed by sudden cooling of the vapour to 93 K. Dinitrogen pentaoxide reacts violently with water, yielding HNO_3, and is a powerful oxidizing agent (e.g. reaction 15.108).

$$N_2O_5 + I_2 \longrightarrow I_2O_5 + N_2 \qquad (15.108)$$

15.9 Oxoacids of nitrogen

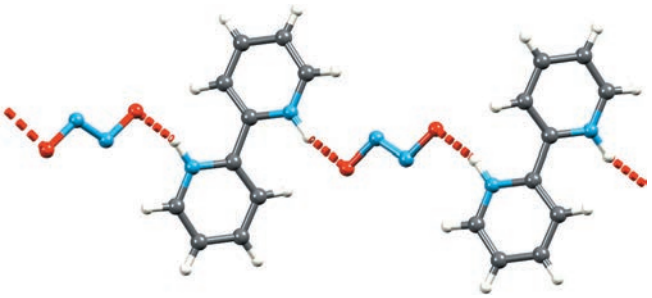
Isomers of $H_2N_2O_2$

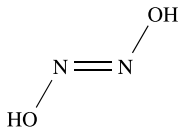
An aqueous solution of the sodium salt of $[N_2O_2]^{2-}$ can be made from organic nitrites by reaction 15.109 or by the reduction of $NaNO_2$ with sodium amalgam. Addition of Ag^+ leads to the precipitation of $Ag_2N_2O_2$. Treatment of this salt with anhydrous HCl in dry diethyl ether leads to the formation of hyponitrous acid, $H_2N_2O_2$.[†]

$$RONO + NH_2OH + 2EtONa \longrightarrow Na_2N_2O_2 + ROH + 2EtOH \qquad (15.109)$$

Free $H_2N_2O_2$ is a weak acid. It is potentially explosive, decomposing spontaneously into N_2O and H_2O. The hyponitrite ion, $[N_2O_2]^{2-}$, exists in both the *trans*- and *cis*-forms. The *trans*-configuration is kinetically the more stable and has been confirmed in the solid state structure of $Na_2N_2O_2{\cdot}5H_2O$. The *cis*-form can be prepared as $Na_2N_2O_2$ by heating solid Na_2O with gaseous N_2O. Spectroscopic data for $H_2N_2O_2$ also indicate a *trans*-configuration (structure **15.51**). In the 2,2'-bipyridinium salt, O····H–N hydrogen-bonded interactions between the O atoms of the $[N_2O_2]^{2-}$ anions and the NH groups of the 2,2'-bipyridinium cations (**15.52**) lead to the formation of chains in the solid state (Fig. 15.18).

[†] Although the name hyponitrous acid remains in common use, it is no longer recommended by the IUPAC. The recommendation is to use *diazenediol* (which derives from the substitution of each H atom in diazene (HN=NH) by an OH group), or bis(hydroxidonitrogen)(*N*–*N*).





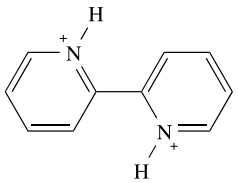


Fig. 15.18. Part of one of the hydrogen-bonded chains in the solid state structure of the 2,2'-bipyridinium salt of $[N_2O_2]^{2-}$. The structure was determined by X-ray diffraction at 173 K [N. Arulsamy *et al.* (1999) *Inorg. Chem.*, vol. 38, p. 2716].

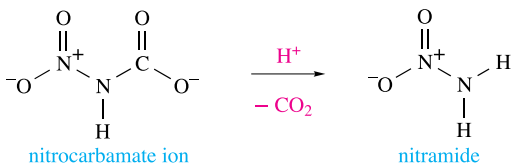
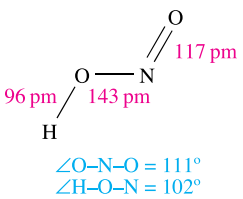


(15.51)

(15.52)



The reaction of acid with potassium nitrocarbamate results in the formation of nitramide (eq. 15.110) which is an isomer of hyponitrous acid. Nitramide has been structurally characterized; one N atom is trigonal planar (O_2NN) and the other is trigonal pyramidal (H_2NN). The compound is potentially explosive, and undergoes base-catalysed decomposition to N_2O and H_2O.

nitrocarbamate ion — nitramide (15.110)

Nitrous acid, HNO_2

Nitrous acid is known only in solution and in the vapour phase. In the latter, it has structure **15.53**. It is a weak acid ($pK_a = 3.37$), but is unstable with respect to disproportionation in solution (eq. 15.111). It may be prepared *in situ* by reaction 15.112, the water-soluble reagents being chosen so as to give an insoluble metal salt ($BaSO_4$) as a product. $AgNO_2$ is insoluble but other metal nitrites are soluble in water.

∠O–N–O = 111°
∠H–O–N = 102°

(15.53)

$$3HNO_2 \longrightarrow 2NO + HNO_3 + H_2O \qquad (15.111)$$

$$Ba(NO_2)_2 + H_2SO_4 \xrightarrow{aqu} BaSO_4 + 2HNO_2 \qquad (15.112)$$

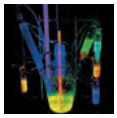
Sodium nitrite is an important reagent in the preparation of diazonium compounds, e.g. reaction 15.113 in which HNO_2 is prepared *in situ*. Alkali metal nitrates yield the nitrites when heated alone or, better, with Pb (reaction 15.114).

$$PhNH_2 \xrightarrow{NaNO_2,\ HCl,\ <273\,K} [PhN_2]^+Cl^- \qquad (15.113)$$

$$NaNO_3 + Pb \xrightarrow{\Delta} NaNO_2 + PbO \qquad (15.114)$$

Nitrous acid can be oxidized to $[NO_3]^-$ by powerful oxidants such as acidified $[MnO_4]^-$. The products of the reduction of HNO_2 depend on the reducing agent:

- NO is formed with I^- or Fe^{2+};
- N_2O is produced with Sn^{2+};
- NH_2OH results from reduction by SO_2;
- NH_3 is formed with Zn in alkaline solution.



Kinetic rather than thermodynamic control over a reaction is illustrated by the fact that, in dilute solution, HNO_2, but not HNO_3, oxidizes I^- to I_2. Equations 15.115 show that the values of E^o_{cell} for these redox reactions are similar; nitrous acid is a faster, rather than a more powerful, oxidizing agent than dilute nitric acid.

$$\left.\begin{aligned} I_2 + 2e^- &\rightleftharpoons 2I^- && E^o = +0.54\,V \\ [NO_3]^- + 3H^+ + 2e^- &\rightleftharpoons HNO_2 + H_2O && E^o = +0.93\,V \\ HNO_2 + H^+ + e^- &\rightleftharpoons NO + H_2O && E^o = +0.98\,V \end{aligned}\right\} \qquad (15.115)$$

Nitric acid, HNO_3, and its derivatives

Nitric acid is an important industrial chemical (Box 15.8) and is manufactured on a large scale in the Ostwald process, which is closely tied to NH_3 production in the Haber–Bosch process. The first step is the oxidation of NH_3 to NO (eq. 15.23). After cooling, NO is mixed with air and absorbed in a countercurrent of water. The reactions involved are summarized in scheme 15.116. This produces HNO_3 in a concentration of ≈60% by weight and it can be concentrated to 68% by distillation.

$$\left.\begin{aligned} 2NO + O_2 &\rightleftharpoons 2NO_2 \\ 2NO_2 &\rightleftharpoons N_2O_4 \\ N_2O_4 + H_2O &\longrightarrow HNO_3 + HNO_2 \\ 2HNO_2 &\longrightarrow NO + NO_2 + H_2O \\ 3NO_2 + H_2O &\longrightarrow 2HNO_3 + NO \end{aligned}\right\} \qquad (15.116)$$

APPLICATIONS

Box 15.8 Commercial demand for HNO_3 and $[NH_4][NO_3]$

The industrial production of nitric acid (scheme 15.116) is carried out on a large scale and its manufacture is closely linked to that of ammonia. About 80% of all HNO_3 produced is converted into fertilizers, with $[NH_4][NO_3]$ being a key product:

$$NH_3 + HNO_3 \longrightarrow [NH_4][NO_3]$$

The commercial grade of $[NH_4][NO_3]$ contains ≈34% nitrogen. For fertilizers, it is manufactured in the form of pellets which are easily handled. Its high solubility in water ensures efficient uptake by the soil.

Ammonium nitrate has other important applications: about 25% of the manufactured output is used directly in explosives, but its ready accessibility makes it a target for misuse, e.g. in the Oklahoma City bombing in 1995. The potentially explosive nature of $[NH_4][NO_3]$ also makes it a high-risk chemical for transportation.

Nitric acid is usually produced as an aqueous solution containing 50–68% HNO_3 by weight, and this is highly suitable for use in the fertilizer industry. However, for applications of HNO_3 as a nitrating agent in the production of, for example, explosives, acid containing >98% HNO_3 by weight is needed. Ordinary distillation is not appropriate because HNO_3 and H_2O form an azeotrope (see text). Alternative methods are dehydration using concentrated H_2SO_4, or by oxidation of NH_3 and of the NO so-formed, followed by a final oxidation step:

A circular gauze, woven from rhodium/platinum wire for use as a catalyst in the commercial manufacture of HNO_3 by oxidation of NH_3.

$$4NH_3 + 5O_2 \xrightarrow{Pt/Rh} 4NO + 6H_2O$$

$$2NO + O_2 \rightleftharpoons 2NO_2$$

$$2NO_2 \rightleftharpoons N_2O_4$$

$$2N_2O_4 + O_2 + 2H_2O \rightleftharpoons 4HNO_3$$

See also Box 15.3: Ammonia: an industrial giant.

Pure nitric acid can be made in the laboratory by adding H_2SO_4 to KNO_3 and distilling the product *in vacuo*. It is a colourless liquid, but must be stored below 273 K to prevent slight decomposition (eq. 15.117) which gives the acid a yellow colour.

$$4HNO_3 \longrightarrow 4NO_2 + 2H_2O + O_2 \qquad (15.117)$$

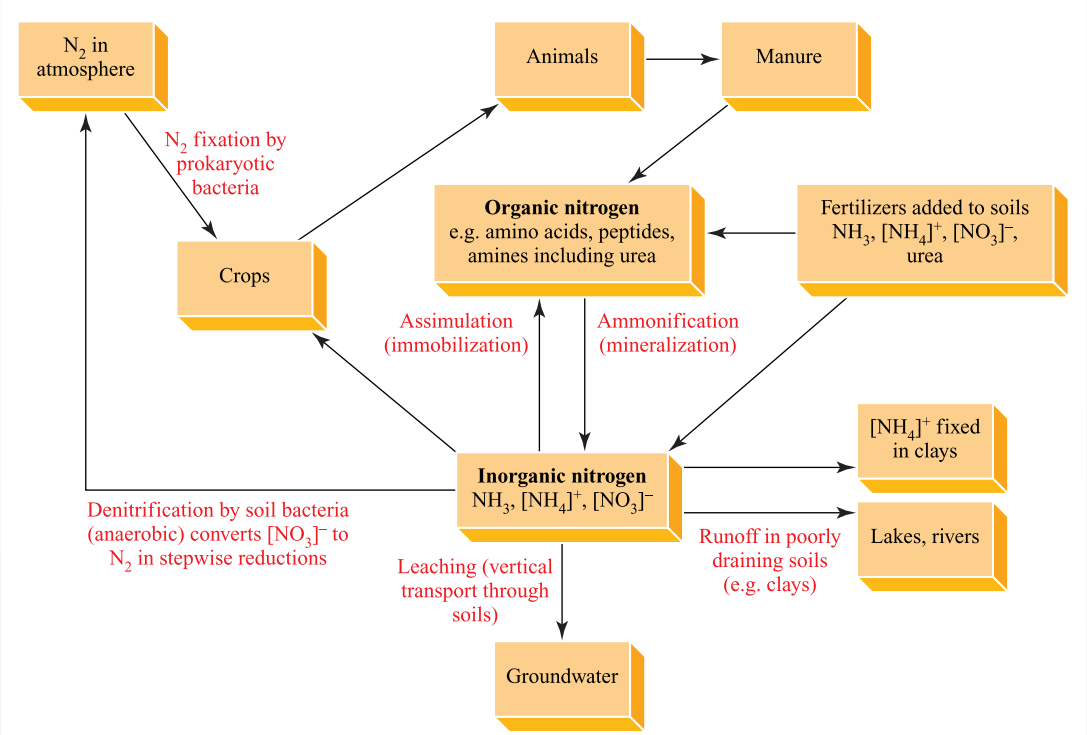
Ordinary concentrated HNO_3 is the *azeotrope* containing 68% by weight of HNO_3 and boiling at 393 K. Photochemical decomposition occurs by reaction 15.117. Fuming HNO_3 is orange owing to the presence of an excess of NO_2.

An ***azeotrope*** is a mixture of two liquids that distils unchanged, the composition of liquid and vapour being the same. Unlike a pure substance, the composition of the azeotropic mixture depends on pressure.

In aqueous solution, HNO_3 acts as a strong acid which attacks most metals, often more rapidly if a trace of HNO_2 is present. Exceptions are Au and the *platinum-group metals* (see Section 22.9); Fe and Cr are passivated by concentrated HNO_3. Equations 9.8–9.10 illustrate HNO_3 acting as a base.

Tin, arsenic and a few *d*-block metals are converted to their oxides when treated with HNO_3, but others form nitrates. Only Mg, Mn and Zn liberate H_2 from *very dilute* nitric acid. If the metal is a more powerful reducing agent than H_2, reaction with HNO_3 reduces the acid to N_2, NH_3, NH_2OH or N_2O. Other metals liberate NO or NO_2 (e.g. reactions 15.118 and 15.119).

$$3Cu(s) + 8HNO_3(aq) \xrightarrow{\text{dilute}} 3Cu(NO_3)_2(aq) + 4H_2O(l) + 2NO(g) \qquad (15.118)$$

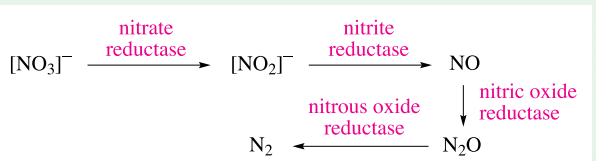


$$Cu(s) + 4HNO_3(aq) \xrightarrow{\text{conc}} Cu(NO_3)_2(aq) + 2H_2O(l) + 2NO_2(g) \qquad (15.119)$$

Large numbers of metal nitrate salts are known. Anhydrous nitrates of the group 1 metals, Sr^{2+}, Ba^{2+}, Ag^+ and Pb^{2+} are readily accessible, but for other metals, anhydrous nitrate salts are typically prepared using N_2O_4 (see Section 9.11). The preparations of anhydrous $Mn(NO_3)_2$

ENVIRONMENT

Box 15.9 The nitrogen cycle, and nitrates and nitrites in waste water



[Adapted from: D.S. Powlson and T.M. Addiscott (2004) in *Encyclopedia of Soils in the Environment*, ed. D. Hillel, Elsevier, Oxford, vol. 3, p. 21.]

The global nitrogen cycle includes chemical changes and nitrogen transport between the oceans, land and atmosphere, and involves natural and man-made sources of nitrogen. The diagram above gives a simplified nitrogen cycle, highlighting the processes that are coupled to agriculture. Sources of nitrates in groundwater (i.e. levels above those occurring naturally) include nitrate-based fertilizers and decaying organic material, as well as septic tanks, industrial effluent and waste from food processing factories.

Levels of $[NO_3]^-$ in waste water are controlled by legislation, limits being recommended by the World Health Organization, Environmental Protection Agency and European Union. Nitrites, because of their toxicity, must also be removed. One of the principal concerns arising from nitrates and nitrites in drinking water is their association with the disease *methaemoglobinaemia* ('blue baby syndrome'). This is primarily suffered by infants and results in the blood having a lower than normal O_2-carrying capacity. In the body, bacteria in the digestive system convert $[NO_3]^-$ to $[NO_2]^-$ which is able to irreversibly oxidize Fe^{2+} in haemoglobin to Fe^{3+}. The product is methaemoglobin and in this state, the iron can no longer bind O_2.

Nitrate salts are highly soluble and their removal from aqueous solution by techniques based on precipitation is not viable. Methods of nitrate removal include anion exchange, reverse osmosis (see Box 16.3), and enzymic denitrification. Ion-exchange involves passing the nitrate-containing water through a tank filled with resin beads on which chloride ions are adsorbed. In most conventional water purification systems, resins bind anions preferentially in the order $[SO_4]^{2-} > [NO_3]^- > Cl^- > [HCO_3]^- > [OH]^-$. Thus, as water containing nitrate ions passes through the resin, $[NO_3]^-$ exchanges for Cl^-, leaving $[NO_3]^-$ ions adsorbed on the surface. However, if the water contains significant amounts of sulfate, $[SO_4]^{2-}$ binds preferentially. Specialized resins must therefore be used for sulfate-rich wastes. Once the ion-exchange process has exhausted the resin of Cl^- ion, the system is regenerated by passing aqueous NaCl through the resin.

Removal of nitrates using enzymic denitrification takes advantage of the fact that certain anaerobic bacteria reduce $[NO_3]^-$ and $[NO_2]^-$ to N_2 in a sequence of steps, each involving a specific enzyme:

Other methods of removing $[NO_2]^-$ involve oxidation to $[NO_3]^-$ (using $[OCl]^-$ or H_2O_2 as oxidant), and removing the $[NO_3]^-$ as detailed above, or using urea or sulfamic acid to reduce $[NO_2]^-$ to N_2 (see end-of-chapter problem 15.41).

and $Co(NO_3)_2$ by slow dehydration of the corresponding hydrated salts using concentrated HNO_3 and phosphorus(V) oxide illustrate an alternative strategy. Nitrate salts of all metals and cations such as $[NH_4]^+$ are soluble in water. Alkali metal nitrates decompose on heating to the nitrite (reaction 15.120; see also eq. 15.114). The decomposition of NH_4NO_3 depends on the temperature (eqs. 15.8 and 15.93). Most metal nitrates decompose to the oxide when heated (eq. 15.121), but silver and mercury(II) nitrates give the respective metal (eq. 15.122)

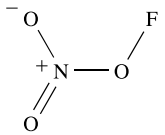
$$2KNO_3 \xrightarrow{\Delta} 2KNO_2 + O_2 \qquad (15.120)$$

$$2Cu(NO_3)_2 \xrightarrow{\Delta} 2CuO + 4NO_2 + O_2 \qquad (15.121)$$

$$2AgNO_3 \xrightarrow{\Delta} 2Ag + 2NO_2 + O_2 \qquad (15.122)$$

Many organic and inorganic compounds are oxidized by concentrated HNO_3, although nitrate ion in aqueous solution is usually a very *slow* oxidizing agent (see above). *Aqua regia* contains free Cl_2 and ONCl and attacks Au (eq. 15.123) and Pt with the formation of chlorido complexes.

$$\underbrace{Au + HNO_3 + 4HCl}_{\text{conc}\quad\text{conc}} \longrightarrow HAuCl_4 + NO + 2H_2O \qquad (15.123)$$



aqua regia

Aqua regia is a mixture of concentrated nitric and hydrochloric acids.

Concentrated HNO_3 oxidizes I_2, P_4 and S_8 to HIO_3, H_3PO_4 and H_2SO_4 respectively.

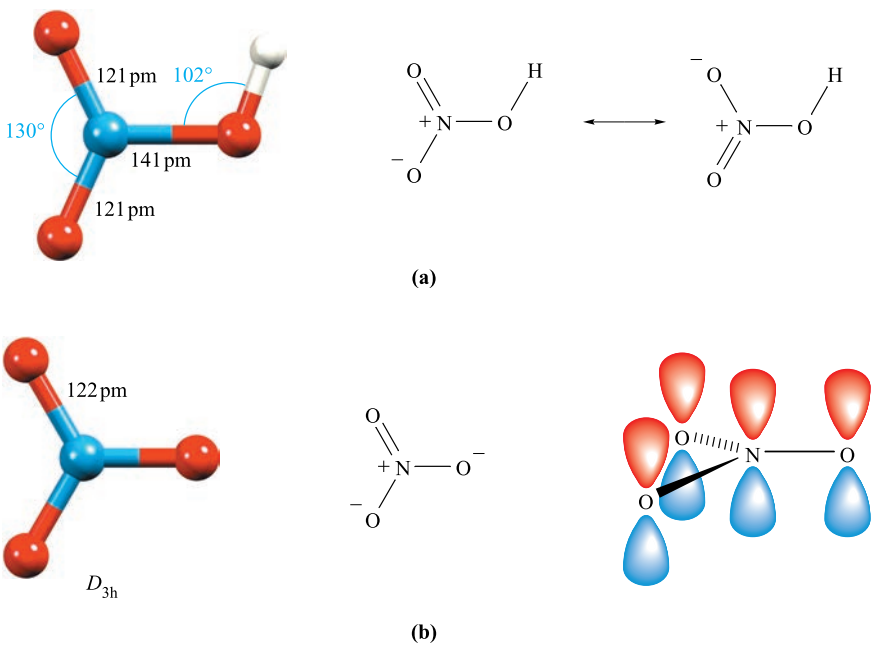
The molecular structure of HNO_3 is shown in Fig. 15.19a. Differences in N–O bond distances are readily understood in terms of the resonance structures shown. The nitrate ion has a trigonal planar (D_{3h}) structure and the equivalence of the bonds may be rationalized using valence bond or molecular orbital theory (Figs. 5.25 and 15.19b). We considered an MO treatment for the bonding in $[NO_3]^-$ in Fig. 5.25 and described how interaction between the N 2*p* orbital and a ligand-group orbital involving in-phase O 2*p* orbitals gives rise to one occupied MO in $[NO_3]^-$ that has π-bonding character delocalized over all four atoms.

The hydrogen atom in HNO_3 can be replaced by fluorine by treating dilute HNO_3 or KNO_3 with F_2. The product, fluorine nitrate, **15.54**, is an explosive gas which reacts slowly with H_2O but rapidly with aqueous alkali (eq. 15.124).

(15.54)

$$2FONO_2 + 4[OH]^- \longrightarrow 2[NO_3]^- + 2F^- + 2H_2O + O_2 \qquad (15.124)$$

The reaction of $NaNO_3$ with Na_2O at 570 K leads to the formation of Na_3NO_4 (sodium orthonitrate), and K_3NO_4



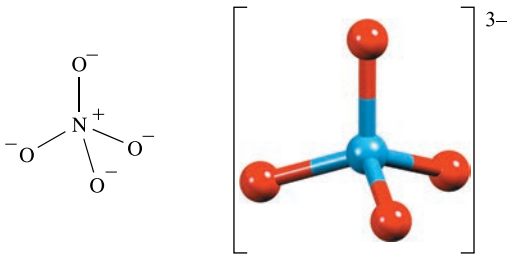


Fig. 15.19. (a) The gas-phase planar structure of HNO_3, and appropriate resonance structures. (b) The molecular structure of the planar $[NO_3]^-$ anion; the equivalence of the three N–O bonds can be rationalized by valence bond theory (one of three resonance structures is shown) or by MO theory (partial π-bonds are formed by overlap of N and O 2*p* atomic orbitals and the π-bonding is delocalized over the NO_3-framework as was shown in Fig. 5.25). Colour code: N, blue; O, red; H, white.

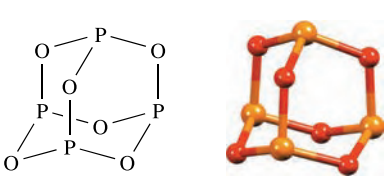
may be prepared similarly. X-ray diffraction data confirm that the $[NO_4]^{3-}$ ion is tetrahedral with N–O bond lengths of 139 pm, consistent with single bond character. Structure **15.55** includes a valence bond picture of the bonding. The free acid H_3NO_4 is not known.

(15.55)

15.10 Oxides of phosphorus, arsenic, antimony and bismuth

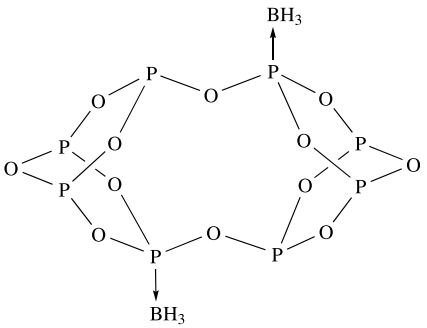
Each of the group 15 elements from P to Bi forms two oxides, E_2O_3 (or E_4O_6) and E_2O_5 (or E_4O_{10}), the latter becoming less stable as the group is descended:



- E_2O_5 (E = P, As, Sb, Bi) are acidic;
- P_4O_6 is acidic;
- As_4O_6 and Sb_4O_6 are amphoteric;
- Bi_2O_3 is basic.

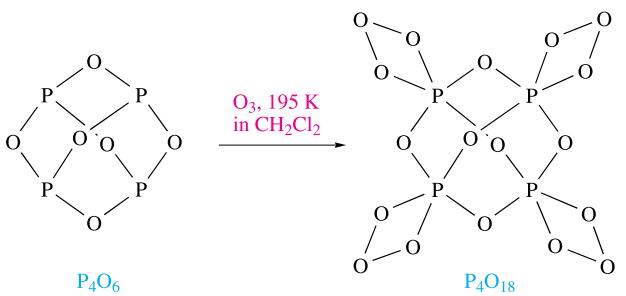
In addition to describing the common oxides of the group 15 elements, the section below introduces several other oxides of phosphorus.

Oxides of phosphorus



Phosphorus(III) oxide, P_4O_6, is obtained by burning white phosphorus in a restricted supply of O_2. It is a colourless, volatile solid (mp 297 K, bp 447 K) with molecular structure **15.56**. The P–O bond distances (165 pm) are consistent with single bonds, and the angles P–O–P and O–P–O are 128° and 99° respectively. The oxide is soluble in diethyl ether or benzene, but reacts with cold water (eq. 15.125).

$$P_4O_6 + 6H_2O \longrightarrow 4H_3PO_3 \qquad (15.125)$$

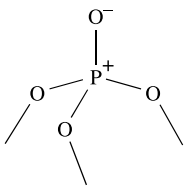


(15.56)

Each P atom in P_4O_6 carries a lone pair of electrons and P_4O_6 can therefore act as a Lewis base. Adducts with one and two equivalents of BH_3 have been reported, but the reaction of P_4O_6 with one equivalent of $Me_2S{\cdot}BH_3$ followed by slow crystallization from toluene solution at 244 K gives $P_8O_{12}(BH_3)_2$ (**15.57**) rather than an adduct of P_4O_6. The solid state structure confirms that dimerization of P_4O_6 has occurred through P–O bond cleavage in structure **15.56** and reformation of P–O bonds between monomeric units. Free P_8O_{12} has not, to date, been isolated.

(15.57)

Oxidation of P_4O_6 with O_2 gives P_4O_{10} (see below), while ozone oxidation leads to the formation of P_4O_{18} (eq. 15.126) which has been structurally characterized. The square-based pyramidal environment of each P atom is related to that found in phosphite ozonides $(RO)_3PO_3$ (see Fig. 16.5). In solution, P_4O_{18} decomposes above 238 K with gradual release of O_2, but the decomposition of dry P_4O_{18} powder is explosive.



(15.126)

The most important oxide of phosphorus is P_4O_{10} (phosphorus(V) oxide), commonly called *phosphorus pentoxide*. It can be made directly from P_4 (eq. 15.10) or by oxidizing P_4O_6. In the vapour phase, phosphorus(V) oxide contains P_4O_{10} molecules with structure **15.58**; the $P–O_{bridge}$ and $P–O_{terminal}$ bond distances are 160 and 140 pm. When the vapour is condensed rapidly, a volatile and extremely hygroscopic solid is obtained which also contains P_4O_{10} molecules. If this solid is heated in a closed vessel for several hours and the melt maintained at a high temperature before being allowed to cool, the solid obtained is macromolecular. Three polymorphic forms exist at ordinary pressure and

temperature, with the basic building block being unit **15.59**. In each polymorph, only three of the four O atoms are involved in interconnecting the PO_4 units via P–O–P bridges. Phosphorus(V) oxide has a great affinity for water (eq. 15.127), and is the anhydride of the wide range of oxoacids described in Section 15.11. It is used as a drying agent (see Box 12.3).

(15.58)

(15.59)

$$P_4O_{10} + 6H_2O \longrightarrow 4H_3PO_4 \qquad (15.127)$$

Three other oxides of phosphorus, P_4O_7 (**15.60**), P_4O_8 (**15.61**) and P_4O_9 (**15.62**), have structures that are related to those of P_4O_6 and P_4O_{10}.

(15.60)

(15.61)

(15.62)

These oxides are mixed P(III)P(V) species, each centre bearing a terminal oxo group being P(V). For example, P_4O_8 is made by heating P_4O_6 in a sealed tube at 710 K, the other product being red phosphorus (eq. 15.128).

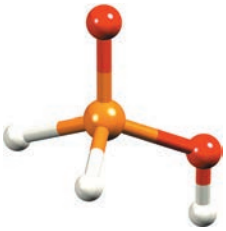
$$4P_4O_6 \xrightarrow{710\,K} 3P_4O_8 + 4P(red) \qquad (15.128)$$

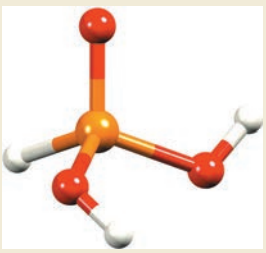
Oxides of arsenic, antimony and bismuth

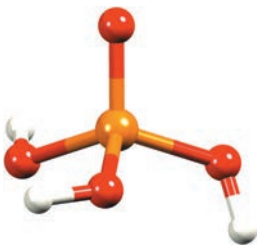
The normal combustion products of As and Sb are As(III) and Sb(III) oxides (eq. 15.13). The vapour and high-temperature solid polymorph of each oxide contains E_4O_6 (E = As or Sb) molecules structurally related to **15.56**. Lower temperature polymorphs have layer structures containing trigonal pyramidal As or Sb atoms. Condensation of As_4O_6 vapour above 520 K leads to the formation of As_2O_3 glass. Arsenic(III) oxide is an important precursor in arsenic chemistry and is made industrially from the sulfide (Section 15.2). Dissolution of As_2O_3 in water gives a very weakly acidic solution, and it is probable that the species present is $As(OH)_3$ (*arsenous acid*) although this has never been isolated. Crystallization of aqueous solutions of $As(OH)_3$ yields As_2O_3. Arsenic(III) oxide dissolves in aqueous alkali to give salts containing the $[AsO_2]^-$ ion, and in aqueous HCl with the formation of $AsCl_3$. The properties of Sb_2O_3 in water and aqueous alkali or HCl resemble those of As_2O_3.

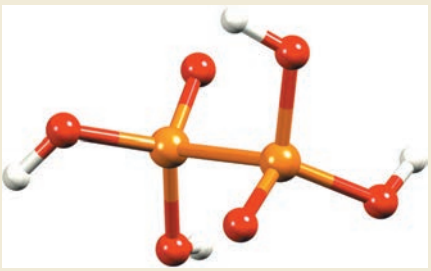
Bismuth(III) oxide occurs naturally as *bismite*, and is formed when Bi combines with O_2 on heating. In contrast to earlier members of group 15, molecular species are not observed for Bi_2O_3, and the structure is more like that of a typical *metal* oxide.

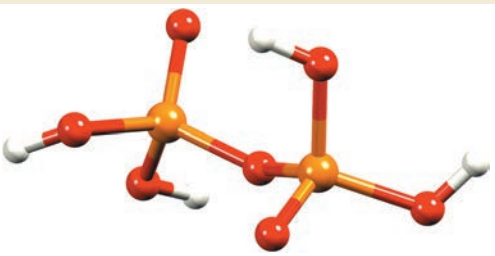
Arsenic(V) oxide is most readily made by reaction 15.129 than by direct oxidation of the elements. The route makes use of the fact that As_2O_5 is the acid anhydride of arsenic acid, H_3AsO_4. In the solid state, As_2O_5 has a 3-dimensional structure consisting of As–O–As linked octahedral AsO_6 and tetrahedral AsO_4-units.

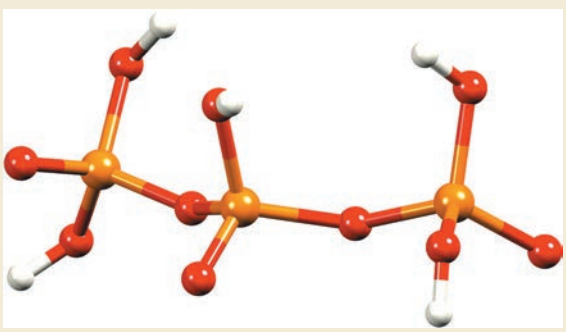












$$As_2O_3 \xrightarrow{\text{conc } HNO_3} 2H_3AsO_4 \xrightarrow{\text{dehydration}} As_2O_5 + 3H_2O \qquad (15.129)$$

Antimony(V) oxide may be made by reacting Sb_2O_3 with O_2 at high temperatures and pressures. It crystallizes with a 3-dimensional structure in which the Sb atoms are octahedrally sited with respect to six O atoms. Bismuth(V) oxide is poorly characterized, and its formation requires the action of strong oxidants (e.g. alkaline hypochlorite) on Bi_2O_3.

15.11 Oxoacids of phosphorus

Table 15.8 lists selected oxoacids of phosphorus. This is an important group of compounds, but the acids are difficult to classify in a straightforward manner. It should be remembered that the basicity of each acid corresponds to the number of OH-groups, *and not simply to the total number of hydrogen atoms*, e.g. H_3PO_3 and H_3PO_2 are dibasic and monobasic respectively (Table 15.8). The P-attached hydrogens do not ionize in aqueous solution, and diagnostic absorptions in the IR spectra of these compounds confirm the presence of P–H bonds. The IR spectrum of aqueous H_3PO_2 exhibits absorptions at 2408, 1067 and 811 cm^{-1} assigned to the stretching, deformation

Table 15.8 Selected oxoacids of phosphorus; older names that are still in common use are given in parentheses.

Formula	Name	Structure	pK_a values
H_3PO_2	Phosphinic acid		$pK_a = 1.24$
H_3PO_3	Phosphonic acid (phosphorous acid)		$pK_a(1) = 2.00$; $pK_a(2) = 6.59$
H_3PO_4	Phosphoric acid (orthophosphoric acid)		$pK_a(1) = 2.21$; $pK_a(2) = 7.21$; $pK_a(3) = 12.67$
$H_4P_2O_6$	Hypodiphosphoric acid		$pK_a(1) = 2.2$; $pK_a(2) = 2.8$; $pK_a(3) = 7.3$; $pK_a(4) = 10.0$
$H_4P_2O_7$	Diphosphoric acid		$pK_a(1) = 0.85$; $pK_a(2) = 1.49$; $pK_a(3) = 5.77$; $pK_a(4) = 8.22$
$H_5P_3O_{10}$	Triphosphoric acid		$pK_a(1) \leq 0$ $pK_a(2) = 0.89$; $pK_a(3) = 4.09$; $pK_a(4) = 6.98$; $pK_a(5) = 9.93$

and rocking modes of the PH_2 group. The band at 2408 cm^{-1} is the most easily observed. In the IR spectrum of aqueous H_3PO_3, an absorption at 2440 cm^{-1} corresponds to the P–H stretching mode.

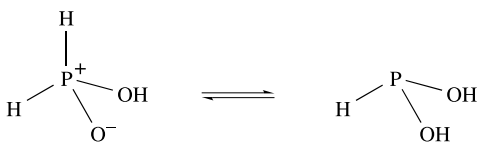
Self-study exercise

The absorption at 2408 cm^{-1} in the IR spectrum of aqueous H_3PO_2 shifts when the sample is fully deuterated. Explain why this shift occurs, and calculate the wavenumber at which the new band should be observed.

[*Ans.* 1735 cm^{-1}]

Phosphinic acid, H_3PO_2

The reaction of white phosphorus with aqueous alkali (eq. 15.11) produces the phosphinate ion, $[H_2PO_2]^-$. By using $Ba(OH)_2$ as alkali, precipitating the Ba^{2+} ions as $BaSO_4$, and evaporating the aqueous solution, white deliquescent crystals of H_3PO_2 can be obtained. In aqueous solution, H_3PO_2 is a fairly strong monobasic acid (eq. 15.130 and Table 15.8).



$$H_3PO_2 + H_2O \rightleftharpoons [H_3O]^+ + [H_2PO_2]^- \qquad (15.130)$$

Phosphinic acid and its salts are reducing agents. $NaH_2PO_2{\cdot}H_2O$ is used industrially in a non-electrochemical reductive process which reduces Ni^{2+} to Ni, and plates nickel onto, for example, steel. The so-called *electroless nickel* coatings also contain phosphorus, and the amount of P present influences the corrosion and wear-resistance properties of the coating. For example, coatings with a high P content (11–13%) exhibit enhanced resistance to attack by acids, whereas lowering the P content to <4% makes the coating more resistant to corrosion by alkalis.

When heated, H_3PO_2 disproportionates according to eq. 15.131, the products being determined by reaction temperature.

$$\left.\begin{aligned} &3H_3PO_2 \xrightarrow{\Delta} PH_3 + 2H_3PO_3 \\ &\text{or} \\ &2H_3PO_2 \xrightarrow{\Delta} PH_3 + H_3PO_4 \end{aligned}\right\} \qquad (15.131)$$

Intramolecular transfer of a proton to the terminal O atom in phosphinic acid produces a tautomer in which the P atom is 3-coordinate:

In practice, this equilibrium lies far over to the left-hand side, with a ratio $H_2PO(OH):HP(OH)_2 > 10^{12}:1$. $HP(OH)_2$ carries a lone pair of electrons and, in 2003, the tautomer

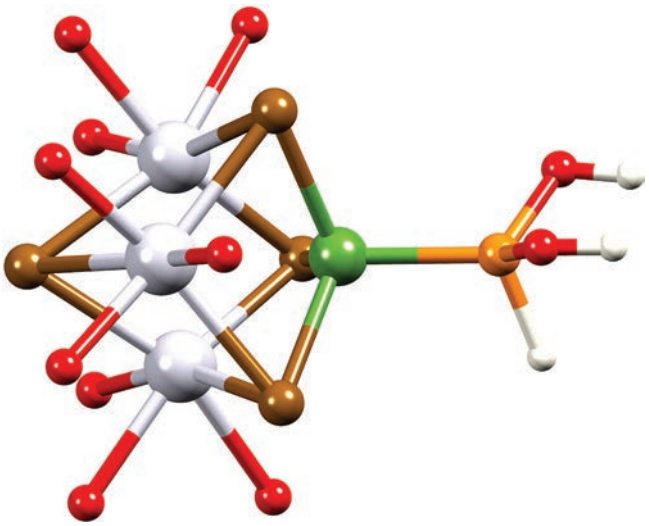


Fig. 15.20. The structure of $[W_3(OH_2)_9NiSe_4\{PH(OH)_2\}]^{4+}$ determined by X-ray diffraction [M.N. Sokolov *et al.* (2003) *Chem. Commun.*, p. 140]. The H atoms in the structure were not fully located. Colour code: P, orange; W, silver; Ni, green; Se, brown; O red; H, white.

was stabilized by coordination to $[W_3(OH_2)_9NiX_4]^{4+}$ (X = S, Se) (Fig. 15.20). The presence of one P–H bond was confirmed by the appearance of a doublet (J_{PH} 393 Hz) in the ^{31}P NMR spectrum.

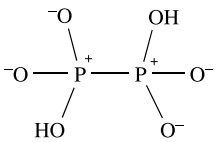
Phosphonic acid, H_3PO_3

Phosphonic acid (often called *phosphorous acid*) may be crystallized from the solution obtained by adding ice-cold water to P_4O_6 (eq. 15.125) or PCl_3 (eq. 15.78). Pure H_3PO_3 forms colourless, deliquescent crystals (mp 343 K) and in the solid state, molecules of the acid (Table 15.8) are linked by hydrogen bonds to form a 3-dimensional network. In aqueous solution, it is dibasic (eqs. 15.132 and 15.133).

$$H_3PO_3(aq) + H_2O(l) \rightleftharpoons [H_3O]^+(aq) + [H_2PO_3]^-(aq) \qquad (15.132)$$

$$[H_2PO_3]^-(aq) + H_2O(l) \rightleftharpoons [H_3O]^+(aq) + [HPO_3]^{2-}(aq) \qquad (15.133)$$

Salts containing the $[HPO_3]^{2-}$ ion are called *phosphonates*. Although the name 'phosphite' remains in common use, it is a possible source of confusion since esters of type $P(OR)_3$ are also called phosphites, e.g. $P(OEt)_3$ is triethylphosphite.



Phosphonic acid is a reducing agent, but disproportionates when heated (eq. 15.134).

$$4H_3PO_3 \xrightarrow{470\ K} PH_3 + 3H_3PO_4 \qquad (15.134)$$

Hypodiphosphoric acid, $H_4P_2O_6$

The reaction between red phosphorus and NaOCl or $NaClO_2$ yields $Na_2H_2P_2O_6$. This can be converted in aqueous solution into the dihydrate of the free acid which is best formulated

as $[H_3O]_2[H_2P_2O_6]$. Dehydration using P_4O_{10} gives $H_4P_2O_6$. The first indication of a P–P bonded dimer (i.e. rather than H_2PO_3) came from the observation that the acid was diamagnetic, and X-ray diffraction data for the salt $[NH_4]_2[H_2P_2O_6]$ have confirmed this structural feature. All four terminal P–O bonds are of equal length (157 pm), and the bonding description in diagram **15.63** is consistent with this observation. In keeping with our comments on hypervalent species in Section 15.3, this description is more appropriate than a pair of resonance structures, each involving one P=O and one P–O^- bond. The acid is thermodynamically unstable with respect to disproportionation and reaction 15.135 occurs slowly in aqueous solution. For this reason, $H_4P_2O_6$ cannot be made by reduction of H_3PO_4 or by oxidation of H_3PO_3 in aqueous media. Hence the need to use a precursor (i.e. elemental phosphorus) in which the P–P bond is already present.

(15.63)

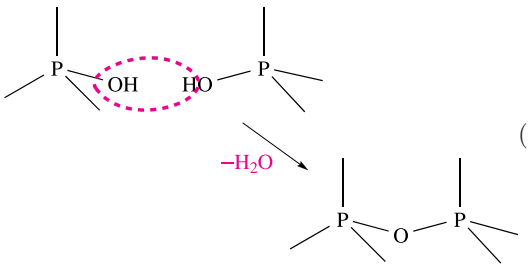
$$H_4P_2O_6 + H_2O \longrightarrow H_3PO_3 + H_3PO_4 \qquad (15.135)$$

Phosphoric acid, H_3PO_4, and its derivatives

Phosphoric acid is made from phosphate rock (eq. 15.136) or by hydration of P_4O_{10} (eq. 15.127).

$$Ca_3(PO_4)_2 + 3H_2SO_4 \xrightarrow{\text{conc}} 2H_3PO_4 + 3CaSO_4 \qquad (15.136)$$

The pure acid forms deliquescent, colourless crystals (mp 315 K). It has a molecular structure (Table 15.8) with P–OH and P–O bond distances of 157 and 152 pm. In the crystalline state, extensive hydrogen bonding links H_3PO_4 molecules into a layered network. On standing, crystalline H_3PO_4 rapidly forms a viscous liquid. In this and in the commercially available 85% (by weight with water) acid, extensive hydrogen bonding is responsible for the syrupy nature of the acid. In dilute aqueous solutions, acid molecules are hydrogen-bonded to water molecules rather than to each other.



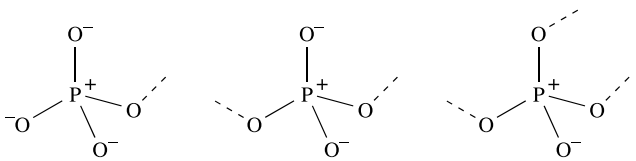
Phosphoric acid is very stable and has no oxidizing properties except at very high temperatures. Aqueous H_3PO_4 is a tribasic acid (Table 15.8) and salts containing $[H_2PO_4]^-$, $[HPO_4]^{2-}$ and $[PO_4]^{3-}$ can be isolated. Thus, three Na^+ salts can be prepared under suitable neutralization conditions. Two of the most commonly encountered sodium and potassium salts are $Na_2HPO_4{\cdot}12H_2O$ and KH_2PO_4. Sodium phosphates are extensively used for buffering aqueous solutions, and tri-*n*-butyl phosphate is a valuable solvent for the extraction of metal ions from aqueous solution (see Box 7.3).

When H_3PO_4 is heated at 510 K, it is dehydrated to diphosphoric acid (eq. 15.137). Comparison of the structures of these acids (Table 15.8) shows that water is eliminated with concomitant P–O–P bridge formation. Further heating yields triphosphoric acid (eq. 15.138).

$$2H_3PO_4 \xrightarrow{\Delta} H_4P_2O_7 + H_2O \qquad (15.137)$$

$$H_3PO_4 + H_4P_2O_7 \xrightarrow{\Delta} H_5P_3O_{10} + H_2O \qquad (15.138)$$

Such species containing P–O–P bridges are commonly called *condensed phosphates* and eq. 15.139 shows the general condensation process.



(15.139)

The *controlled* hydrolysis of P_4O_{10} is sometimes useful as a means of preparing condensed phosphoric acids. In principle, the condensation of phosphate ions (e.g. reaction 15.140) should be favoured at low pH, but in practice such reactions are usually slow.

$$2[PO_4]^{3-} + 2H^+ \rightleftharpoons [P_2O_7]^{4-} + H_2O \qquad (15.140)$$

Clearly, the number of OH groups in a particular unit determines the extent of the condensation processes. In condensed phosphate anion formation, chain-terminating end groups (**15.64**) are formed from $[HPO_4]^{2-}$, chain members (**15.65**) from $[H_2PO_4]^-$, and cross-linking groups (**15.66**) from H_3PO_4.

(15.64) **(15.65)** **(15.66)**

In free condensed acids such as $H_5P_3O_{10}$ (Table 15.8), different phosphorus environments can be distinguished by ^{31}P NMR spectroscopy or chemical methods:

- the pK_a values for successive proton dissociations depend on the position of the OH group; terminal P atoms carry

ENVIRONMENT

Box 15.10 Phosphate fertilizers: essential to crops but are they damaging our lakes?

Worldwide demand for fertilizers is enormous and world consumption is increasing at a rate of between 2% and 3% per year. Phosphorus is an essential plant nutrient and up to 90% (depending on the country) of phosphate rock (see Section 15.2) that is mined is consumed in the manufacture of phosphorus-containing fertilizers. Insoluble phosphate rock is treated with concentrated H_2SO_4 to generate soluble *superphosphate* fertilizers containing $Ca(H_2PO_4)_2$ mixed with $CaSO_4$ and other sulfates. Reaction between phosphate rock and H_3PO_4 gives *triple superphosphate*, mainly $Ca(H_2PO_4)_2$. Ammonium phosphate fertilizers are valuable sources of both N and P. Environmentalists are concerned about the effects that phosphates and polyphosphates from fertilizers and detergents have on the natural balance of lake populations. Phosphates in run-off water which flows into lakes contribute to the excessive growth of algae (the formation of *algal bloom* as shown in the photograph opposite) and the *eutrophication* of the lake. Algae produce O_2 during photosynthesis. However, the presence of large amounts of dead algae provides a ready food supply for aerobic organisms. The net result of excessive algal blooms, therefore, is a depletion in lakes of O_2 which in turn affects fish and other aquatic life. When water is classed as hypereutrophic, it is at an extreme end of its trophic state. The latter is qualitatively measured by monitoring the phosphorus, nitrogen and chlorophyll concentrations, and the transparency of the water. The chlorophyll concentration is determined by the amount of plant and algal growth. The transparency decreases with increased algal blooms and sedimentary particles, and is measured by lowering a Secchi disk (a disk with white and black segments) into the water until it is no longer visible. This depth is referred to as the Secchi depth. The table below shows approximate divisions between trophic states based on these measurements:

Trophic state	[Phosphorus]/ $\mu g\ dm^{-3}$	[Nitrogen]/ $\mu g\ dm^{-3}$	[Chlorophyll]/ $\mu g\ dm^{-3}$	Secchi depth/m
Oligotrophic	<10	<400	<3	>6
Mesotrophic	10–35	400–600	3–8	6–3
Eutrophic	35–100	600–1500	8–40	3–1
Hypereutrophic	>100	>1500	>40	<1

Eutrophication can occur as a natural process, although the term is most often applied to situations that have been exacerbated by external influences.

Fertilizers are a major source of phosphates entering rivers and lakes. However, domestic and industrial waste water (e.g. from detergent manufacturing) also contains $[PO_4]^{3-}$ and condensed phosphates, and the levels that must be removed before the waste can be discharged are controlled by legislation. In most cases, phosphates are removed by methods based on precipitation (this is the reverse of the situation for nitrate removal: see Box 15.9). Fe^{3+}, Al^{3+} and Ca^{2+} are most commonly used to give precipitates that can be separated by filtration. Values of K_{sp} for $FePO_4{\cdot}2H_2O$, $AlPO_4$ and $Ca_2(PO_4)_3$ are 9.91×10^{-16}, 9.84×10^{-21} and 2.07×10^{-33} respectively.

The issue of phosphates in lakes is not clear-cut: field studies indicate that adding phosphates to acid lakes (the result of acid rain pollution) stimulates plant growth, which in turn leads to a production of $[OH]^-$, which neutralizes excess acid.

Eutrophication of a lake.

one strongly and one weakly acidic proton, while each P atom in the body of the chain bears one strongly acidic group;
- cross-linking P–O–P bridges are hydrolysed by water much faster than other such units.

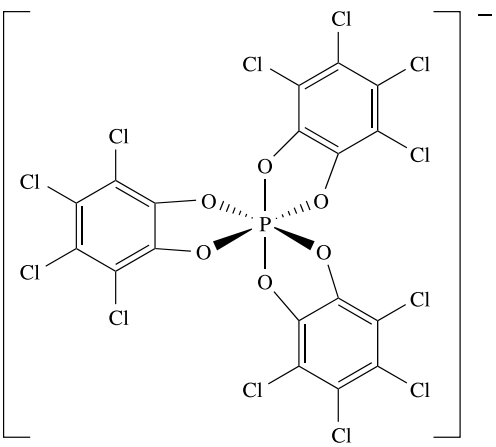
Condensed phosphates play a significant role in biology (Box 15.11).

The simplest condensed phosphoric acid, $H_4P_2O_7$, is a solid at 298 K and can be obtained from reaction 15.137 or, in a purer form, by reaction 15.141. It is a stronger acid than H_3PO_4 (Table 15.8).

$$5H_3PO_4 + POCl_3 \longrightarrow 3H_4P_2O_7 + 3HCl \qquad (15.141)$$

The sodium salt $Na_4P_2O_7$ is obtained by heating Na_2HPO_4 at 510 K. Note the electronic and structural relationship between $[P_2O_7]^{4-}$ (in which the terminal P–O bond distances are equal) and $[Si_2O_7]^{6-}$, **14.23**. In aqueous solution, $[P_2O_7]^{4-}$ is very slowly hydrolysed to $[PO_4]^{3-}$, and the two ions can be distinguished by chemical tests, e.g. addition of Ag^+ ions precipitates white $Ag_4P_2O_7$ or pale yellow Ag_3PO_4.

The acid referred to as 'metaphosphoric acid' with an empirical formula of HPO_3 is actually a sticky mixture of polymeric acids, obtained by heating H_3PO_4 and $H_4P_2O_7$ at ≈600 K. More is known about the salts of these acids than about the acids themselves. For example, $Na_3P_3O_9$ can be isolated by heating NaH_2PO_4 at 870–910 K and maintaining the melt at 770 K to allow water vapour to escape. It contains the cyclic $[P_3O_9]^{3-}$ ion (*cyclo*-triphosphate ion, Fig. 15.21a) which has a chair conformation. In alkaline solution, $[P_3O_9]^{3-}$ hydrolyses to $[P_3O_{10}]^{5-}$ (triphosphate ion, Fig. 15.21b). The salts $Na_5P_3O_{10}$ and $K_5P_3O_{10}$ (along with several hydrates) are well characterized and $Na_5P_3O_{10}$ (manufactured by reaction 15.142) is used in detergents where it acts as a water softener. However, concerns that phosphates in waste water are associated with the eutrophication of lakes and rivers (Box 15.10) have been responsible for the replacement of phosphates in detergents by zeolites (see Section 14.9). Uses of polyphosphates as sequestering agents were mentioned in Sections 12.7 and 12.8. The parent acid $H_5P_3O_{10}$ has not been prepared in a pure form, but solution titrations allow pK_a values to be determined (Table 15.8).



$$2Na_2HPO_4 + NaH_2PO_4 \xrightarrow{550-650\,K} Na_5P_3O_{10} + 2H_2O \qquad (15.142)$$

The salt $Na_4P_4O_{12}$ may be prepared by heating $NaHPO_4$ with H_3PO_4 at 670 K and slowly cooling the melt. Alternatively, the volatile form of P_4O_{10} may be treated with ice-cold aqueous NaOH and $NaHCO_3$. Figure 15.21c shows the structure of $[P_4O_{12}]^{4-}$, in which the P_4O_4-ring adopts a chair conformation. Several salts of the $[P_6O_{18}]^{6-}$ ion (Fig. 15.21d) are also well characterized; the Na^+ salt is made by heating NaH_2PO_4 at ≈1000 K.

The discussion above illustrates how changes in the conditions of heating Na_2HPO_4 or NaH_2PO_4 cause product variation. Carefully controlled conditions are needed to obtain long-chain polyphosphates. Depending on the relative orientations of the PO_4-units, several modifications can be made. Cross-linked polyphosphates (some of which are glasses) can be made by heating NaH_2PO_4 with P_4O_{10}.

Chiral phosphate anions

Although the octahedral ion $[Sb(OH)_6]^-$ exists (see Section 15.12), the analogous phosphorus-containing anion has not been isolated. However, related anions containing chelating *O*,*O*'-donor ligands are known and we introduce them here because of their stereoselective applications. An example is anion **15.67** which has D_3 symmetry (see worked example 3.9) and is chiral (Fig. 15.22). The importance of anions of this family lies in their ability to discriminate between chiral cations.[†] We return to this in Section 19.8.

TRISPHAT

(15.67)

15.12 Oxoacids of arsenic, antimony and bismuth

'Arsenous acid' ($As(OH)_3$ or H_3AsO_3) has not been isolated. Aqueous solutions of As_2O_3 (see Section 15.10) probably contain H_3AsO_3, and metal arsenites (e.g. M_3AsO_3 where M = Ag or alkali metal) are known. Although there is little evidence for the existence of an acid of formula As(O)OH, salts of $[AsO_2]^-$ (meta-arsenites) are known. Sodium meta-arsenite, $NaAsO_2$ (commercially

[†] For an overview, see: J. Lacour and V. Hebbe-Viton (2003) *Chem. Soc. Rev.*, vol. 32, p. 373 – 'Recent developments in chiral anion mediated asymmetric chemistry'; J. Lacour (2010) *C. R. Chemie*, vol. 13, p. 985 – 'Chiral hexacoordinated phosphates: From pioneering studies to modern uses in stereochemistry'.

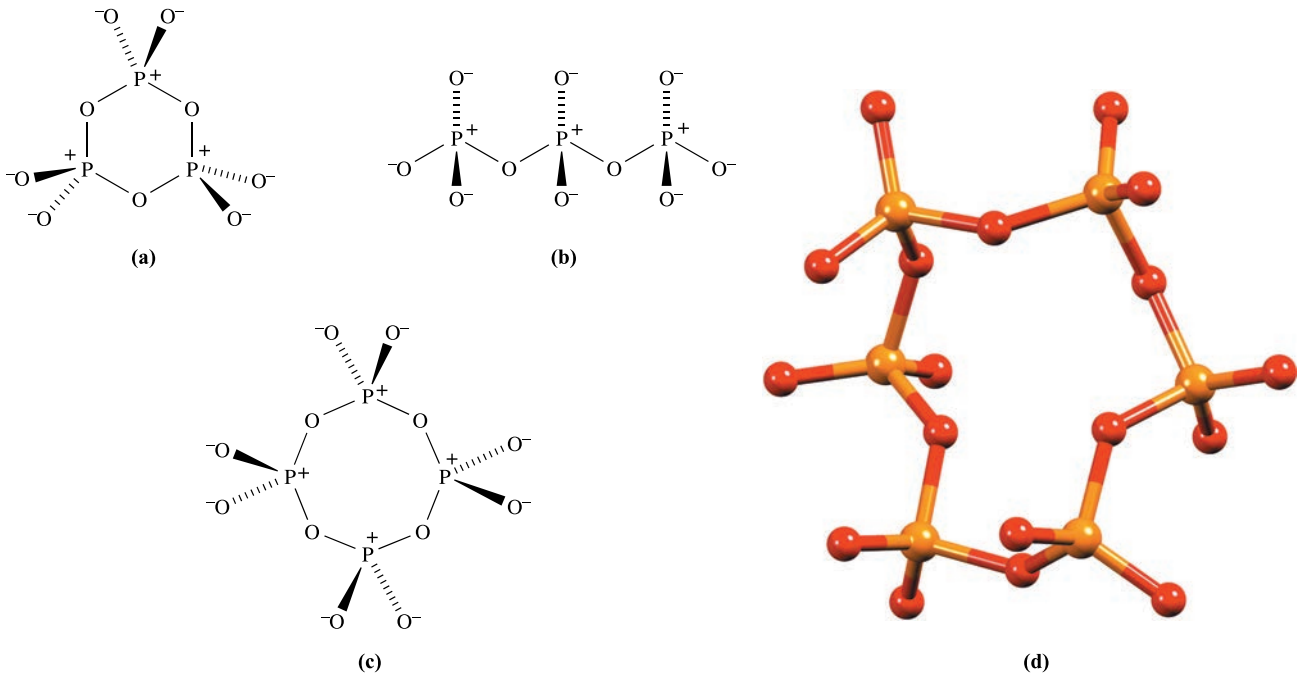


Fig. 15.21. Schematic representations of the structures of (a) $[P_3O_9]^{3-}$, (b) $[P_3O_{10}]^{5-}$ and (c) $[P_4O_{12}]^{4-}$. available), contains Na^+ ions and infinite chains, **15.68**, with trigonal pyramidal As(III) centres.

(15.68)

Arsenic acid, H_3AsO_4, is obtained by dissolving As_2O_5 in water or by oxidation of As_2O_3 using nitric acid (reaction 15.129). Values of $pK_a(1) = 2.25$, $pK_a(2) = 6.77$ and $pK_a(3) = 11.60$ for H_3AsO_4 show that it is of similar acidic strength to phosphoric acid (Table 15.8). Salts derived from H_3AsO_4 and containing the $[AsO_4]^{3-}$, $[HAsO_4]^{2-}$ or $[H_2AsO_4]^-$ ions can be prepared under appropriate conditions. In acidic solution, H_3AsO_4 acts as an oxidizing agent and the pH-dependence of the ease of oxidation or reduction is understood in terms of half-equation 15.143 and the relevant discussion in Section 8.2.

$$H_3AsO_4 + 2H^+ + 2e^- \rightleftharpoons H_3AsO_3 + H_2O \qquad E^\circ = +0.56\,V \qquad (15.143)$$

Condensed polyarsenate ions are kinetically much less stable with respect to hydrolysis (i.e. cleavage of As−O−As bridges) than condensed polyphosphate ions, and only monomeric $[AsO_4]^{3-}$ exists in aqueous solution. Thus, $Na_2H_2As_2O_7$ can be made by dehydrating NaH_2AsO_4 at 360 K. Further dehydration (410 K) yields $Na_3H_2As_3O_{10}$ and, at 500 K, polymeric $(NaAsO_3)_n$ is formed. In the solid state, the latter contains infinite chains of tetrahedral AsO_4 units linked by As−O−As bridges. All these condensed arsenates revert to $[AsO_4]^{3-}$ on adding water.

Oxoacids of Sb(III) are not stable, and few antimonite salts are well characterized. Meta-antimonites include $NaSbO_2$ which can be prepared as the trihydrate from Sb_2O_3 and

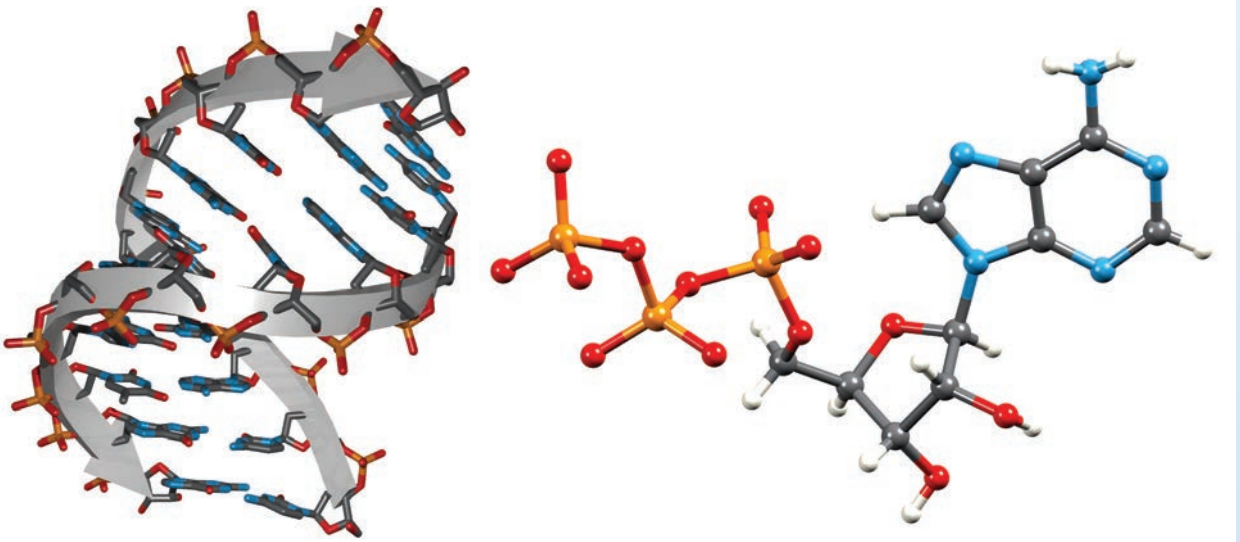
BIOLOGY AND MEDICINE

Box 15.11 Biological significance of phosphates

Phosphates play an enormously important role in biological systems. The genetic substances deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) are phosphate esters (see Fig. 10.14). The form of DNA originally characterized is referred to as B-DNA and possesses a right-handed helix supported by hydrogen-bonded, complementary nucleobase pairs. Other common forms include A-DNA (right-handed) and Z-DNA (left-handed). The phosphate groups lie on the outside of the helix as shown in the left-hand diagram below.

Bones and teeth are constructed from *collagen* (fibrous protein) and single crystals of *hydroxyapatite*, $Ca_5(OH)(PO_4)_3$. Tooth decay involves acid attack on the phosphate, but the addition of fluoride ion to water supplies facilitates the formation of fluoroapatite, which is more resistant to decay.

$$Ca_5(OH)(PO_4)_3 + F^- \longrightarrow Ca_5F(PO_4)_3 + [OH]^-$$



All living cells contain *adenosine triphosphate*, ATP, which consists of adenine, ribose and triphosphate units. The structure of $[ATP]^{4-}$ is shown on the right below. Hydrolysis results in the loss of a phosphate group and converts ATP to ADP (adenosine diphosphate), releasing energy which is used for functions such as cell growth and muscle movement. In a simplified form:

$$[ATP]^{4-} + 2H_2O \longrightarrow [ADP]^{3-} + [HPO_4]^{2-} + [H_3O]^+$$

and, at the standard state usually employed in discussions of biochemical processes (pH 7.4 and $[CO_2] = 10^{-5}$ mol dm^{-3}), $\Delta G \approx -40$ kJ per mole of reaction. Conversely, energy released by, for example, the oxidation of carbohydrates can be used to convert ADP to ATP (see Section 29.4); thus ATP is continually being reformed, ensuring a continued supply of stored energy in the body.

Colour code: P, orange; O, red; C, grey; N, blue; H, white.

aqueous NaOH; the anhydrous salt has a polymeric structure. No oxoacids of Sb(V) are known, and neither is the tetrahedral anion '$[SbO_4]^{3-}$'. However, well-defined antimonates can be obtained, for example, by dissolving antimony(V) oxide in aqueous alkali and crystallizing the product. Some antimonates contain the octahedral $[Sb(OH)_6]^-$ ion, e.g. $Na[Sb(OH)_6]$ (originally formulated as $Na_2H_2Sb_2O_7{\cdot}5H_2O$) and $[Mg(OH_2)_6][Sb(OH)_6]_2$ (with the old formula of $Mg(SbO_3)_2{\cdot}12H_2O$). The remaining antimonates should be considered as mixed metal oxides. Their solid state structures consist of 3-dimensional arrays in which Sb(V) centres are octahedrally coordinated by six O atoms and connected by Sb−O−Sb bridges, e.g. $NaSbO_3$, $FeSbO_4$, $ZnSb_2O_6$ and $FeSb_2O_6$ (Fig. 15.23).

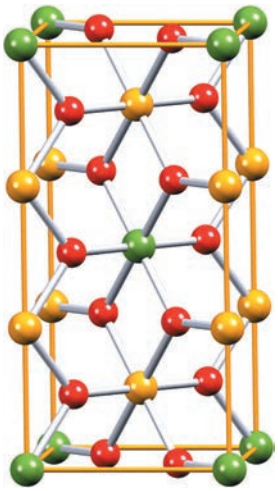

Fig. 15.23. The unit cell of $FeSb_2O_6$ which has a *trirutile* lattice; compare with the rutile unit cell in Fig. 6.24. Colour code: Sb, yellow; Fe, green; O, red; the edges of the unit cell are defined in yellow.

No oxoacids of Bi are known, although some bismuthate salts are well characterized. Sodium bismuthate is an insoluble, orange solid, obtained by fusing Bi_2O_3 with NaOH in air or with Na_2O_2. It is a very powerful oxidizing agent, e.g. in the presence of acid, it oxidizes Mn(II) to $[MnO_4]^-$, and liberates Cl_2 from hydrochloric acid. Like antimonates, some of the bismuthates are better considered as mixed metal oxides. An example is the Bi(III)–Bi(V) compound $K_{0.4}Ba_{0.6}BiO_{3-x}$ ($x \approx 0.02$) which has a perovskite-type structure (Fig. 6.26) and is of interest as a Cu-free superconductor at 30 K (see Section 28.4).

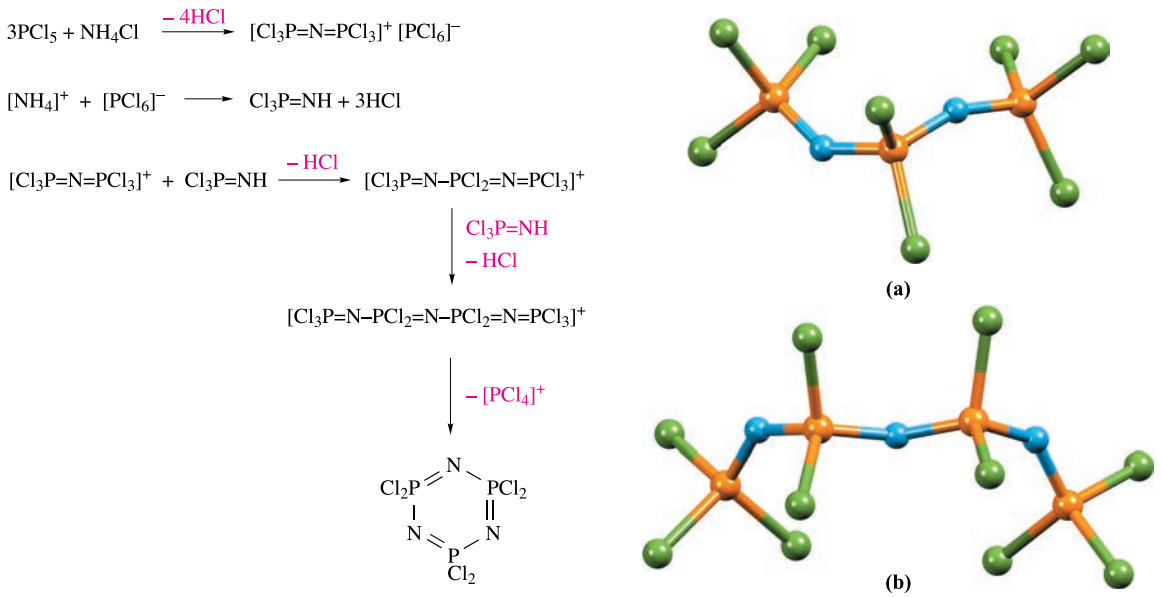
15.13 Phosphazenes

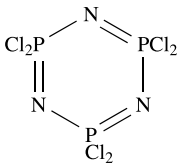
Phosphazenes are a group of P(V)/N(III) compounds featuring chain or cyclic structures, and are oligomers of the hypothetical $N{\equiv}PR_2$. The reaction of PCl_5 with NH_4Cl in a chlorinated solvent (e.g. C_6H_5Cl) gives a mixture of colourless solids of formula $(NPCl_2)_n$ in which the predominant species have $n = 3$ or 4. The compounds $(NPCl_2)_3$ and $(NPCl_2)_4$ are readily separated by distillation under reduced pressure. Although eq. 15.144 summarizes the overall reaction, the mechanism is complicated. There is some evidence to support the scheme in Fig. 15.24 which illustrates the formation of the trimer.

$$n\mathrm{PCl_5} + n\mathrm{NH_4Cl} \longrightarrow (\mathrm{NPCl_2})_n + 4n\mathrm{HCl} \qquad (15.144)$$

Reaction 15.144 is the traditional method of preparing $(NPCl_2)_3$, but yields are typically ≈50%. Improved yields can be obtained by using reaction 15.145. Again, although this looks straightforward, the reaction pathway is complicated and the formation of $(NPCl_2)_3$ competes with that of $Cl_3P{=}NSiMe_3$ (eq. 15.146). Yields of $(NPCl_2)_3$ can be optimized by ensuring a slow rate of addition of PCl_5 to $N(SiMe_3)_3$ in CH_2Cl_2. Yields of $Cl_3P{=}NSiMe_3$ (a precursor for phosphazene polymers, see below) are optimized if $N(SiMe_3)_3$ is added rapidly to PCl_5 in CH_2Cl_2, and hexane is then added.

$$3\mathrm{N(SiMe_3)_3} + 3\mathrm{PCl_5} \longrightarrow (\mathrm{NPCl_2})_3 + 9\mathrm{Me_3SiCl} \qquad (15.145)$$





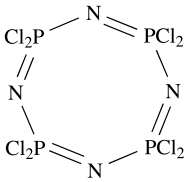


Fig. 15.24. Proposed reaction scheme for the formation of the cyclic phosphazene $(NPCl_2)_3$, and the structures of (a) $[Cl_3P{=}N{-}PCl_2{=}N{=}PCl_3]^+$ and (b) $[Cl_3P{=}N{-}(PCl_2{=}N)_2{=}PCl_3]^+$. Both were determined by X-ray diffraction for the chloride salts [E. Rivard *et al*. (2004) *Inorg. Chem*., vol. 43, p. 2765]. Colour code: P, orange; N, blue; Cl, green.

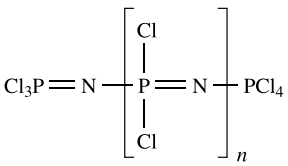
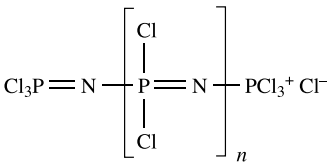
$$N(SiMe_3)_3 + PCl_5 \longrightarrow Cl_3P{=}NSiMe_3 + 2Me_3SiCl \qquad (15.146)$$

Reaction 15.144 can be adapted to produce $(NPBr_2)_n$ or $(NPMe_2)_n$ by using PBr_5 or Me_2PCl_3 (in place of PCl_5) respectively. The fluoro derivatives $(NPF_2)_n$ ($n = 3$ or 4) are not made directly, but are prepared by treating $(NPCl_2)_n$ with NaF suspended in MeCN or $C_6H_5NO_2$.

(15.69)



(15.70)

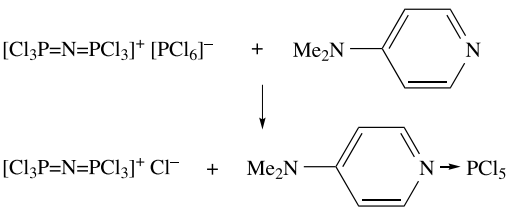


The Cl atoms in $(NPCl_2)_3$, **15.69**, and $(NPCl_2)_4$, **15.70**, readily undergo nucleophilic substitutions, e.g. the following groups can be introduced:

- F using NaF (see above);
- NH_2 using liquid NH_3;
- NMe_2 using Me_2NH;
- N_3 using LiN_3;
- OH using H_2O;
- Ph using LiPh.

Two substitution pathways are observed. If the group that first enters *decreases* the electron density on the P centre (e.g. F replaces Cl), the second substitution occurs at the *same* P atom. If the electron density *increases* (e.g. NMe_2 substitutes for Cl), then the second substitution site is at a different P centre.

(15.71)



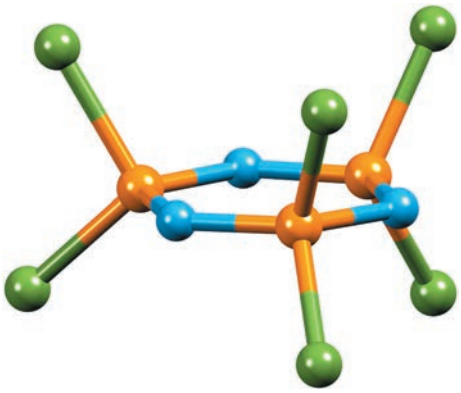
(15.72)

Small amounts of linear polymers are also produced in reaction 15.145, and their yield can be increased by using excess PCl_5. Such polymers may exist in either covalent (**15.71**) or ionic (**15.72**) forms. Polymers of $(NPCl_2)_3$ with molecular masses in the range 10^6, but with a wide mass distribution, result from heating molten $(NPCl_2)_3$ at 480–520 K. Room temperature cationic-polymerization can be achieved using $Cl_3P{=}NSiMe_3$ as a precursor (eq. 15.147). This leads to polymers with molecular masses around 10^5 and with a relatively small mass distribution.

$$Cl_3P{=}NSiMe_3 \xrightarrow[(e.g.\ PCl_5)\ 297\ K]{\text{Cationic initiator}} [Cl_3P{=}N(PCl_2{=}N)_nPCl_3]^+[PCl_6]^- \qquad (15.147)$$

The first step in reaction 15.147 is the formation of $[Cl_3P{=}N{=}PCl_3]^+[PCl_6]^-$, which can be converted to the chloride salt by reaction 15.148. This is a convenient route to $[Cl_3P{=}N{=}PCl_3]^+Cl^-$, which is a precursor to higher polymers (e.g. eq. 15.149).

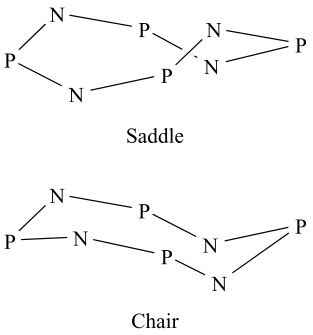
(15.148)



$$[Cl_3P{=}N{=}PCl_3]^+Cl^- + n\,Cl_3P{=}NSiMe_3 \xrightarrow{-n\,Me_3SiCl} [Cl_3P{=}N{-}(PCl_2{=}N)_x{=}PCl_3]^+Cl^- \quad x = 1, 2, 3 \qquad (15.149)$$

The structures of the $[Cl_3P{=}N{-}(PCl_2{=}N)_x{=}PCl_3]^+$ cations for x = 1 and 2 are shown in Fig. 15.24. The P–N–P bond angles in these polyphosphazenes lie in the range 134–157°, and the P–N bond distances are all similar (153–158 pm). This indicates that the bonding is delocalized, rather than the combination of double and single bonds that is traditionally drawn. The bonding is best described in terms of contributions from charge-separated resonance structures (i.e. ionic bonding), and negative hyperconjugation involving $n(N) \longrightarrow \sigma^*(P{-}Cl)$ electron donation where $n(N)$ represents the N lone pair. This is analogous to the negative hyperconjugation in $N(SiH_3)_3$ (Section 14.6).

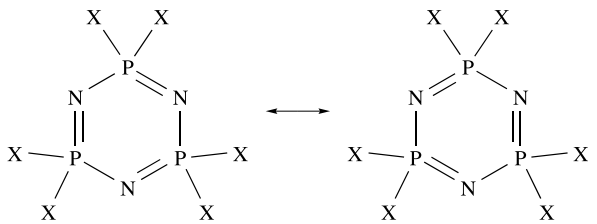
The $[Ph_3P{=}N{=}PPh_3]^+$ ion (commonly abbreviated to $[PPN]^+$) is related to $[Cl_3P{=}N{=}PCl_3]^+$, and is often used to stabilize salts containing large anions (see Box 24.1).



The Cl atoms in the polymers are readily replaced, and this is a route to some commercially important materials. Treatment with sodium alkoxides, NaOR, yields linear polymers $[NP(OR)_2]_n$ which have water-resistant properties, and when $R = CH_2CF_3$, the polymers are inert enough for use in the construction of artificial blood vessels and organs. Many phosphazene polymers are used in fire-resistant materials (see Box 17.1).

The structures of $(NPCl_2)_3$, $(NPCl_2)_4$, $(NPF_2)_3$ and $(NPF_2)_4$ are shown in Fig. 15.25. Each of the 6-membered rings is planar, while the 8-membered rings are puckered. In $(NPF_2)_4$, the ring adopts a saddle conformation

	X = Cl	X = F
P—N / pm	158	156
P—X / pm	199	152
∠ P–N–P / deg	121	120
∠ N–P–N / deg	118	121
∠ X–P–X / deg	102	99



(a)

(b)

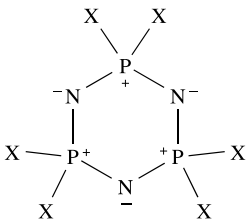


Fig. 15.25. (a) Structural parameters for the phosphazenes $(NPX_2)_3$ (X = Cl or F); colour code: P, orange, N, blue; X, green. (b) Schematic representations of the P_4N_4 ring conformations in $(NPF_2)_4$ (saddle conformation only) and $(NPCl_2)_4$ (saddle and chair conformations).

(Fig. 15.25b),[†] but two ring conformations exist for $(NPCl_2)_4$. The metastable form has a saddle conformation, while the stable form of $(NPCl_2)_4$ adopts a chair conformation (Fig. 15.25b). Although structures **15.69** and **15.70** indicate double and single bonds in the rings, crystallographic data show that the P−N bond lengths in a given ring are equal. Data for $(NPCl_2)_3$ and $(NPF_2)_3$ are given in Fig. 15.25a; in $(NPF_2)_4$, d(P−N) = 154 pm, and in the saddle and chair conformers of $(NPCl_2)_4$, d(P−N) = 157 and 156 pm respectively. The P−N bond distances are significantly shorter than expected for a P−N single bond (e.g. 177 pm in the anion in $Na[H_3NPO_3]$), indicating a degree of multiple bond character. Resonance structures **15.73** could be used to describe the bonding in the planar 6-membered rings, but both involve hypervalent P atoms.

(15.73)

Traditional bonding descriptions for the 6-membered rings have involved N(2*p*)–P(3*d*) overlap, both in and perpendicular to the plane of the P_3N_3-ring. However, this model is not consistent with current opinion that phosphorus makes little or no use of its 3*d* orbitals. Structure **15.74** provides another resonance form for a 6-membered cyclophosphazene, and is consistent with the observed P−N bond equivalence, as well as the observation that the N and P atoms are subject to attack by electrophiles and nucleophiles, respectively. Theoretical results are consistent with highly polarized $P^{\delta+}-N^{\delta-}$ bonds and the absence of aromatic character in the P_3N_3-ring.[‡] As for the linear polyphosphazenes, both ionic bonding and negative hyperconjugation appear to contribute to the bonding in cyclic phosphazenes.

(15.74)

Self-study exercise

The azido derivative, $N_3P_3(N_3)_6$, is fully combusted according to the equation:

$$N_3P_3(N_3)_6(s) + \tfrac{15}{4}O_2(g) \longrightarrow \tfrac{3}{4}P_4O_{10}(s) + \tfrac{21}{2}N_2(g)$$

and the standard enthalpy of combustion has been determined as $-4142\,kJ\,mol^{-1}$. Calculate the value of $\Delta_fH^o(N_3P_3(N_3)_6, s)$ given that $\Delta_fH^o(P_4O_{10}, s) = -2984\,kJ\,mol^{-1}$. Comment on the fact that $N_3P_3(N_3)_6$ is classed as a 'high energy density material'. What is the origin of the large difference between the value of $\Delta_fH^o(N_3P_3(N_3)_6, s)$ and that of $\Delta_fH^o(N_3P_3Cl_6, s) = -811\,kJ\,mol^{-1}$?

[*Ans.* $+1904\,kJ\,mol^{-1}$]

[†] Prior to 2001, the ring was thought to be planar; the correct conformation was previously masked by a crystallographic disorder (see Box 15.5). See: A.J. Elias *et al.* (2001) *J. Am. Chem. Soc.*, vol. 123, p. 10299.

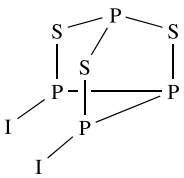
15.14 Sulfides and selenides

Sulfides and selenides of phosphorus



Sulfur–nitrogen compounds are described in Section 16.10, and in this section we look at the molecular sulfides and selenides formed by phosphorus. Although the structures of the sulfides (Fig. 15.26) appear to be closely related to those of the oxides (Section 15.10), there are some notable differences, e.g. P_4O_6 and P_4S_6 are not isostructural. The bond distances *within* the cages of all the sulfides indicate single P−P and P−S bonds. The data for P_4S_3 shown in Fig. 15.26 are typical. The terminal P−S bonds are shorter than those in the cage (e.g. 191 versus 208 pm in P_4S_{10}), and this can be rationalized in terms of a greater ionic contribution to the terminal bonds. Only some of the sulfides are prepared by direct combination of the elements. Above 570 K, white phosphorus combines with sulfur to give P_4S_{10} which is the most useful of the phosphorus sulfides. It is a thiating agent (i.e. one that introduces sulfur into a system) in organic reactions, and is a precursor to organothiophosphorus compounds. The reaction of red phosphorus with sulfur above 450 K yields P_4S_3, and P_4S_7 can also be made by direct combination under appropriate conditions. The remaining sulfides in Fig. 15.26 are made by one of the general routes:

- abstraction of sulfur using PPh_3 (e.g. reaction 15.150);
- treatment of a phosphorus sulfide with sulfur (e.g. reaction 15.151);
- treatment of a phosphorus sulfide with phosphorus (e.g. reaction 15.152);
- reaction of α- (**15.75**) or β-$P_4S_3I_2$ (**15.76**) with $(Me_3Sn)_2S$ (reaction 15.153).

There is ^{31}P NMR spectroscopic evidence that P_4S_8 has been prepared by treating P_4S_9 with PPh_3.

(15.75)

(15.76)

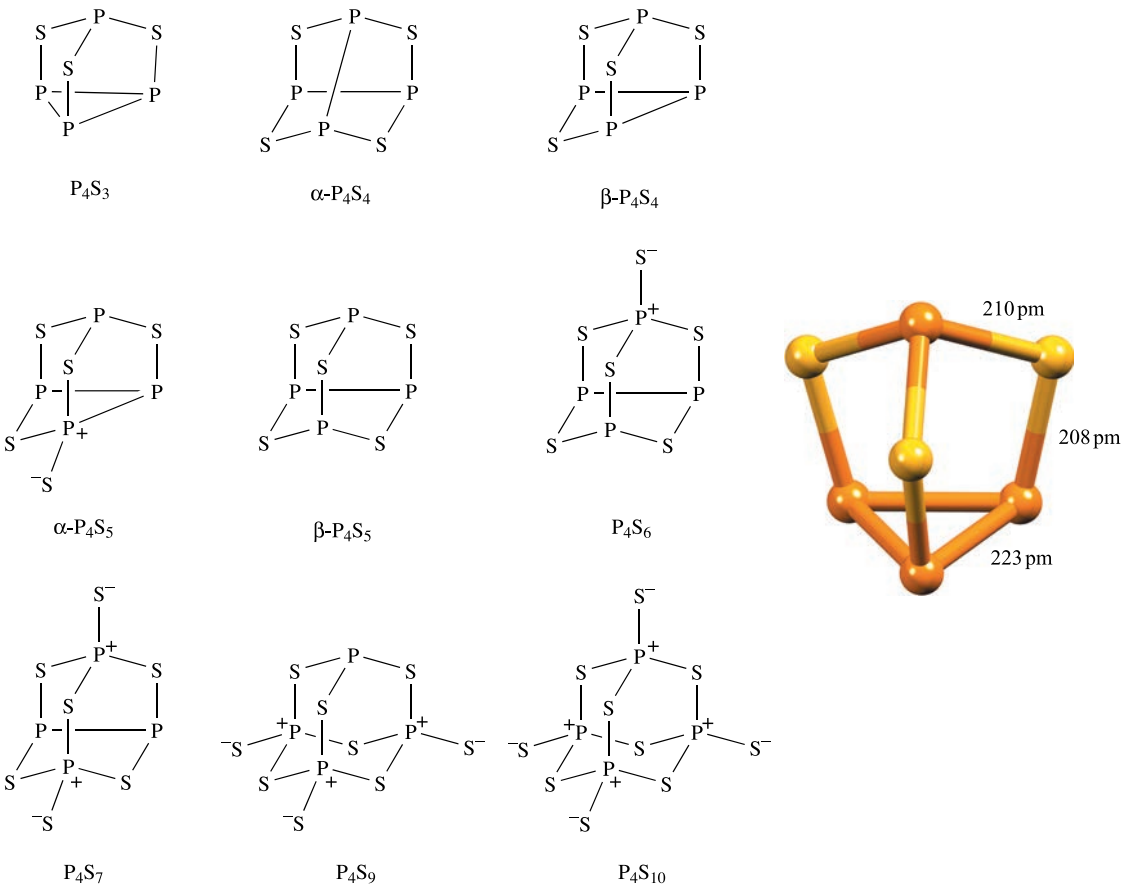


Fig. 15.26. Schematic representations of the molecular structures of phosphorus sulfides, and the structure (X-ray diffraction) of P_4S_3 [L.Y. Goh *et al.* (1995) *Organometallics*, vol. 14, p. 3886]. Colour code: S, yellow; P, orange.

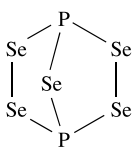
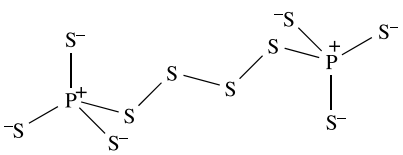
$$P_4S_7 + Ph_3P \longrightarrow P_4S_6 + Ph_3P{=}S \quad (15.150)$$

$$P_4S_3 \xrightarrow{\text{excess sulfur}} P_4S_9 \quad (15.151)$$



$$P_4S_{10} \xrightarrow{\text{red phosphorus}} \alpha\text{-}P_4S_5 \quad (15.152)$$

$$\beta\text{-}P_4S_3I_2 + (Me_3Sn)_2S \longrightarrow \beta\text{-}P_4S_4 + 2Me_3SnI \quad (15.153)$$



Phosphorus sulfides ignite easily, and P_4S_3 is used in 'strike anywhere' matches; it is combined with $KClO_3$, and the compounds inflame when subjected to friction. (In safety matches, the head of the match contains $KClO_3$ and this reacts with red phosphorus which is combined with glass powder on the side of the match box; see end-of-chapter problem 15.42). Whereas P_4S_3 does not react with water, other phosphorus sulfides are slowly hydrolysed (e.g. reaction 15.154).

$$P_4S_{10} + 16H_2O \longrightarrow 4H_3PO_4 + 10H_2S \quad (15.154)$$

We have already noted (Section 15.10) that, although sometimes referred to as 'phosphorus pentoxide', phosphorus(V) oxide does not exist as P_2O_5 molecules. In contrast, the vapour of phosphorus(V) sulfide contains some P_2S_5 molecules (although decomposition of the vapour to S, P_4S_7 and P_4S_3 also occurs). The phosphorus selenides P_2Se_5 and P_4Se_{10} are distinct species. Both can be made by direct combination of P and Se under appropriate conditions; P_2Se_5 is also formed by the decomposition of P_3Se_4I, and P_4Se_{10} from the reaction of P_4Se_3 and selenium at 620 K. Structure **15.77** has been confirmed by X-ray diffraction for P_2Se_5; P_4Se_{10} is isostructural with P_4S_{10} and P_4O_{10}.

(15.77)

(15.78)

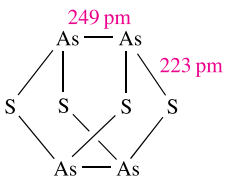
When P_2S_5 is heated under vacuum with Cs_2S and sulfur in a 1:2:7 molar ratio, $Cs_4P_2S_{10}$ is formed. This contains discrete $[P_2S_{10}]^{4-}$ ions (**15.78**), the terminal P–S bonds in which are shorter (201 pm) than the two in the central chain (219 pm).

Self-study exercise

P_2S_7 can be stabilized by using pyridine (py) to form an adduct: $(py)_2P_2S_7$ forms when P_4S_{10} is heated with S_8 in pyridine. The ^{31}P NMR spectrum of $(py)_2P_2S_7$ shows one signal (δ 82.2 ppm). Suggest a structure for the product and draw a resonance structure in which all atoms obey the octet rule.

[*Ans.* see C. Rotter *et al.* (2010) *Chem. Commun.*, vol. 46, p. 5024.]

Arsenic, antimony and bismuth sulfides



Arsenic and antimony sulfide ores are major sources of the group 15 elements (see Section 15.2). In the laboratory, As_2S_3 and As_2S_5 are usually precipitated from aqueous solutions of arsenite or arsenate. Reaction 15.155 proceeds when the H_2S is passed slowly through the solution at 298 K. If the temperature is lowered to 273 K and the rate of flow of H_2S is increased, the product is As_2S_5.

$$2[AsO_4]^{3-} + 6H^+ + 5H_2S \xrightarrow[\text{conc}]{} As_2S_3 + 2S + 8H_2O \quad (15.155)$$

Solid As_2S_3 has the same layer structure as the low-temperature polymorph of As_2O_3, but it vaporizes to give As_4S_6 molecules (see below). As_2S_5 exists in crystalline and vitreous forms, but structural details are not known. Both As_2S_3 and As_2S_5 are readily soluble in alkali metal sulfide solutions with the formation of thioarsenites and thioarsenates (e.g. eq. 15.156); acids decompose these salts, reprecipitating the sulfides.

$$As_2S_3 + 3S^{2-} \longrightarrow 2[AsS_3]^{3-} \quad (15.156)$$

The sulfides As_4S_3 (*dimorphite*), As_4S_4 (*realgar*) and As_2S_3 (*orpiment*) occur naturally; the last two are red and golden-yellow respectively and were used as pigments in early times.[†] The arsenic sulfides As_4S_3, α-As_4S_4, β-As_4S_4 and β-As_4S_5 are structural analogues of the phosphorus sulfides in Fig. 15.26, but As_4S_6 is structurally related to P_4O_6 and As_4O_6 rather than to P_4S_6. The bond distances in α-As_4S_4 (**15.79**) are consistent with As–As and As–S single bonds, and this view of the cage allows a comparison with S_4N_4 (see Section 16.10).

(15.79)

The only well-characterized binary sulfide of Sb is the naturally occurring Sb_2S_3 (*stibnite*), which has a double-chain structure in which each Sb(III) is pyramidally sited

[†] For wider discussions of inorganic pigments, see: R.J.H. Clark and P.J. Gibbs (1997) *Chem. Commun.*, p. 1003 – 'Identification of lead(II) sulfide and pararealgar on a 13th century manuscript by Raman microscopy', and Further reading in Box 4.1.

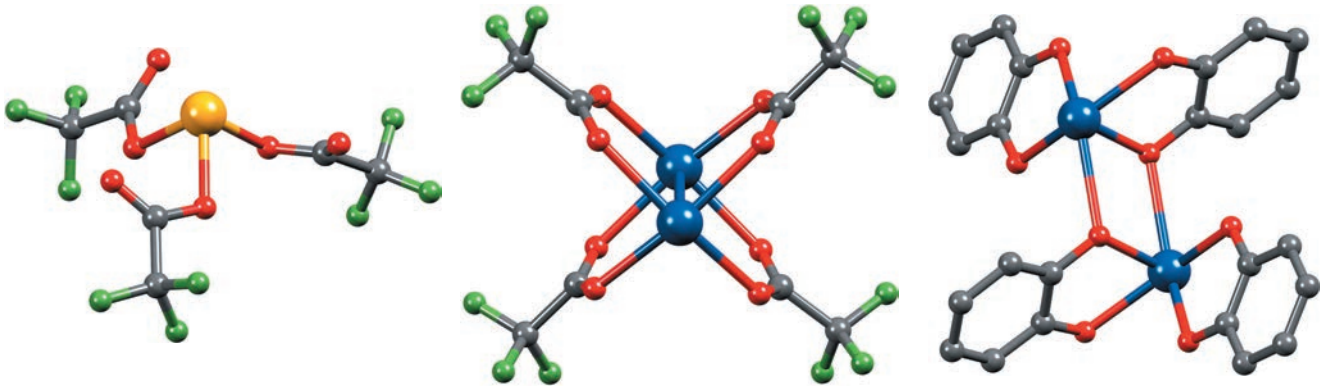


Fig. 15.27. The structures (X-ray diffraction) of (a) (*R*)-$[Sb(O_2CCF_3)_3]$ [D.P. Bullivant *et al.* (1980) *J. Chem. Soc., Dalton Trans.*, p. 105], (b) $Bi_2(O_2CCF_3)_4$ [E.V. Dikarev *et al.* (2004) *Inorg. Chem.*, vol. 43, p. 3461] and (c) $[Bi_2(C_6H_4O_2)_4]^{2-}$, crystallized as a hydrated ammonium salt [G. Smith *et al.* (1994) *Aust. J. Chem.*, vol. 47, p. 1413]. Colour code: Sb, yellow; Bi, blue; O, red; F, green; C, grey.

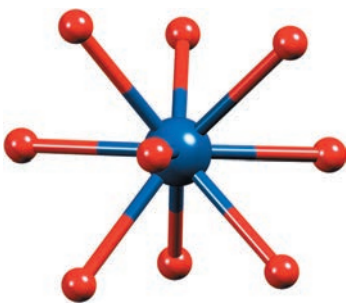
with respect to three S atoms. The sulfide can be made by direct combination of the elements. A metastable red form can be precipitated from aqueous solution, but reverts to the stable black form on heating. Like As_2S_3, Sb_2S_3 dissolves in alkali metal sulfide solutions (see eq. 15.156). Bismuth(III) sulfide, Bi_2S_3, is isostructural with Sb_2S_3, but in contrast to its As and Sb analogues, Bi_2S_3 does not dissolve in alkali metal sulfide solutions.



15.15 Aqueous solution chemistry and complexes

Many aspects of the aqueous solution chemistry of the group 15 elements have already been covered:

- acid–base properties of NH_3, PH_3, N_2H_4 and HN_3 (Section 15.5);
- redox behaviour of nitrogen compounds (Section 15.5 and Fig. 15.7);
- the *brown ring test* for nitrate ion (Section 15.8);
- oxoacids (Sections 15.9, 15.11 and 15.12);
- condensed phosphates (Section 15.11);
- lability of condensed arsenates (Section 15.12);
- sequestering properties of polyphosphates (Section 15.11).

In this section we focus on the formation of aqueous solution species by Sb(III) and Bi(III). Solutions of Sb(III) contain either hydrolysis products or complex ions. The former are commonly written as $[SbO]^+$, but by analogy with Bi(III) (see below), this is oversimplified. Complexes are formed with ligands such as oxalate, tartrate or trifluoroacetate ions, and it is usual to observe an arrangement of donor atoms about the Sb atom that reflects the presence of a stereochemically active lone pair of electrons, e.g. in $[Sb(O_2CCF_3)_3]$, the Sb(III) centre is in a trigonal pyramidal environment (Fig. 15.27a). The analogous bismuth(III) complex, $Bi(O_2CCF_3)_3$, undergoes an interesting reaction when heated with finely divided Bi in an evacuated, sealed vessel. The product, $Bi_2(O_2CCF_3)_4$ (Fig. 15.27b), is a rare example of a simple, bismuth(II) compound. It is diamagnetic and contains a Bi–Bi bond of length 295 pm (compare $2r_{cov}$ = 304 pm). $Bi_2(O_2CCF_3)_4$ is decomposed by water and other polar solvents and, at ≈500 K, its vapour disproportionates to Bi(III) and Bi(0).

When a mixture of Bi_2O_3 and aqueous trifluoromethanesulfonic acid is heated at reflux, crystals of $[Bi(OH_2)_9][CF_3SO_3]_3$ are obtained after cooling the solution. The $[Bi(OH_2)_9]^{3+}$ ion has a tricapped trigonal prismatic arrangement (**15.80**) of aqua ligands (compare this with the structure of $[ReH_9]^{2-}$ in Fig. 10.15c). However, in highly acidic aqueous media, the cation $[Bi_6(OH)_{12}]^{6+}$ is the dominant species. The six Bi(III) centres are arranged in an octahedron, but at non-bonded separations (Bi···Bi = 370 pm), and each of the 12 Bi–Bi edges is supported by a bridging hydroxido ligand. In more alkaline solutions, $[Bi_6O_6(OH)_3]^{3+}$ is formed and, ultimately, $Bi(OH)_3$ is precipitated. Although there is evidence for the formation of bismuth polyoxido

(15.80)

cations with nuclearities ranging from two to nine in alkaline solutions, few species have been isolated and structural data are sparse. An exception is the $[Bi_9(\mu_3\text{-}O)_8(\mu_3\text{-}OH)_6]^{5+}$ cation which is formed by hydrolysing $BiO(ClO_4)$ with aqueous NaOH and has been structurally characterized as the perchlorate salt. The Bi atoms in $[Bi_9(\mu_3\text{-}O)_8(\mu_3\text{-}OH)_6]^{5+}$ adopt a tricapped trigonal prismatic arrangement with O or OH groups capping the faces. The coordination geometry of Bi(III) is often influenced by the presence of a stereochemically active lone pair; e.g. in the catecholate complex $[Bi_2(C_6H_4O_2)_4]^{2-}$ (Fig. 15.27c), each Bi atom is in a square-based pyramidal environment. Figure 15.14 showed the structures of two complexes of $BiCl_3$ with macrocyclic ligands.

KEY TERMS

The following terms were introduced in this chapter. Do you know what they mean?

- ❑ chemiluminescent reaction
- ❑ acid anhydride
- ❑ azeotrope

PROBLEMS

15.1 What are the formal oxidation states of N or P in the following species? (a) N_2; (b) $[NO_3]^-$; (c) $[NO_2]^-$; (d) NO_2; (e) NO; (f) NH_3; (g) NH_2OH; (h) P_4; (i) $[PO_4]^{3-}$; (j) P_4O_6; (k) P_4O_{10}.

15.2 Using bond enthalpy terms from Tables 14.2 and 15.3, estimate values of $\Delta_r H^o$ for the following reactions:

(a) $2N_2 \longrightarrow N_4$ (tetrahedral structure);
(b) $2P_2 \longrightarrow P_4$ (tetrahedral structure);
(c) $2C_2H_2 \longrightarrow C_4H_4$ (tetrahedrane, with a tetrahedral C_4 core).

15.3 Give a brief account of allotropy among the group 15 elements.

15.4 Write equations for the reactions of (a) water with Ca_3P_2; (b) aqueous NaOH with NH_4Cl; (c) aqueous NH_3 with $Mg(NO_3)_2$; (d) AsH_3 with an excess of I_2 in neutral aqueous solution; (e) PH_3 with KNH_2 in liquid NH_3.

15.5 Explain why (a) a dilute aqueous solution of NH_3 smells of the gas whereas dilute HCl does not retain the acrid odour of gaseous HCl, and (b) ammonium carbamate is used in smelling salts.

15.6 If (at 298 K) pK_b for NH_3 is 4.75, show that pK_a for $[NH_4]^+$ is 9.25.

15.7 Give the relevant half-equations for the oxidation of NH_2OH to HNO_3 by $[BrO_3]^-$, and write a balanced equation for the overall process.

15.8 (a) Write a balanced equation for the preparation of NaN_3 from $NaNH_2$ with $NaNO_3$. (b) Suggest a route for preparing the precursor $NaNH_2$. (c) How might NaN_3 react with $Pb(NO_3)_2$ in aqueous solution?

15.9 (a) We noted that $[N_3]^-$ is isoelectronic with CO_2. Give three other species that are also isoelectronic with $[N_3]^-$. (b) Describe the bonding in $[N_3]^-$ in terms of an MO picture.

15.10 Refer to Fig. 15.12. (a) By considering a number of unit cells of NiAs connected together, confirm that the coordination number of each Ni atom is 6. (b) How does the information contained in the unit cell of NiAs confirm the stoichiometry of the compound?

15.11 Suggest how you might confirm the conformation of N_2H_4 in (a) the gas phase and (b) the liquid phase.

15.12 In each of reactions 15.66, 15.67 and 15.68, $NF_2^\bullet$ reacts with another radical. What is the second radical in each reaction, and how is it formed? Draw a Lewis structure of F_2NNO (the product of reaction 15.68).

15.13 (a) Discuss structural variation among the phosphorus(III) and phosphorus(V) halides, indicating where stereochemical non-rigidity is possible. (b) On what basis is it appropriate to compare the lattice of $[PCl_4][PCl_6]$ with that of CsCl?

15.14 What might you expect to observe (at 298 K) in the ^{19}F NMR spectra of solutions containing (a) $[PF_6]^-$ and (b) $[SbF_6]^-$. Data needed are in Table 15.2.

15.15 Which of the following equations show redox reactions: eqs. 15.64, 15.70, 15.73, 15.111 and 15.123? For each redox reaction, indicate which species is being oxidized and which reduced. Confirm that the changes in oxidation states for the oxidation and reduction processes balance.

15.16 Explain whether it is possible to distinguish between the following pairs of isomers based *only* on the coupling patterns in the ^{31}P NMR spectra: (a) *cis*- and *trans*-$[PF_4(CN)_2]^-$, and (b) *mer*- and *fac*-$[PF_3(CN)_3]^-$.

15.17 Draw the structures of the possible isomers of $[PCl_2F_3(CN)]^-$, and state how many fluorine environments there are based on the structures you have drawn. At room temperature, the ^{19}F NMR spectra of CH_2Cl_2 solutions of two of the isomers exhibit two signals, while the spectrum of the third isomer shows only one signal. Account for these observations.

15.18 Suggest products for the reactions between (a) $SbCl_5$ and PCl_5; (b) KF and AsF_5; (c) NOF and SbF_5; (d) HF and SbF_5.

15.19 (a) Draw the structures of $[Sb_2F_{11}]^-$ and $[Sb_2F_7]^-$, and rationalize them in terms of the VSEPR model. (b) Suggest likely structures for the $[\{BiX_4\}_n]^{n-}$ and $[\{BiX_5\}_n]^{2n-}$ oligomers mentioned in Section 15.7.

15.20 By using an MO approach, rationalize why, in going from NO to $[NO]^+$, the bond order increases, bond distance decreases and NO vibrational wavenumber increases.

15.21 25.0 cm^3 of a 0.0500 M solution of sodium oxalate ($Na_2C_2O_4$) reacted with 24.8 cm^3 of a solution of $KMnO_4$, **A**, in the presence of excess H_2SO_4. 25.0 cm^3 of a 0.0494 M solution of NH_2OH in H_2SO_4 was boiled with an excess of iron(III) sulfate solution, and when the reaction was complete, the iron(II) produced was found to be equivalent to 24.65 cm^3 of solution **A**. The product **B** formed from the NH_2OH in this reaction can be assumed not to interfere with the determination of iron(II). What can you deduce about the identity of **B**?

15.22 Write a brief account that supports the statement that 'all the oxygen chemistry of phosphorus(V) is based on the tetrahedral PO_4 unit'.

15.23 Figure 15.23 shows a unit cell of $FeSb_2O_6$. (a) How is this unit cell related to the rutile-type structure? (b) Why can the solid state structure of $FeSb_2O_6$ not be described in terms of a single unit cell of the rutile-type structure? (c) What is the coordination environment of each atom type? (d) Confirm the stoichiometry of this compound using only the information provided in the unit cell diagram.

15.24 How may NMR spectroscopy be used:

(a) to distinguish between solutions of $Na_5P_3O_{10}$ and $Na_6P_4O_{13}$;
(b) to determine whether F atoms exchange rapidly between non-equivalent sites in AsF_5;
(c) to determine the positions of the NMe_2 groups in $P_3N_3Cl_3(NMe_2)_3$?

15.25 Deduce what you can about the nature of the following reactions.

(a) One mole of NH_2OH reacts with two moles of Ti(III) in the presence of excess alkali, and the Ti(III) is converted to Ti(IV).
(b) When Ag_2HPO_3 is warmed in water, all the silver is precipitated as metal.
(c) When one mole of H_3PO_2 is treated with excess I_2 in acidic solution, one mole of I_2 is reduced; on making the solution alkaline, a second mole of I_2 is consumed.

15.26 Predict the structures of (a) $[NF_4]^+$; (b) $[N_2F_3]^+$; (c) NH_2OH; (d) $SPCl_3$; (e) PCl_3F_2.

15.27 Suggest syntheses for each of the following from $K^{15}NO_3$: (a) $Na^{15}NH_2$, (b) $^{15}N_2$ and (c) $[^{15}NO][AlCl_4]$.

15.28 Suggest syntheses for each of the following from $Ca_3(^{32}PO_4)_2$: (a) $^{32}PH_3$, (b) $H_3{}^{32}PO_3$ and (c) $Na_3{}^{32}PS_4$.

15.29 25.0 cm^3 of a 0.0500 M solution of sodium oxalate reacted with 24.7 cm^3 of a solution of $KMnO_4$, **C**, in the presence of excess H_2SO_4. 25.0 cm^3 of a 0.0250 M solution of N_2H_4 when treated with an excess of alkaline $[Fe(CN)_6]^{3-}$ solution gave $[Fe(CN)_6]^{4-}$ and a product **D**. The $[Fe(CN)_6]^{4-}$ formed was reoxidized to $[Fe(CN)_6]^{3-}$ by 24.80 cm^3 of solution **C**, and the presence of **D** did not influence this determination. What can you deduce about the identity of **D**?

15.30 Comment on the fact that $AlPO_4$ exists in several forms, each of which has a structure which is also that of a form of silica.

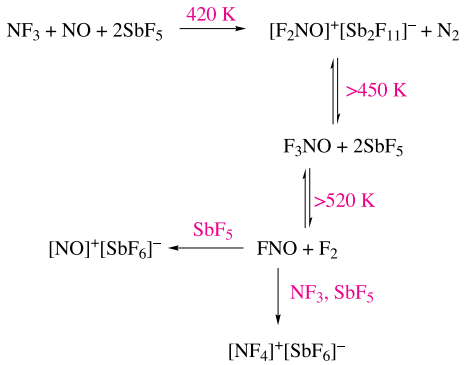
15.31 (a) Explain what is meant by *hyperconjugation* in a phosphazene such as $[Cl_3P{=}N{-}PCl_2{=}N{=}PCl_3]^+$. (b) Draw resonance structures for $[Cl_3P{=}N{-}PCl_2{=}N{=}PCl_3]^+$ which illustrate contributions to the bonding from charge-separated species.

OVERVIEW PROBLEMS

15.32 (a) The ^{31}P and ^{11}B NMR spectra of $Pr_3P{\cdot}BBr_3$ (Pr = *n*-propyl) exhibit a 1 : 1 : 1 : 1 quartet (J = 150 Hz) and a doublet (J = 150 Hz), respectively. Explain the origin of these signals.
(b) Discuss the factors that contribute towards $[NH_4][PF_6]$ being soluble in water.
(c) The ionic compound $[AsBr_4][AsF_6]$ decomposes to Br_2, AsF_3 and $AsBr_3$. The proposed pathway is as follows:

$$[AsBr_4][AsF_6] \longrightarrow [AsBr_4]F + AsF_5$$
$$[AsBr_4]F \longrightarrow AsBr_2F + Br_2$$
$$AsBr_2F + AsF_5 \longrightarrow 2AsF_3 + Br_2$$
$$3AsBr_2F \longrightarrow 2AsBr_3 + AsF_3$$

Discuss these reactions in terms of redox processes and halide redistributions.



15.33 Suggest products for the following reactions; the equations are not necessarily balanced on the left-hand sides.

(a) $PI_3 + IBr + GaBr_3 \longrightarrow$
(b) $POBr_3 + HF + AsF_5 \longrightarrow$
(c) $Pb(NO_3)_2 \xrightarrow{\Delta}$
(d) $PH_3 + K \xrightarrow[\text{liquid } NH_3]{}$
(e) $Li_3N + H_2O \longrightarrow$
(f) $H_3AsO_4 + SO_2 + H_2O \longrightarrow$
(g) $BiCl_3 + H_2O \longrightarrow$
(h) $PCl_3 + H_2O \longrightarrow$

15.34 (a) Draw the structure of P_4S_3 and describe an appropriate bonding scheme for this molecule. Compare the structures of P_4S_{10}, P_4S_3 and P_4, and comment on the formal oxidation states of the P atoms in these species.
(b) The electrical resistivity of Bi at 273 K is $1.07 \times 10^{-6}\ \Omega$ m. How do you expect this property to change as the temperature increases? On what grounds have you drawn your conclusion?
(c) Hydrated iron(III) nitrate was dissolved in hot HNO_3 (100%), and the solution was placed in a desiccator with P_2O_5 until the sample had become a solid residue. The pure Fe(III) product (an ionic salt $[NO_2][\mathbf{X}]$) was collected by sublimation; crystals were extremely deliquescent. Suggest an identity for the product, clearly stating the charges on the ions. The Fe(III) centre has a coordination number of 8. Suggest how this is achieved.

15.35 (a) Predict the ^{31}P NMR spectrum of $[HPF_5]^-$ (assuming a static structure) given that J_{PH} = 939 Hz, $J_{PF(axial)}$ = 731 Hz and $J_{PF(equatorial)}$ = 817 Hz.
(b) The $[BiF_7]^{2-}$ and $[SbF_6]^{3-}$ ions have pentagonal bipyramidal and octahedral structures, respectively. Are these observations consistent with the VSEPR model?

(c) Consider the following reaction scheme (K.O. Christe (1995) *J. Am. Chem. Soc.*, vol. 117, p. 6136):

Discuss the reaction scheme in terms of redox and Lewis acid–base chemistry. Comment on the structures of, and bonding in, the nitrogen-containing species in the scheme.

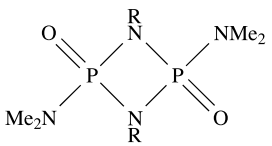
15.36 (a) Sn_3N_4, γ-Si_3N_4 and γ-Ge_3N_4 are the first examples of *nitride spinels*. What is a spinel, and how do the structures of these nitrides relate to that of the oxide Fe_3O_4? Comment on any features that distinguish the nitride spinels from typical oxide analogues.

(b) The reaction between O_3 and $AsCl_3$ at 195 K leads to an As(V) compound **A**. Raman spectra of **A** in CH_2Cl_2 solution are consistent with a molecular structure with C_{3v} symmetry. However, a single-crystal X-ray diffraction study of **A** at 153 K reveals a molecular structure with C_{2h} symmetry. Suggest an identity for **A** and rationalize the experimental data.

15.37 (a) Why does fuming nitric acid appear orange in colour?

(b) By using nitric acid as an example, explain what is meant by the term *azeotrope*.

15.38 (a) Use Wade's rules to rationalize the fact that in $[Pd@Bi_{10}]^{4+}$, the Bi atoms are arranged in a pentagonal antiprism. How is this structure related to that of $[Pd@Pb_{12}]^{2-}$?



(b) At 298 K, ammonium perchlorate decomposes according to the equation:

$$4NH_4ClO_4(s) \longrightarrow 2Cl_2(g) + 2N_2O(g) + 3O_2(g) + 8H_2O(l)$$

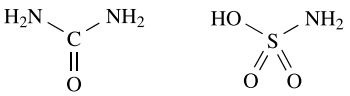
Determine $\Delta_rG^o(298\ K)$ for this decomposition if $\Delta_fG^o(298\ K)$ of $N_2O(g)$, $H_2O(l)$ and $NH_4ClO_4(s)$ are $+104$, -237 and $-89\ kJ\ mol^{-1}$. What part does entropy play in the reaction?

15.39 (a) What would you predict would happen when equimolar amounts of NaN_3 and $NaNO_2$ react in acidic solution? How would you attempt to confirm your prediction?

(b) $POCl_3$ reacts with an excess of Me_2NH to yield compound **A** as the only phosphorus-containing product; compound **A** is miscible with water. **A** contains 40.21%C, 23.45%N and 10.12%H, and each of the solution ^1H and ^{13}C NMR spectra exhibits one signal. Equimolar amounts of **A** and RNH_2 (R = alkyl) react, eliminating dimethylamine to give **B** (shown below).

B

(i) Suggest the identity of **A**, and draw its structure, giving a resonance form in which all non-H atoms obey the octet rule. (ii) What is the origin of the miscibility of **A** with water? (iii) Write a balanced equation for the formation of **A** from $POCl_3$ and Me_2NH.



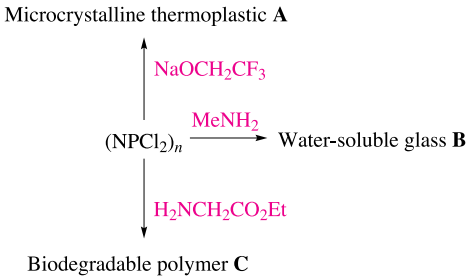
15.40 Electron diffraction and spectroscopic studies of mixed fluoro/chloro phosphorus pentahalides are consistent with trigonal bipyramidal structures in which the most electronegative halogens occupy the axial positions. Confirm that this statement is in agreement with PCl_3F_2, PCl_2F_3 and $PClF_4$ having D_{3h}, C_{2v} and C_{2v} symmetries, respectively. Draw the structure of each compound and state whether the compound is polar.

INORGANIC CHEMISTRY MATTERS

15.41 Box 15.9 deals with the nitrogen cycle and the removal of nitrates and nitrites from waste water. (a) Urea is used to reduce $[NO_2]^-$ to N_2. Write a balanced equation for the reaction of HNO_2 with urea. (b) Sulfamic acid is also used to reduce $[NO_2]^-$ to N_2 during water treatment. Give an equation for this reaction. (c) Nitrites can be removed using H_2O_2, $[OCl]^-$ or HOCl as oxidants. How does the reduction potential for the following process depend on pH?

$$[NO_3]^-(aq) + 3H^+(aq) + 2e^- \rightleftharpoons HNO_2(aq) + H_2O(l)$$
$$E^\circ = +0.93V$$

Suggest products for the reduction of H_2O_2 and HOCl in acidic, aqueous solution. Give equations for the reactions of H_2O_2 with $[NO_2]^-$ in acidic solution, and for $[OCl]^-$ with $[NO_2]^-$ in alkaline solution.



Urea Sulfamic acid

15.42 (a) The head of a safety match contains $KClO_3$ and this reacts with red phosphorus which is combined with glass powder on the side of the match box. Write an equation for the reaction that occurs when the match is struck. Show that changes in oxidation states balance. Comment on the role of the glass powder.

(b) In a 'strike-it-anywhere' match, the match head contains P_4S_3 and $KClO_3$. Use oxidation state changes to suggest what happens when you strike the match, assuming that additional O_2 is required for combustion.

15.43 Polyphosphazenes are an important class of inorganic macromolecule and have many commercial applications, e.g. fire retardants, elastomers, fuel cell membranes, biomedical applications. The scheme opposite shows synthetic routes to three polymers. (a) Outline how $(NPCl_2)_n$ is produced on a large scale starting from PCl_5 and NH_4Cl. (b) What are the identities of the polymers **A–C**?

15.44 Over 95% of the phosphate rock mined in the US is used to manufacture phosphoric acid and phosphate-based fertilizers. The remaining phosphate rock is used for the production of white phosphorus. (a) Give equations to show how phosphate rock is converted to phosphoric acid and to white phosphorus. (b) Phosphate rock is converted to superphosphate fertilizers by treatment with concentrated H_2SO_4 and to triple superphosphate by reaction with H_3PO_4. What is the chemical composition of these fertilizers? Why are they suitable for use as fertilizers when phosphate rock itself is not? (c) What is meant by condensation of phosphates? (d) What is the role of $Na_5[P_3O_{10}]$ in detergents? Why is its use in decline, and what substitute is now favoured? Explain how the newer material carries out the role originally played by $Na_5[P_3O_{10}]$.

16.1 Introduction

The group 16 elements – oxygen, sulfur, selenium, tellurium, polonium and livermorium – are called the ***chalcogens***.

Oxygen occupies so central a position in any treatment of inorganic chemistry that discussions of many of its compounds are dealt with under other elements. The decrease in non-metallic character down the group is easily recognized in the elements:

- oxygen exists only as two gaseous allotropes (O_2 and O_3);
- sulfur has many allotropes, all of which are insulators;
- the stable forms of selenium and tellurium are semiconductors;
- polonium is a metallic conductor.

Knowledge of the chemistry of Po and its compounds is limited because of the absence of a stable isotope[†] and the difficulty of working with ^{210}Po, the most readily available isotope. Polonium-210 is produced by bombarding ^{209}Bi with thermal (or 'slow') neutrons. The neutrons are produced by fission of ^{235}U nuclei, and their kinetic energy is reduced by elastic collisions with ^{12}C or ^{2}H nuclei during passage through graphite or D_2O. Combination of ^{209}Bi with a neutron yields ^{210}Bi, which undergoes β-decay to form ^{210}Po. Polonium-210 is an intense α-emitter ($t_{1/2} = 138$ d) which liberates 520 kJ g^{-1} h^{-1}. This large energy loss causes many compounds of Po to decompose; Po decomposes water, making studies of chemical reactions in aqueous solution difficult. Polonium is a metallic conductor and crystallizes in a simple cubic lattice. It forms volatile, readily hydrolysed halides $PoCl_2$, $PoCl_4$, $PoBr_2$, $PoBr_4$ and PoI_4 and complex ions $[PoX_6]^{2-}$ (X = Cl, Br, I). Polonium(IV) oxide is formed by reaction between Po and O_2 at 520 K; it adopts a fluorite-type structure (see Fig. 6.21) and is sparingly soluble in aqueous alkali.

Livermorium (Lv, $Z = 116$) is the heaviest member of group 16 and its discovery was confirmed by the IUPAC in 2011. It is an artificial and radioactive element made on an 'atom-at-a-time' scale (see Section 27.5). The most stable isotope is ^{293}Lv, but it has an extremely short half-life (≈53 ms). For these reasons, our detailed discussion of the group 16 elements excludes Lv.

[†]For insight into the half-life of ^{209}Po, see: R. Collé, L. Laureano-Perez and I. Outola (2007) *Appl. Radiat. Isotopes*, vol. 65, p. 728 – 'A note on the half-life of ^{209}Po'; R. Collé and A.M. Collé (2016) *J. Radioanal. Nucl. Chem.*, vol. 308, p. 271 – 'On the ^{209}Po half-life error and its confirmation: a critique'.

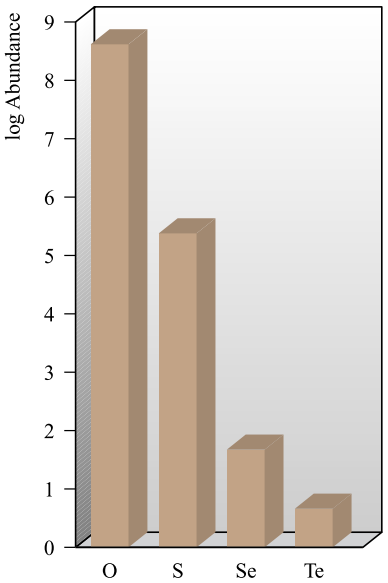

Fig. 16.1. Relative abundances of the group 16 elements (excluding Po) in the Earth's crust. The data are plotted on a logarithmic scale. The units of abundance are parts per billion (1 billion = 10^9). Polonium is omitted because its abundance is only 3×10^{-7} ppb, giving a negative number on the log scale.

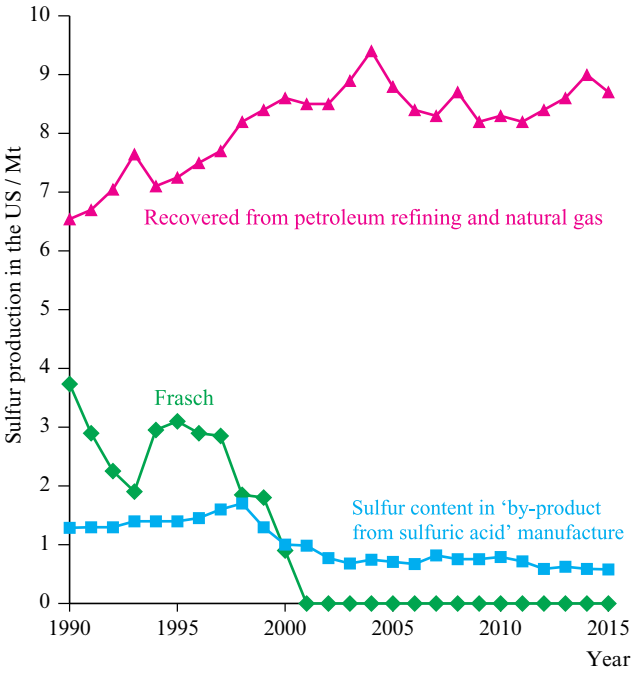

Fig. 16.2. Production of sulfur in the US from 1990 to 2015; note the increasing importance of recovery methods which have now replaced the Frasch process as a source of sulfur in the US. [Data: US Geological Survey.] See text for an explanation of 'by-product from sulfuric acid'.

16.2 Occurrence, extraction and uses

Occurrence

Figure 16.1 illustrates the relative abundances of the group 16 elements in the Earth's crust. Dioxygen makes up 21% of the Earth's atmosphere (see Fig. 15.1b), and 47% of the Earth's crust is composed of O-containing compounds (Fig. 13.2), e.g. water, limestone, silica, silicates, bauxite and haematite. It is a component of innumerable compounds and is essential to life, being converted to CO_2 during respiration. Native sulfur occurs in deposits around volcanoes and hot springs, and sulfur-containing minerals include *iron pyrites* (*fool's gold*, FeS_2), *galena* (PbS), *sphalerite* or *zinc blende* (ZnS), *cinnabar* (HgS), *realgar* (As_4S_4), *orpiment* (As_2S_3), *stibnite* (Sb_2S_3), *molybdenite* (MoS_2) and *chalcocite* (Cu_2S). Selenium and tellurium are relatively rare (Fig. 16.1). Selenium occurs in only a few minerals, while Te is usually combined with other metals, e.g. in *sylvanite* ($AgAuTe_4$).

Extraction

The Frasch process is the traditional means of extracting sulfur from natural deposits. Superheated water (440 K under pressure) is used to melt the sulfur, and compressed air then forces it to the surface. This method is now in decline and many operations have been closed. China, the US, Russia and Canada are the largest producers of sulfur in the world, and Fig. 16.2 shows the dramatic changes in methods of sulfur production in the US between 1990 and 2015. The trend is being followed worldwide as sulfur recovery from crude petroleum refining and natural gas production becomes the dominant production process for environmental reasons. In natural gas, the source of sulfur is H_2S which occurs in concentrations of up to 30%. Sulfur is recovered by reaction 16.1. The third method of production is labelled 'by-product from sulfuric acid' manufacture in Fig. 16.2. This refers to the direct coupling of the manufacture of sulfuric acid (only a fraction of the total produced) to the extraction of metals (e.g. copper) from sulfide ores by roasting in air. The SO_2 evolved is used for the manufacture of H_2SO_4 (see Section 16.9), and in Fig. 16.2, it is included as a source of sulfur (although elemental sulfur is never isolated).

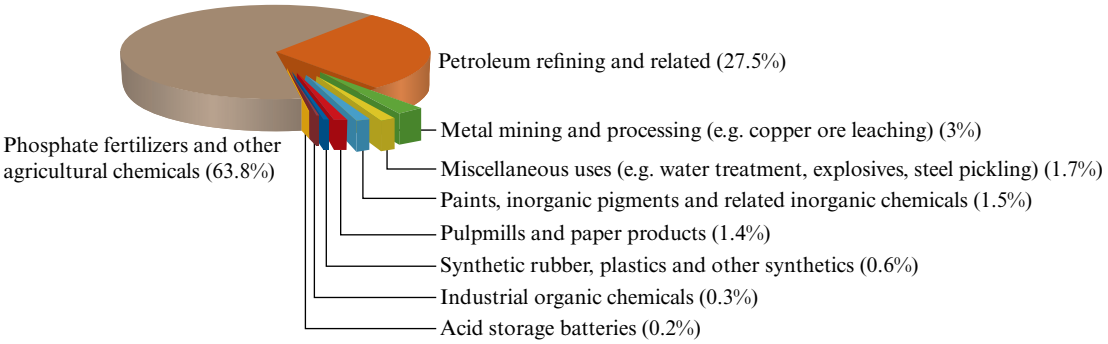
$$2H_2S + O_2 \xrightarrow{\text{activated carbon or alumina catalyst}} 2S + 2H_2O \qquad (16.1)$$

Commercial sources of Se and Te are flue dusts deposited during the refining of, for example, copper sulfide ores and from anode residues from the electrolytic refining of copper.

Uses

The chief use of O_2 is as a fuel (e.g. for oxyacetylene and hydrogen flames), as a supporter of respiration under special conditions (e.g. in air- and spacecraft), and in steel manufacturing.

Sulfur, mainly in the form of sulfuric acid, is an enormously important industrial chemical. The amount of sulfuric acid consumed by a given nation is an indicator



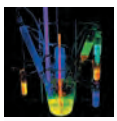


Fig. 16.3. Uses of sulfur and sulfuric acid (by sulfur content) in the US in 2013. [Data: US Geological Survey.]

of that country's industrial development. Figure 16.3 illustrates applications of sulfur and sulfuric acid. Sulfur is usually present in the form of an industrial *reagent* (e.g. in H_2SO_4 in the production of superphosphate fertilizers), and it is not necessarily present in the end-product.

An important property of amorphous-Se is its ability to convert light into electricity, and selenium is used in photoelectric cells, photographic exposure meters, photocopiers and X-ray imaging detectors (Box 16.1). A major use of selenium is in the glass industry. It is used to counteract

APPLICATIONS

Box 16.1 Selenium as a photoconductor

The photoconductive properties of selenium are responsible for its role in photocopiers: the technique of *xerography* developed rapidly in the latter half of the 20th century. Amorphous selenium is deposited by a vaporization technique to provide a thin film (≈50 μm thick) on an Al drum which is then installed in a photocopier. At the start of a photocopying run, the amorphous Se film is charged by a high-voltage corona discharge. Exposure of the amorphous Se film to light, with the image to be copied present in the light beam, creates a latent image which is produced in the form of regions of differing electrostatic potential. The image is developed using powdered toner which distributes itself over the 'electrostatic image'. The latter is then transferred to paper (again electrostatically) and fixed by heat treatment. An amorphous Se-coated photoreceptor drum has a lifetime of ≈100 000 photocopies. Spent drums are recycled, with some of the main recycling units being in Canada, Japan, the Philippines and several European countries. Once the mainstay of the photocopying industry, Se is gradually being replaced by organic photoreceptors, which are preferable to selenium on both performance and environmental grounds.

In the last decade or so, amorphous selenium has been applied as a photoconductor in X-ray image detectors, particularly for biomedical imaging. For this application, flat-panel detectors with large sensing areas (> 30 cm × 30 cm) have been developed. The coating of amorphous Se is typically 500 μm thick, and is deposited over a silicon thin film transistor layer. After applying an electrical potential to the surface, the detector is exposed to an X-ray beam and the electrons released are used to transmit information that ultimately provides an image.

A medical technician laminating an amorphous selenium-containing X-ray imaging plate.

* For amorphous Te.
** $\Delta_{EA} H^o_1(298\,K)$ is the enthalpy change associated with the process $X(g) + e^- \longrightarrow X^-(g) \approx -\Delta U(0\,K)$; see Section 1.10. $\Delta_{EA} H^o_2(298\,K)$ refers to the process $X^-(g) + e^- \longrightarrow X^{2-}(g)$.

the green tint caused by iron impurities in soda-lime silica glasses, and is also added to architectural plate glass to reduce solar heat transmission. In the form of CdS_xSe_{1-x}, selenium is used as a red pigment in glass and ceramics. Crystalline Se is a semiconductor. Tellurium is used as an additive (≤0.1%) to low-carbon steels in order to improve the machine qualities of the metal. This accounts for about half of the world's consumption of tellurium. Catalytic applications are also important, and other applications stem from its semiconducting properties, e.g. cadmium telluride has recently been incorporated into solar cells (see Box 14.2). However, uses of Te are limited, partly because Te compounds are readily absorbed by the body and excreted in the breath and perspiration as foul-smelling organic derivatives.

16.3 Physical properties and bonding considerations

Table 16.1 lists selected physical properties of the group 16 elements. The trend in electronegativity values has important consequences as regards the ability of O−H bonds to form hydrogen bonds. This pattern follows that in group 15. While O−H····X and X−H····O (X = O, N, F) interactions are relatively strong hydrogen bonds, those involving sulfur are weak, and typically involve a strong hydrogen-bond donor with sulfur acting as a weak acceptor (e.g. O−H····S).† In the case of S−H····S hydrogen bonds, the calculated hydrogen bond enthalpy is ≈5 kJ mol^{-1} in H_2S····H_2S, compared with ≈20 kJ mol^{-1} for the O−H····O hydrogen bond in H_2O····H_2O (see Table 10.4).

In comparing Table 16.1 with analogous tables in Chapters 11–15, you should note the importance of *anion*, rather than cation, formation. With the possible exception of PoO_2, there is no evidence that group 16 compounds contain *monatomic cations*. Thus Table 16.1 lists values only of the *first* ionization energies to illustrate the expected decrease on descending the group. Electron affinity data for oxygen show that reaction 16.2 for E = O is highly endothermic, and O^{2-} ions exist in ionic lattices only because of the high lattice energies of metal oxides (see Section 6.17).

†See: T. Steiner (2002) *Angew. Chem. Int. Ed.*, vol. 41, p. 48 – 'The hydrogen bond in the solid state'.

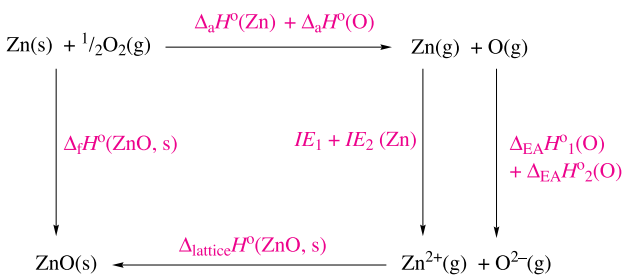
$$\left.\begin{array}{l} E(g) + 2e^- \longrightarrow E^{2-}(g) \qquad (E = O, S) \\ \Delta_r H^\circ(298\,K) = \Delta_{EA} H^\circ{}_1(298\,K) + \Delta_{EA} H^\circ{}_2(298\,K) \end{array}\right\} \quad (16.2)$$

Reaction 16.2 for E = S is also endothermic (Table 16.1), but less so than for O since the repulsion between electrons is less in the larger anion. However, the energy needed to compensate for this endothermic step tends not to be available since lattice energies for sulfides are much lower than those of the corresponding oxides because of the much greater radius of the S^{2-} ion. Consequences of this are that:

- high oxidation state oxides (e.g. MnO_2) often have no sulfide analogues;
- agreement between calculated and experimental values of lattice energies (see Section 6.15) for many *d*-block metal sulfides is much poorer than for oxides, indicating significant covalent contributions to the bonding.

Similar considerations apply to selenides and tellurides.

Worked example 16.1 Thermochemical cycles for metal oxides and sulfides



(a) Using data from the Appendices and the value $\Delta_f H^\circ$ (ZnO, s) = −350 kJ mol^{-1}, determine the enthalpy change (at 298 K) for the process:

$$\mathbf{Zn^{2+}(g) + O^{2-}(g) \longrightarrow ZnO(s)}$$

(b) What percentage contribution does $\Delta_{EA} H^\circ{}_2$(O) make to the overall enthalpy change for the following process?

$$\mathbf{Zn(s) + \tfrac{1}{2}O_2(g) \longrightarrow Zn^{2+}(g) + O^{2-}(g)}$$

(a) Set up an appropriate Born–Haber cycle:

From Appendix 8, for Zn: $IE_1 = 906\,kJ\,mol^{-1}$, $IE_2 = 1733\,kJ\,mol^{-1}$

From Appendix 9, for O: $\Delta_{EA} H^\circ{}_1 = -141\,kJ\,mol^{-1}$, $\Delta_{EA} H^\circ{}_2 = 798\,kJ\,mol^{-1}$

From Appendix 10: $\Delta_a H^\circ(Zn) = 130\,kJ\,mol^{-1}$, $\Delta_a H^\circ(O) = 249\,kJ\,mol^{-1}$

From the thermochemical cycle, applying Hess's law:

$$\begin{aligned} \Delta_{lattice} H^\circ(ZnO, s) &= \Delta_f H^\circ(ZnO, s) - \Delta_a H^\circ(Zn) - \Delta_a H^\circ(O) - IE_1 - IE_2 \\ &\quad - \Delta_{EA} H^\circ{}_1 - \Delta_{EA} H^\circ{}_2 \\ &= -350 - 130 - 249 - 906 - 1733 + 141 - 798 \\ &= -4025\,kJ\,mol^{-1} \end{aligned}$$

(b) The process:

$$Zn(s) + \tfrac{1}{2}O_2(g) \longrightarrow Zn^{2+}(g) + O^{2-}(g)$$

is part of the Hess cycle shown in part (a). The enthalpy change for this process is given by:

$$\begin{aligned} \Delta H^\circ &= \Delta_a H^\circ(Zn) + \Delta_a H^\circ(O) + IE_1 + IE_2 + \Delta_{EA} H^\circ{}_1 \\ &\quad + \Delta_{EA} H^\circ{}_2 \\ &= 130 + 249 + 906 + 1733 - 141 + 798 \\ &= 3675\,kJ\,mol^{-1} \end{aligned}$$

As a percentage of this,

$$\Delta_{EA} H^\circ{}_2 = \frac{798}{3675} \times 100 \approx 22\%$$

Self-study exercises

1. Given that $\Delta_f H^\circ(Na_2O, s) = -414\,kJ\,mol^{-1}$, determine the enthalpy change for the process:

   $$2Na^+(g) + O^{2-}(g) \longrightarrow Na_2O(s)$$

   [*Ans.* $-2528\,kJ\,mol^{-1}$]

2. What percentage contribution does $\Delta_{EA} H^\circ{}_2$(O) make to the overall enthalpy change for the following process? How significant is this contribution in relation to each of the other contributions?

   $$2Na(s) + \tfrac{1}{2}O_2(g) \longrightarrow 2Na^+(g) + O^{2-}(g)$$

   [*Ans.* ≈38%]

3. NaF and CaO both adopt NaCl-type structures. Consider the enthalpy changes that contribute to the overall value of ΔH°(298 K) for each of the following processes:

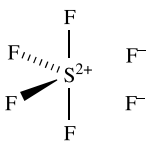
   $$Na(s) + \tfrac{1}{2}F_2(g) \longrightarrow Na^+(g) + F^-(g)$$

   $$Ca(s) + \tfrac{1}{2}O_2(g) \longrightarrow Ca^{2+}(g) + O^{2-}(g)$$

   Assess the relative role that each enthalpy contribution plays to determining the sign and magnitude of ΔH° for each process.

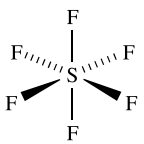
Some bond enthalpy terms for compounds of the group 16 elements are given in Table 16.2. In discussing groups 14

Table 16.2 Some covalent bond enthalpy terms ($kJ\,mol^{-1}$) for bonds involving oxygen, sulfur, selenium and tellurium.



O–O	O=O	O–H	O–C	O–F	O–Cl
146	498	464	359	190†	205†
S–S	S=S	S–H	S–C	S–F	S–Cl
266	427	366	272	326†	255†
Se–Se		Se–H		Se–F	Se–Cl
192		276		285†	243†
Te–Te		Te–H		Te–F	
149		238		335†	

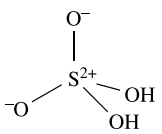
† Values for O–F, S–F, Se–F, Te–F, O–Cl, S–Cl and Se–Cl derived from OF_2, SF_6, SeF_6, TeF_6, OCl_2, S_2Cl_2 and $SeCl_2$ respectively.



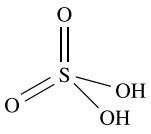
and 15, we emphasized the importance of $(p$–$p)\pi$-bonding for the first element in each group. We also pointed out that the failure of nitrogen to form 5-coordinate species such as NF_5 can be explained in terms of the N atom being too small to accommodate five F atoms around it. These factors are also responsible for some of the differences between O and its heavier congeners. For example:

- there are no stable sulfur analogues of CO and NO (although CS_2 and OCS are well known);
- the highest fluoride of oxygen is OF_2, but the later elements form SF_6, SeF_6 and TeF_6.

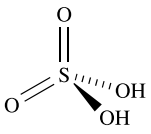
Coordination numbers above 4 for S, Se and Te can be achieved using a valence set of *ns* and *np* orbitals, with *d*-orbitals playing little or no role as valence orbitals (see Chapter 5). Thus, valence structures such as **16.1** can be used to represent the bonding in SF_6, although a set of resonance structures is required in order to rationalize the equivalence of the six S–F bonds. When describing the *structure* of SF_6, diagram **16.2** is more enlightening than **16.1**. Provided that you keep in mind that a line between two atoms does not represent a localized single bond, then **16.2** is an acceptable (and useful) representation of the molecule.



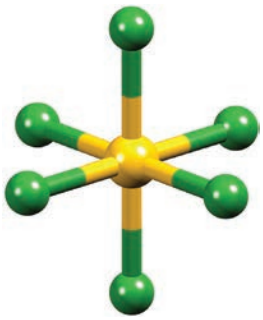
(16.1)



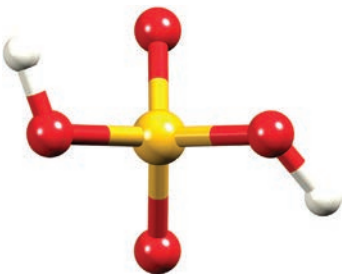
(16.2)



Similarly, while diagram **16.3** is a resonance form for H_2SO_4 which describes the S atom obeying the octet rule, structures **16.4** and **16.5** are useful for a rapid appreciation of the oxidation state of the S atom and coordination environment of the S atom. For these reasons, throughout the chapter we shall use diagrams analogous to **16.2**, **16.4** and **16.5** for hypervalent compounds of S, Se and Te. We shall also use 3-dimensional representations of the type shown in **16.6** (SF_6) and **16.7** (H_2SO_4) to provide structural information, but these should not be used to draw conclusions about the distribution of bonding electrons within the molecule.



(16.3)



(16.4)

(16.5)

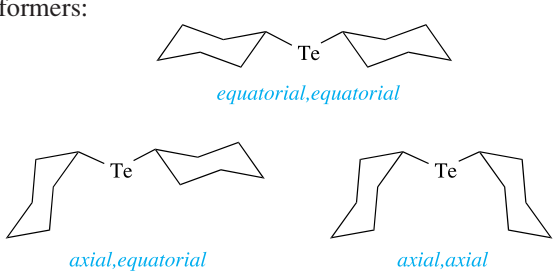
(16.6)

(16.7)

Values in Table 16.2 illustrate the particular weakness of the O–O and O–F bonds and this can be rationalized in terms of lone pair repulsions (see Fig. 15.2). Note that O–H and O–C bonds are much stronger than S–H and S–C bonds.

NMR active nuclei and isotopes as tracers

Despite its low abundance (Table 16.1), ^{17}O has been used in studies of, for example, hydrated ions in aqueous solution and polyoxometallates (see Section 22.7).



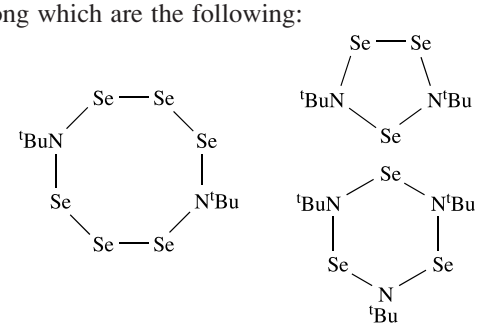
The isotope ^{18}O is present to an extent of 0.2% in naturally occurring oxygen and is commonly used as a (non-radioactive) tracer for the element. The usual tracer for sulfur is ^{35}S, which is made by an (n,p) reaction on ^{35}Cl; ^{35}S is a β-emitter with $t_{\frac{1}{2}} = 87$ days.

Worked example 16.2 NMR spectroscopy using ^{77}Se and ^{125}Te nuclei

The solution ^{125}Te NMR spectrum of Te(*cyclo*-$C_6H_{11})_2$ at 298 K shows one broad signal. On increasing the temperature to 353 K, the signal sharpens. On cooling to 183 K, the signal splits into three signals at δ 601, 503 and 381 ppm with relative integrals of 25 : 14 : 1. Rationalize these data.

Te(*cyclo*-$C_6H_{11})_2$ contains only one Te environment, but the Te atom can be in either an equatorial or axial

position of the cyclohexyl ring. This leads to three possible conformers:



On steric grounds, the most favoured is the *equatorial,equatorial* conformer, and the least favoured is the *axial,axial* conformer. Signals at δ 601, 503 and 381 ppm in the low-temperature spectrum can be assigned to the *equatorial, equatorial*, *axial,equatorial* and *axial,axial* conformers respectively. At higher temperatures, the cyclohexyl rings undergo ring inversion (ring-flipping), causing the Te atom to switch between axial and equatorial positions. This interconverts the three conformers of Te(*cyclo*-$C_6H_{11})_2$. At 353 K, the interconversion is faster than the NMR timescale and one signal is observed (its chemical shift is the weighted average of the three signals observed at 183 K). On cooling from 353 to 298 K, the signal broadens, before splitting at lower temperatures.

[For a figure of the variable temperature spectra of Te(*cyclo*-$C_6H_{11})_2$, see: K. Karaghiosoff *et al.* (1999) *J. Organomet. Chem.*, vol. 577, p. 69.]

Self-study exercises

Data: see Table 16.1.

1. The reaction of $SeCl_2$ with $^tBuNH_2$ in differing molar ratios leads to the formation of a series of compounds, among which are the following:

How many signals would you expect to see for each compound in the ^{77}Se NMR spectrum?

[*Ans.* See: T. Maaninen *et al.* (2000) *Inorg. Chem.*, vol. 39, p. 5341]

2. The ^{125}Te NMR spectrum (263 K) of an MeCN solution of the $[Me_4N]^+$ salt of $[MeOTeF_6]^-$ shows a septet of quartets with values of $J_{TeF} = 2630$ Hz and $J_{TeH} = 148$ Hz. The ^{19}F NMR spectrum exhibits a singlet with two satellite peaks. In the solid state, $[MeOTeF_6]^-$ has a pentagonal bipyramidal structure with the MeO group in an axial position. (a) Interpret the ^{125}Te and ^{19}F NMR spectroscopic data. (b) Sketch the ^{19}F NMR spectrum and indicate where you would measure J_{TeF}.

[*Ans.* See: A. R. Mahjoub *et al.* (1992) *Angew. Chem. Int. Ed.*, vol. 31, p. 1036]

16.4 The elements

Dioxygen

Dioxygen is obtained industrially by the liquefaction and fractional distillation of air, and is stored and transported as a liquid. Convenient laboratory preparations of O_2 are the electrolysis of aqueous alkali using Ni electrodes, and decomposition of H_2O_2 (eq. 16.3). A mixture of $KClO_3$ and MnO_2 used to be sold as 'oxygen mixture' (eq. 16.4) and the thermal decompositions of many other oxo salts (e.g. KNO_3, $KMnO_4$ and $K_2S_2O_8$) produce O_2.

$$2H_2O_2 \xrightarrow{MnO_2 \text{ or Pt catalyst}} O_2 + 2H_2O \qquad (16.3)$$

$$2KClO_3 \xrightarrow{\Delta,\ MnO_2 \text{ catalyst}} 3O_2 + 2KCl \qquad (16.4)$$

Caution! Chlorates are potentially explosive.

Dioxygen is a colourless gas, but condenses to a pale blue liquid or solid. Its bonding was described in Sections 2.2 and 2.3. In all phases, it is paramagnetic with a *triplet* ground state, i.e. the two unpaired electrons have the same spin, with the valence electron configuration being:

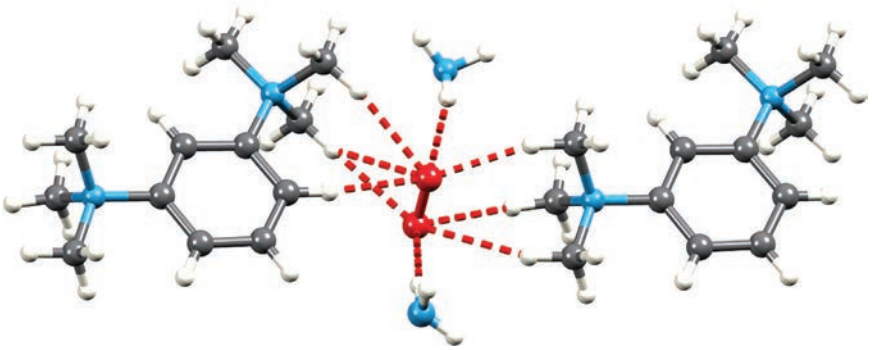
$$\sigma_g(2s)^2\sigma_u^*(2s)^2\sigma_g(2p_z)^2\pi_u(2p_x)^2\pi_u(2p_y)^2\pi_g^*(2p_x)^1\pi_g^*(2p_y)^1$$

This triplet ground state is designated by the term symbol $^3\Sigma_g^-$. In this state, O_2 is a powerful oxidizing agent (see eq. 8.29 and associated discussion) but, fortunately, the kinetic barrier is often high. If it were not, almost all organic chemistry would have to be carried out in closed systems. The O_2 molecule possesses two excited states that lie 94.7 and 157.8 kJ mol^{-1} above the ground state. The first excited state is a singlet state (designated by the term symbol $^1\Delta_g$) with two spin-paired electrons in the π_g^* level occupying one MO:

$$\sigma_g(2s)^2\sigma_u^*(2s)^2\sigma_g(2p_z)^2\pi_u(2p_x)^2\pi_u(2p_y)^2\pi_g^*(2p_x)^2\pi_g^*(2p_y)^0$$

In the higher excited state (singlet state, $^1\Sigma_g^+$), the two electrons occupy different MOs as in the ground state, but have *opposite* spins. The blue colour of liquid and solid O_2 arises from the simultaneous excitation by a single photon of two O_2 molecules from their ground to excited states. The associated absorption of energy corresponds to absorption of light in the red to green region of the visible part of the

THEORY



Box 16.2 Accurate determination of the O–O bond distance in $[O_2]^-$

Textbook discussions of MO theory of homonuclear diatomic molecules often consider the trends in bond distances in $[O_2]^+$, O_2, $[O_2]^-$ and $[O_2]^{2-}$ (see end-of-chapter problem 2.10) in terms of the occupancy of molecular orbitals. However, the determination of the bond distance in the superoxide ion $[O_2]^-$ has not been straightforward owing to disorder problems in the solid state and, as a result, the range of reported values for d(O–O) is large. Cation exchange in liquid NH_3 has been used to isolate the salt $[1,3\text{-}(NMe_3)_2C_6H_4][O_2]_2{\cdot}3NH_3$ from $[NMe_4][O_2]$. In the solid state, each $[O_2]^-$ ion is fixed in a particular orientation by virtue of a hydrogen-bonded network.

The figure below shows the N–H····O interactions between solvate NH_3 and $[O_2]^-$, and the weak C–H····O interactions between cation methyl groups and $[O_2]^-$. Structural parameters for the hydrogen bonds indicate that the interactions are very weak. Consequently, the length of the bond in the $[O_2]^-$ anion ought not to be significantly perturbed by their presence. In $[1,3\text{-}(NMe_3)_2C_6H_4][O_2]_2{\cdot}3NH_3$, there are two crystallographically independent anions with O–O distances of 133.5 and 134.5 pm.

Colour code: O, red; N, blue; C, grey; H, white.

spectrum (see end-of-chapter problem 16.5). Singlet dioxygen (the $^1\Delta_g$ state) can be generated photochemically by irradiation of O_2 in the presence of an organic dye as sensitizer, or non-photochemically by reactions such as 16.5 and 16.16.[†]

$$H_2O_2 + NaOCl \longrightarrow O_2(^1\Delta_g) + NaCl + H_2O \qquad (16.5)$$

Singlet O_2 is short-lived, but extremely reactive, combining with many organic compounds, e.g. in reaction 16.6, $O_2(^1\Delta_g)$ acts as a dienophile in a Diels–Alder reaction.

(16.6)

At high temperatures, O_2 combines with most elements, exceptions being the halogens and noble gases, and N_2 unless under special conditions. Reactions with the group 1 metals are of particular interest, oxides, peroxides, superoxides and suboxides being possible products. Bond lengths in O_2, $[O_2]^-$ and $[O_2]^{2-}$ are 121, 134 and 149 pm (see Box 16.2), consistent with a weakening of the bond caused by increased occupation of the π^* MOs (see Fig. 2.10).

The first ionization energy of O_2 is 1168 kJ mol^{-1} and it may be oxidized by very powerful oxidizing agents such as PtF_6 (eq. 16.7). The bond distance of 112 pm in $[O_2]^+$ is in keeping with the trend for O_2, $[O_2]^-$ and $[O_2]^{2-}$. Other salts include $[O_2]^+[SbF_6]^-$ (made from irradiation of O_2 and F_2 in the presence of SbF_5, or from O_2F_2 and SbF_5) and $[O_2]^+[BF_4]^-$ (eq. 16.8).

$$O_2 + PtF_6 \longrightarrow [O_2]^+[PtF_6]^- \qquad (16.7)$$

$$2O_2F_2 + 2BF_3 \longrightarrow 2[O_2]^+[BF_4]^- + F_2 \qquad (16.8)$$

The chemistry of O_2 is an enormous topic, and examples of its reactions can be found throughout this book. Its biological role is discussed in Chapter 29.

Ozone

Ozone, O_3, is usually prepared in up to 10% concentration by the action of a silent electrical discharge between two concentric metallized tubes in an apparatus called an *ozonizer*. Electrical discharges in thunderstorms convert O_2 into ozone. The action of UV radiation on O_2, or heating O_2 above 2750 K followed by rapid quenching,

[†]For an introduction to singlet state O_2, see: C.E. Wayne and R.P. Wayne (1996) *Photochemistry*, OUP, Oxford.

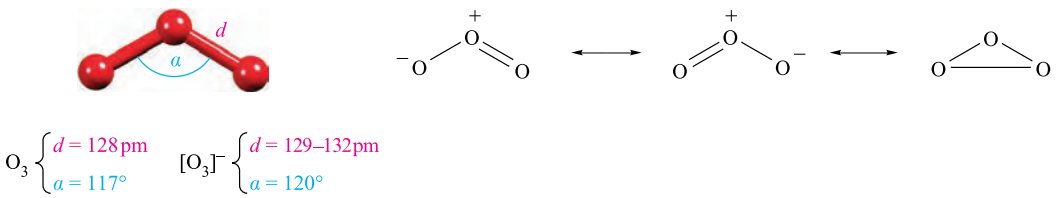

Fig. 16.4. The structures of O_3 and $[O_3]^-$, and contributing resonance structures in O_3. The O–O bond order in O_3 is taken to be 1.5.

also produces O_3. In each of these processes, O atoms are produced and combine with O_2 molecules. Pure ozone can be separated from reaction mixtures by fractional liquefaction. The liquid is blue and boils at 163 K to give a perceptibly blue gas with a characteristic 'electric' smell. Molecules of O_3 are bent (Fig. 16.4). Ozone absorbs strongly in the UV region, and its presence in the upper atmosphere of the Earth is essential in protecting the planet's surface from over-exposure to UV radiation from the Sun (see Box 14.6).

Ozone is highly endothermic (eq. 16.9). The pure liquid is dangerously explosive, and the gas is a very powerful oxidizing agent (eq. 16.10).

$$\tfrac{3}{2}O_2(g) \longrightarrow O_3(g) \quad \Delta_f H^\circ(O_3, g, 298\,K) = +142.7\,kJ\,mol^{-1} \qquad (16.9)$$

$$O_3(g) + 2H^+(aq) + 2e^- \rightleftharpoons O_2(g) + H_2O(l) \qquad E^\circ = +2.07\,V \qquad (16.10)$$

The value of E° in eq. 16.10 refers to pH = 0 (see Box 8.1), and at higher pH, E becomes less positive: +1.65 V at pH = 7, and +1.24 V at pH = 14. The presence of high concentrations of alkali stabilizes O_3 both thermodynamically and kinetically. Ozone is much more reactive than O_2 (hence the use of O_3 in water purification, see Box 14.1). Reactions 16.11–16.13 typify this high reactivity, as does the reaction of ozone with alkenes to give ozonides.

$$O_3 + S + H_2O \longrightarrow H_2SO_4 \qquad (16.11)$$

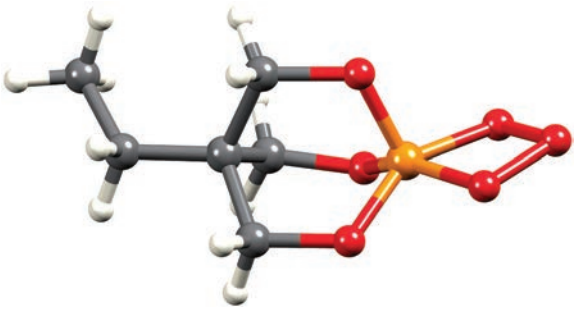
$$O_3 + 2I^- + H_2O \longrightarrow O_2 + I_2 + 2[OH]^- \qquad (16.12)$$

$$4O_3 + PbS \longrightarrow 4O_2 + PbSO_4 \qquad (16.13)$$

Potassium ozonide, KO_3 (formed in reaction 16.14), is an unstable red salt which contains the paramagnetic $[O_3]^-$ ion (Fig. 16.4). Ozonide salts are known for all the alkali metals. The compounds $[Me_4N][O_3]$ and $[Et_4N][O_3]$ have been prepared using reactions of the type shown in eq. 16.15. Ozonides are explosive, but $[Me_4N][O_3]$ is relatively stable, decomposing above 348 K (see also Sections 11.6 and 11.8).

$$2KOH + 5O_3 \longrightarrow 2KO_3 + 5O_2 + H_2O \qquad (16.14)$$

$$CsO_3 + [Me_4N][O_2] \xrightarrow{\text{liquid } NH_3} CsO_2 + [Me_4N][O_3] \qquad (16.15)$$



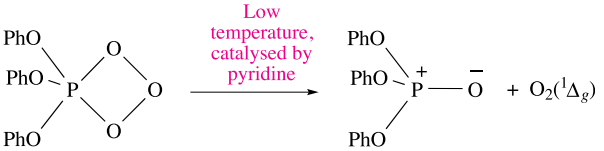


Fig. 16.5. The structure (X-ray diffraction at 188 K) of the phosphite ozonide $EtC(CH_2O)_3PO_3$ [A. Dimitrov *et al.* (2001) *Eur. J. Inorg. Chem.*, p. 1929]. Colour code: P, orange; O, red; C, grey; H, white.

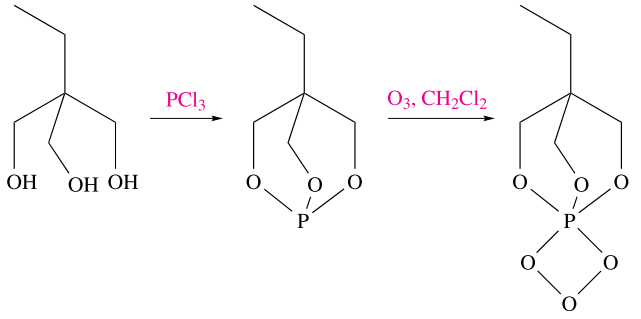
Self-study exercise



The reaction of CsO_2 and CsO_3 in liquid NH_3 at 200 K in the presence of a small amount of NH_4Cl results in the formation of $Cs_3(O_3)(O_2)\cdot NH_3$. (a) Crystallographic data give O–O bond distances of 132.6, 130.7 and 123.1 pm. Comment on these bond lengths in terms of the O–O bond orders. (b) The closest $[O_2]^- \cdots [O_3]^-$ separation is 344.6 pm. Use data in Appendix 6 to comment on whether or not there is a meaningful interaction between the ions.

[*Ans.* See Fig. 16.4 and H. Nuss *et al.* (2012) *Z. Anorg. Allg. Chem.*, vol. 638. p. 501]

Phosphite ozonides, $(RO)_3PO_3$, have been known since the early 1960s, and are made *in situ* as precursors to singlet oxygen (eq. 16.16). The ozonides are stable only at low temperatures, and it is only with the use of modern low-temperature crystallographic methods that structural data are now available. Figure 16.5 shows the structure of the phosphite ozonide prepared by the steps in scheme 16.17. In the PO_3 ring, the P–O and O–O bond lengths are 167 and 146 pm, respectively; the ring is close to planar, with a dihedral angle of 7°.

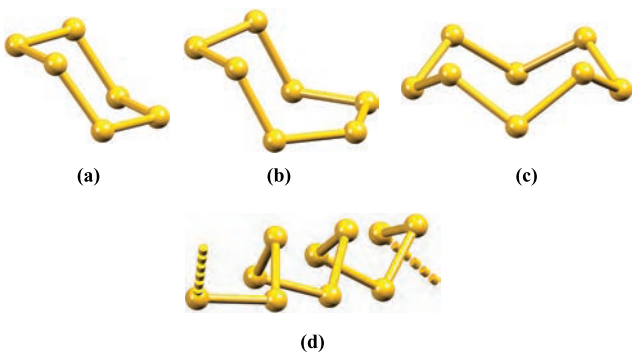
(16.16)

(16.17)

Sulfur: allotropes

The allotropy of sulfur is complicated, and we describe only the best-established species. The tendency for catenation (see Section 14.3) by sulfur is high and leads to the formation of both rings of varying sizes and chains. Allotropes of known structure include cyclic S_6, S_7, S_8, S_9, S_{10}, S_{11}, S_{12}, S_{18} and S_{20} (all with puckered rings, e.g. Figs. 16.6a–c) and fibrous sulfur (*catena*-S_∞, Figs. 16.6d and 3.20a). In most of these, the S−S bond distances are 206 ± 1 pm, indicative of single bond character; the S−S−S bond angles lie in the range 102–108°. The ring conformations of S_6 (chair) and S_8 (crown) are readily envisaged but other rings have more complicated conformations. The structure of S_7 (Fig. 16.6b) is noteworthy because of the wide range of S−S bond lengths (199–218 pm) and angles (101.5–107.5°). The energies of interconversion between the cyclic forms are very small.

The most stable allotrope is orthorhombic sulfur (the α-form and standard state of the element) and it occurs naturally as large yellow crystals in volcanic areas. At 367.2 K, the α-form transforms reversibly into monoclinic sulfur (β-form). Both the α- and β-forms contain S_8 rings; the density of the α-form is 2.07 g cm^{-3}, compared with 1.94 g cm^{-3} for the β-form in which the packing of the rings is less efficient. However, if single crystals of the α-form are rapidly heated to 385 K, they melt before the α ⟶ β transformation occurs. If crystallization takes place at 373 K, the S_8 rings adopt the structure of the β-form, but the crystals must be cooled rapidly to 298 K. On standing at 298 K, a β ⟶ α transition occurs within a few weeks. β-Sulfur melts at 401 K, but this is not a true melting point, since some breakdown of S_8 rings takes place, causing the melting point to be depressed.



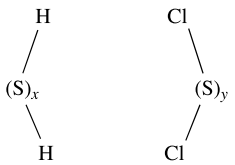


Fig. 16.6. Representations of the structures of some allotropes of sulfur: (a) S_6, (b) S_7, (c) S_8 and (d) *catena*-S_∞ (the chain continues at each end).

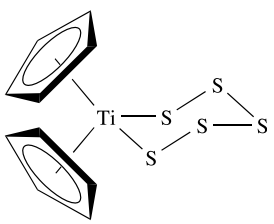

Rhombohedral sulfur (the ρ-form) comprises S_6 rings and is obtained by the ring closure reaction 16.18. It decomposes in light to S_8 and S_{12}.

$$S_2Cl_2 + H_2S_4 \xrightarrow{\text{dry diethyl ether}} S_6 + 2HCl \qquad (16.18)$$

(16.8) **(16.9)**

Similar ring closures starting from H_2S_x (**16.8**) and S_yCl_2 (**16.9**) lead to larger rings, but a more recent strategy makes use of $[(C_5H_5)_2TiS_5]$ (**16.10**) which is prepared by reaction 16.19 and contains a coordinated $[S_5]^{2-}$ ligand. The Ti(IV) complex reacts with S_yCl_2 to give *cyclo*-S_{y+5}, allowing synthesis of a series of sulfur allotropes. All the *cyclo*-allotropes are soluble in CS_2.

(16.10)

$$2NH_3 + H_2S + \tfrac{1}{2}S_8 \longrightarrow [NH_4]_2[S_5]$$

$$\xrightarrow{[(C_5H_5)_2TiCl_2]} [(C_5H_5)_2TiS_5] \qquad (16.19)$$

By rapidly quenching molten sulfur at 570 K in ice-water, fibrous sulfur (which is insoluble in water) is produced. Fibrous sulfur, *catena*-S_∞, contains infinite, helical chains (Fig. 16.6d) and slowly reverts to α-sulfur on standing. α-Sulfur melts to a mobile yellow liquid which darkens in colour as the temperature is raised. At 433 K, the viscosity increases enormously as S_8 rings break by homolytic S−S bond fission, giving diradicals which react together to form polymeric chains containing $\leq 10^6$ atoms. The viscosity reaches a maximum at ≈473 K, and then decreases up to the boiling point (718 K). At this point the liquid contains a mixture of rings and shorter chains. The vapour above

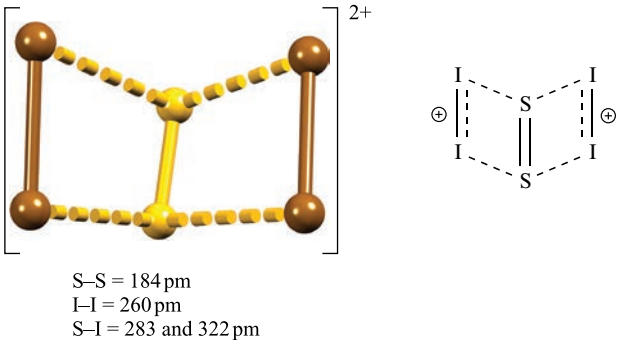

Fig. 16.7. The structure of $[S_2I_4]^{2+}$ determined by X-ray diffraction at low temperature for the $[AsF_6]^-$ salt [S. Brownridge *et al.* (2005) *Inorg. Chem.*, vol. 44, p. 1660], and a representation of the bonding in terms of S_2 interacting with two $[I_2]^+$. Colour code: S, yellow; I, brown.

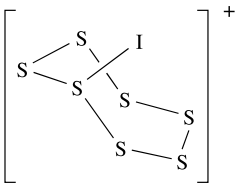
liquid sulfur at 473 K consists mainly of S_8 rings, but at higher temperatures, smaller molecules predominate, and above 873 K, paramagnetic S_2 (a diradical like O_2) becomes the main species. Dissociation into atoms occurs above 2470 K.

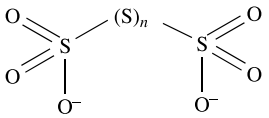
Small molecular allotropes S_n with $n < 6$ are highly reactive and are not usually included in discussions of elemental sulfur. However, in 2013, S_3 was isolated within a metal-organic framework (i.e. a 3-dimensional network constructed using metal coordination chemistry) after sulfur vapour at 533 K had diffused into the framework. S_3 has a non-linear structure analogous to that of O_3.[†]

Sulfur: reactivity



Sulfur is a reactive element. It burns in air with a blue flame to give SO_2, and reacts with F_2, Cl_2 and Br_2 (scheme 16.20). For the syntheses of other halides and oxides, see Sections 16.7 and 16.8.

$$S_8 \begin{cases} \xrightarrow{F_2} SF_6 \\ \xrightarrow{Cl_2} S_2Cl_2 \\ \xrightarrow{Br_2} S_2Br_2 \end{cases} \qquad (16.20)$$



Sulfur does not react directly with I_2, but in the presence of AsF_5 or SbF_5 in liquid SO_2, the salts $[S_7I][EF_6]$ (E = As or Sb) are produced which contain the $[S_7I]^+$ cation (**16.11**). If an excess of I_2 is used, the products are $[S_2I_4][EF_6]_2$ (E = As or Sb). The $[S_2I_4]^{2+}$ cation has the 'open-book' structure shown in Fig. 16.7. The bonding can be considered in terms of S_2 interacting with two $[I_2]^+$ ions by means of donation of the unpaired electron in the π^* MO of each $[I_2]^+$ into a vacant MO of S_2. On the basis of the short S–S bond, stretching mode at 734 cm^{-1}, and theoretical investigations, it is proposed that the S–S bond order lies between 2.2 and 2.4.

[†] See: H. Ohtsu *et al.* (2013) *J. Am. Chem. Soc.*, vol. 135, p. 11449 – 'Selective trapping of labile S_3 in a porous coordination network and the direct X-ray observation'.

When treated with hot aqueous alkali, sulfur forms a mixture of polysulfides, $[S_x]^{2-}$, and polythionates (**16.12**), while oxidizing agents convert it to H_2SO_4.

(16.11)

(16.12)

Saturated hydrocarbons are dehydrogenated when heated with sulfur, and further reaction with alkenes occurs. An application of this reaction is in the vulcanization of rubber, in which soft rubber is toughened by cross-linking of the polyisoprene chains, making it suitable for use in, for example, tyres. The reactions of sulfur with CO or $[CN]^-$ yield OCS (**16.13**) or the thiocyanate ion (**16.14**), while treatment with sulfites gives thiosulfates (eq. 16.21, and eq. 16.116 and accompanying discussion).

(16.13) **(16.14)**

$$Na_2SO_3 + \tfrac{1}{8}S_8 \xrightarrow{H_2O,\ 373\ K} Na_2S_2O_3 \qquad (16.21)$$

The oxidation of S_8 by AsF_5 or SbF_5 in liquid SO_2 (see Section 9.5) yields salts containing the cations $[S_4]^{2+}$, $[S_8]^{2+}$ and $[S_{19}]^{2+}$ (Fig. 16.8). In reaction 16.22, AsF_5 acts as an oxidizing agent *and* a fluoride acceptor (eq. 16.23).

$$S_8 + 3AsF_5 \xrightarrow{\text{liquid } SO_2} [S_8][AsF_6]_2 + AsF_3 \qquad (16.22)$$

$$\left.\begin{aligned} AsF_5 + 2e^- &\longrightarrow AsF_3 + 2F^- \\ AsF_5 + F^- &\longrightarrow [AsF_6]^- \end{aligned}\right\} \qquad (16.23)$$

Two-electron oxidation of S_8 results in a change in ring conformation (compare Fig. 16.8a with Fig. 16.6c). The red $[S_8]^{2+}$ cation was originally reported as being blue, but the blue colour is now known to arise from the presence of radical impurities such as $[S_5]^+$.[‡] In S_8, all the S–S bond lengths are equal (206 pm) and the distance between two S atoms across the ring from one another is greater than the sum of the van der Waals radii (r_v = 185 pm). Crystallographic data for the $[AsF_6]^-$ salt of $[S_8]^{2+}$ (Fig. 16.8c) illustrates (i) a variation in S–S bond distances around the ring and (ii) cross-ring S–S separations that are smaller than the sum of the van der Waals radii, i.e. $[S_8]^{2+}$ exhibits *transannular* interactions. The most important transannular interaction corresponds to the shortest S····S contact and Fig. 16.8d shows a resonance structure that describes an appropriate bonding contribution.

[‡] See: T.S. Cameron *et al.* (2000) *Inorg. Chem.*, vol. 39, p. 5614.

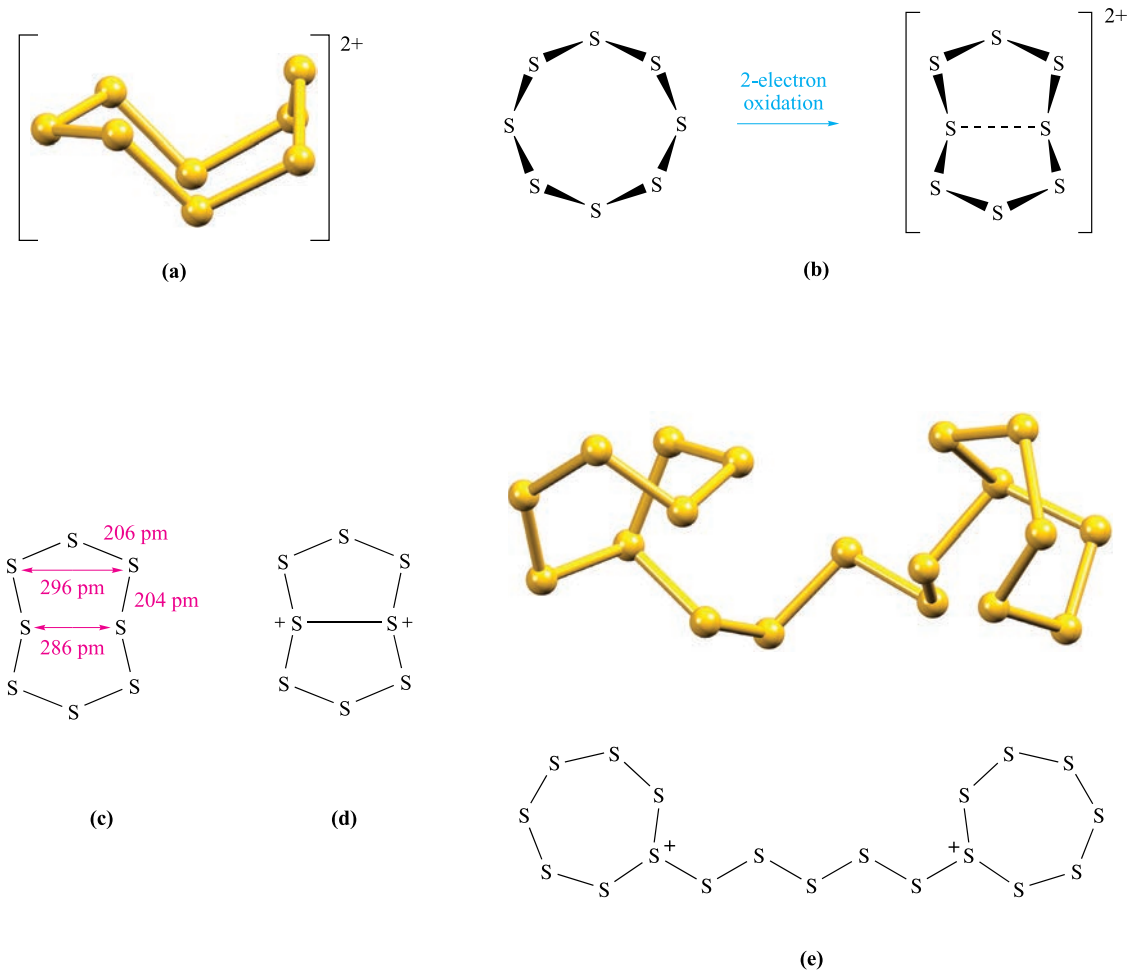


Fig. 16.8. (a) The structure of $[S_8]^{2+}$. (b) The change in conformation of the ring during oxidation of S_8 to $[S_8]^{2+}$. (c) Structural parameters for $[S_8]^{2+}$ from the $[AsF_6]^-$ salt. (d) One resonance structure that accounts for the transannular interaction in $[S_8]^{2+}$. (e) The structure of the $[S_{19}]^{2+}$ cation, determined by X-ray diffraction for the $[AsF_6]^-$ salt [R.C. Burns *et al.* (1980) *Inorg. Chem.*, vol. 19, p. 1423], and a schematic representation showing the localization of positive charge.

The $[S_4]^{2+}$ cation is square (S–S = 198 pm) with delocalized bonding. It is isoelectronic with $[P_4]^{2-}$ (see the self-study exercise on p. 505). In $[S_{19}]^{2+}$ (Fig. 16.8e), two 7-membered, puckered rings are connected by a 5-atom chain. The positive charge can be considered to be localized on the two 3-coordinate S centres.

A cyclic species has an ***annular*** form, and a ***transannular*** interaction is one between atoms across a ring.

Selenium and tellurium

Selenium possesses several allotropes. Crystalline, red monoclinic selenium exists in three forms, each containing Se_8 rings with the crown conformation of S_8 (Fig. 16.6c). Black selenium consists of larger polymeric rings. The thermodynamically stable allotrope is grey selenium which contains infinite, helical chains (Se–Se = 237 pm), the axes of which lie parallel to one another.

Elemental selenium can be prepared by reaction 16.24. By substituting Ph_3PSe in this reaction by Ph_3PS, rings of composition Se_nS_{8-n} (n = 1–5) can be produced (see end-of-chapter problem 4.42).

$$4SeCl_2 + 4Ph_3PSe \longrightarrow Se_8 + 4Ph_3PCl_2 \qquad (16.24)$$

Unlike S and Se, Te has only one crystalline form. It is a silvery-white metallic-looking solid consisting of infinite, helical chains, Te_∞. The Te–Te bond distances within a chain are 284 pm, but there are close contacts (four per Te atom at 350 pm) between chains (Fig. 16.9). The decrease in E–E bond enthalpy (S–S > Se–Se > Te–Te, Table 16.2) contributes to the fact that the thermodynamically stable form of tellurium is Te_∞ whereas that of sulfur

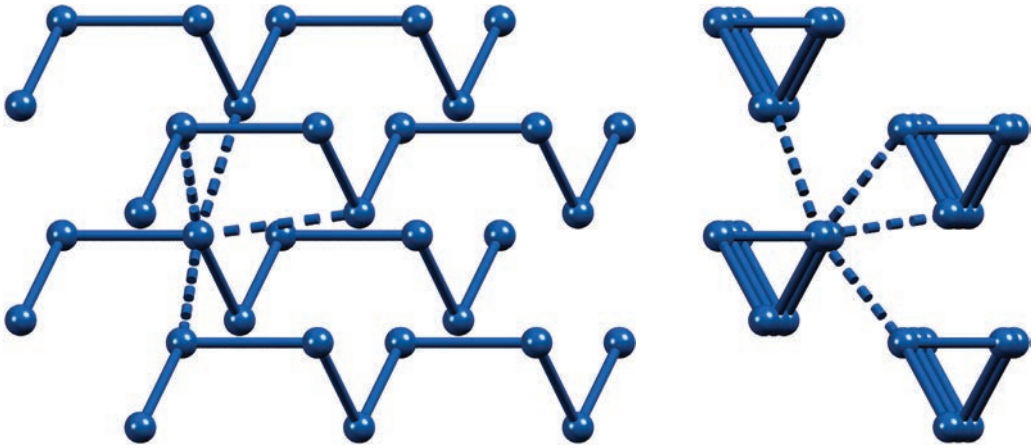

Fig. 16.9. (a) Parts of four helical Te_∞ chains (Te–Te = 284 pm) in the solid state structure of elemental tellurium showing short contacts (Te···Te = 350 pm) between chains. (b) A view down the helical chains.

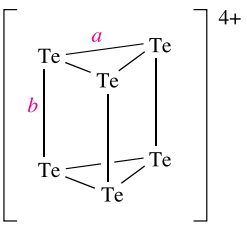
is *cyclo*-S_8.[†] Although *cyclo*-Te_8 is not known as an allotrope of tellurium, it has been characterized in several compounds:

- $Cs_3[Te_{22}]$ with composition $[Cs^+]_3[Te_6^{3-}][cyclo\text{-}Te_8]_2$;[‡]
- $Cs_4[Te_{28}]$ with composition $[Cs^+]_4[Te_6^{2-}]_2[cyclo\text{-}Te_4]_2[cyclo\text{-}Te_8]_2$;
- $[Ru(cyclo\text{-}Te_8)]Cl_2$ in which the Ru^{2+} centres are coordinated between pairs of Te_8 molecules to form infinite chains.

Other neutral *cyclo*-Te_n molecules stabilized within solid state compounds are Te_6 (e.g. in $[Rh(cyclo\text{-}Te_6)]Cl_3$) and Te_9 (in $[Ru(cyclo\text{-}Te_9)][InCl_4]_2$.

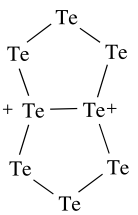
The photoconductivity of Se (see Box 16.1) and Te arises because, in the solid, the band gap of 1.66 eV is small enough for the influence of visible light to cause the promotion of electrons from the filled bonding MOs to the unoccupied antibonding MOs (see Section 6.8).



Although less reactive, Se and Te are chemically similar to sulfur. This resemblance extends to the formation of cations such as $[Se_4]^{2+}$, $[Te_4]^{2+}$, $[Se_8]^{2+}$ and $[Te_8]^{2+}$. The salt $[Se_8][AsF_6]_2$ can be made in an analogous manner to $[S_8][AsF_6]_2$ in liquid SO_2 (eq. 16.22), whereas reaction 16.25 is carried out in fluorosulfonic acid (see Section 9.8). Newer methods use metal halides (e.g. $ReCl_4$ and WCl_6) as oxidizing agents, e.g. the formation of $[Te_8]^{2+}$ (eq. 16.26). Reaction 16.27 (in AsF_3 solvent) produces $[Te_6]^{4+}$, **16.15**, which has no S or Se analogue.

$$4Se + S_2O_6F_2 \xrightarrow{HSO_3F} [Se_4][SO_3F]_2 \xrightarrow{Se,\ HSO_3F} [Se_8][SO_3F]_2 \quad (16.25)$$

$$2ReCl_4 + 15Te + TeCl_4 \xrightarrow{\Delta,\ \text{sealed tube}} 2[Te_8][ReCl_6] \quad (16.26)$$



$$6Te + 6AsF_5 \xrightarrow{AsF_3} [Te_6][AsF_6]_4 + 2AsF_3 \quad (16.27)$$

The structures of $[Se_4]^{2+}$, $[Te_4]^{2+}$ and $[Se_8]^{2+}$ mimic those of their S analogues, but $[Te_8]^{2+}$ exists in two forms. In $[Te_8][ReCl_6]$, $[Te_8]^{2+}$ is structurally similar to $[S_8]^{2+}$ and $[Se_8]^{2+}$, but in $[Te_8][WCl_6]_2$, the cation has the bicyclic structure, i.e. resonance structure **16.16** is dominant.

a lies in the range 266–269 pm
b lies in the range 306–315 pm

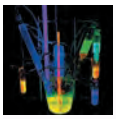
16.5 Hydrides

Water, H_2O



Aspects of the chemistry of water have already been covered as follows:

- the properties of H_2O (Section 7.2);
- acids, bases and ions in aqueous solution (Chapter 7);
- 'heavy water', D_2O (Section 10.3);
- comparison of the properties of H_2O and D_2O (Table 10.2);
- hydrogen bonding (Section 10.6).

Water purification is discussed in Box 16.3.

[†] T. Chivers and R.S. Laitinen (2015) *Chem. Soc. Rev.*, vol. 44, p. 1725 – 'Tellurium: a maverick among the chalcogens'.

[‡] $[Te_6^{3-}]$ represents part of an infinite sheet, see: W.S. Sheldrick and M. Wachold (1995) *Angew. Chem. Int. Ed.*, vol. 34, p. 450.

APPLICATIONS

Box 16.3 Purification of water

The simplest method for the removal of all solid solutes from water is distillation, but because of the high boiling point and enthalpy of vaporization (Table 7.1), this method is expensive. If the impurities are ionic, ion exchange is an effective (and relatively cheap) means of purification. The treatment involves the passage of water down a column of an organic resin containing acidic groups and then down a similar column containing basic groups:

$$\text{Resin}-SO_3H + M^+ + X^- \longrightarrow [\text{Resin}-SO_3]^-M^+ + H^+ + X^-$$

Acidic resin

$$[\text{Resin}-NR_3]^+[OH]^- + H^+ + X^- \longrightarrow [\text{Resin}-NR_3]^+X^- + H_2O$$

Basic resin

After treatment, *deionized water* is produced. The resins are reactivated by treatment with dilute H_2SO_4 and Na_2CO_3 solutions respectively. Reverse osmosis at high pressures is also an important process in water purification, with cellulose acetate as the usual membrane. The latter prevents the passage of dissolved solutes or insoluble impurities. The removal of nitrates is highlighted in Box 15.9.

The purification of drinking water is a complicated industrial process. Water may be abundant on the Earth, but impurities such as microorganisms, particulate materials and chemicals usually make it unfit for human consumption. Coagulation and separation methods are used to remove many particles. In the coagulation step, coagulants are dispersed throughout the water by rapid mixing. This is followed by a slower flocculation process in which coagulants and suspended impurities come together to form 'floc' which can then be separated by sedimentation. Aluminium and iron(III) salts are widely used in the coagulation stages, and the treatment relies upon the formation of polymeric species in solution. Pre-polymerized coagulants are commercially available and include polyaluminium silicate sulfate (PASS) and polyferric sulfate (PFS). About two-thirds of all $Al_2(SO_4)_3$ manufactured goes into water treatment processes, with the paper manufacturing industry consuming about a half of this amount.

Flocculation and settling stage for purifying drinking water at a waterworks operated by SMAT, the metropolitan water company of Turin, Italy.

Hydrogen peroxide, H_2O_2

The oldest method for the preparation of H_2O_2 is reaction 16.28. The hydrolysis of peroxydisulfate (produced by electrolytic oxidation of $[HSO_4]^-$ at high current densities using Pt electrodes) has also been an important route to H_2O_2 (eq. 16.29).

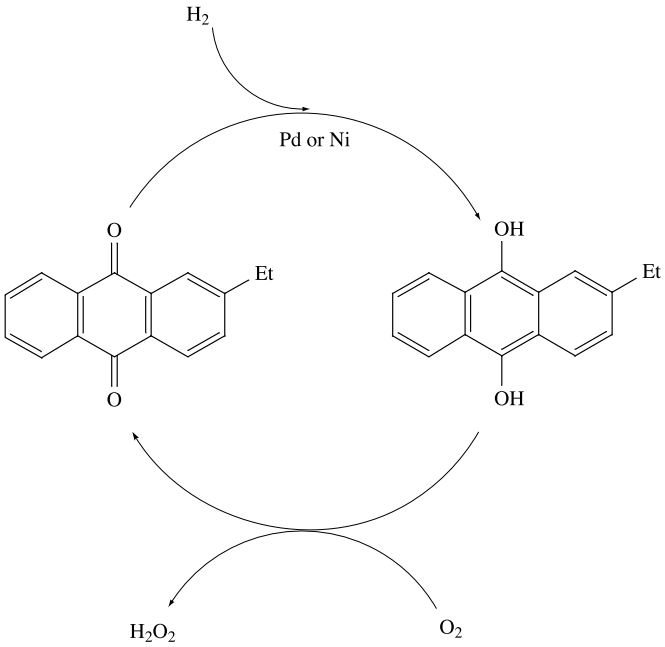
$$BaO_2 + H_2SO_4 \longrightarrow BaSO_4 + H_2O_2 \qquad (16.28)$$

$$2[NH_4][HSO_4] \xrightarrow[-H_2]{\text{electrolytic oxidation}} [NH_4]_2[S_2O_8] \xrightarrow{H_2O} 2[NH_4][HSO_4] + H_2O_2 \qquad (16.29)$$

Nowadays, H_2O_2 is manufactured by the oxidation of 2-ethylanthraquinol (or a related alkyl derivative). The H_2O_2 formed is extracted into water and the organic product is reduced back to starting material. The process is summarized in the catalytic cycle in Fig. 16.10.[†]

Some physical properties of H_2O_2 are given in Table 16.3. Like water, it is strongly hydrogen-bonded. Pure or strongly concentrated aqueous solutions of H_2O_2 readily decompose (eq. 16.30) in the presence of alkali, heavy metal ions or heterogeneous catalysts (e.g. Pt or MnO_2), and traces of complexing agents (e.g. 8-hydroxyquinoline, **16.17**) or adsorbing materials (e.g. sodium stannate, $Na_2[Sn(OH)_6]$) are often added as stabilizers.

[†] For overviews of H_2O_2 production processes, see: W.R. Thiel (1999) *Angew. Chem. Int. Ed.*, vol. 38, p. 3157 – 'New routes to hydrogen peroxide: alternatives for established processes?'; J.M. Campos-Martin, G. Blanco-Brieva and J.L.G. Fierro (2006) *Angew. Chem. Int. Ed.*, vol. 45, p. 6962 – 'Hydrogen peroxide synthesis: An outlook beyond the anthraquinone process'.



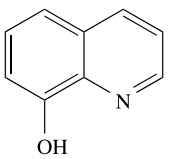


Fig. 16.10. The catalytic cycle used in the industrial manufacture of hydrogen peroxide; O_2 is converted to H_2O_2 during the oxidation of the organic alkylanthraquinol. The organic product is reduced by H_2 in a Pd- or Ni-catalysed reaction. Such cycles are discussed in detail in Chapter 25.

Table 16.3 Selected properties of H_2O_2.

Property	
Physical appearance at 298 K	Colourless (very pale blue) liquid
Melting point / K	272.6
Boiling point / K	425 (decomposes)
$\Delta_f H^o(298\,K)$ / kJ mol^{-1}	−187.8
$\Delta_f G^o(298\,K)$ / kJ mol^{-1}	−120.4
Dipole moment / debye	1.57
O–O bond distance (gas phase) / pm	147.5
∠O–O–H (gas phase) / deg	95

$$H_2O_2(l) \longrightarrow H_2O(l) + \tfrac{1}{2}O_2(g)$$
$$\Delta_r H^o(298\,K) = -98\,kJ\,per\,mole\,of\,H_2O_2 \quad (16.30)$$

(16.17)

Mixtures of H_2O_2 and organic or other readily oxidized materials are dangerously explosive, and H_2O_2 mixed with hydrazine has been used as a rocket propellant. A major application of H_2O_2 is in the paper and pulp industry where it is replacing chlorine as a bleaching agent (see Fig. 17.2). Other uses are as an antiseptic, in water pollution control and for the manufacture of sodium peroxoborate (see Section 13.7) and peroxycarbonates (see Section 14.9).

Figure 16.11 shows the gas-phase structure of H_2O_2 and bond parameters are listed in Table 16.3. The internal dihedral angle is sensitive to the surroundings (i.e. the extent of hydrogen bonding) being 111° in the gas phase, 90° in the solid state and 180° in the adduct $Na_2C_2O_4{\cdot}H_2O_2$. In this last example, H_2O_2 has a *trans*-planar conformation and the O lone pairs appear to interact with the Na^+ ions. Values of the dihedral angle in organic peroxides, ROOR, show wide variations (≈80°–145°).

In aqueous solution, H_2O_2 is partially ionized (eq. 16.31), and in alkaline solution, is present as the $[HO_2]^-$ ion.

$$H_2O_2 + H_2O \rightleftharpoons [H_3O]^+ + [HO_2]^-$$
$$K_a = 2.4 \times 10^{-12} \quad (298\,K) \qquad (16.31)$$

Hydrogen peroxide is a powerful oxidizing agent as is seen from the standard reduction potential (at pH = 0) in eq. 16.32. For example, H_2O_2 oxidizes I^- to I_2, SO_2 to H_2SO_4 and (in alkaline solution) Cr(III) to Cr(VI). Powerful oxidants such as $[MnO_4]^-$ and Cl_2 will oxidize H_2O_2 (eqs. 16.33–16.35), and in alkaline solution, H_2O_2 is a good reducing agent (eq. 16.36).

$$H_2O_2 + 2H^+ + 2e^- \rightleftharpoons 2H_2O \qquad E^o = +1.78\,V \quad (16.32)$$

$$O_2 + 2H^+ + 2e^- \rightleftharpoons H_2O_2 \qquad E^o = +0.70\,V \quad (16.33)$$

$$2[MnO_4]^- + 5H_2O_2 + 6H^+ \longrightarrow 2Mn^{2+} + 8H_2O + 5O_2 \qquad (16.34)$$

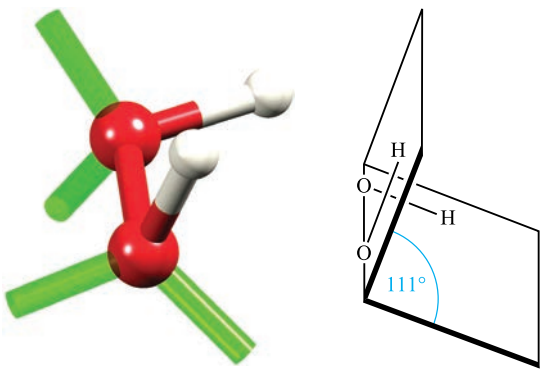

Fig. 16.11. The gas-phase structure of H_2O_2. The directions in which the lone pairs point are indicated by the green cylinders. The angle shown as 111° is the *internal dihedral angle*, the angle between the planes containing each OOH-unit; see Table 16.3 for other bond parameters.

$$Cl_2 + H_2O_2 \longrightarrow 2HCl + O_2 \quad (16.35)$$

$$O_2 + 2H_2O + 2e^- \rightleftharpoons H_2O_2 + 2[OH]^- \quad E^o_{[OH^-]=1} = -0.15\,V \quad (16.36)$$

Tracer studies using ^{18}O show that in these redox reactions $H_2(^{18}O)_2$ is converted to $(^{18}O)_2$, confirming that no oxygen from the solvent (which is not labelled) is incorporated and the O–O bond is not broken.

Worked example 16.3 Redox reactions of H_2O_2 in aqueous solution

Use data from Appendix 11 to determine $\Delta G^o(298\,K)$ for the oxidation of $[Fe(CN)_6]^{4-}$ by H_2O_2 in aqueous solution at pH = 0. Comment on the significance of the value obtained.

First, look up the appropriate half-equations and corresponding E^o values:

$$[Fe(CN)_6]^{3-}(aq) + e^- \rightleftharpoons [Fe(CN)_6]^{4-}(aq) \quad E^o = +0.36\,V$$

$$H_2O_2(aq) + 2H^+(aq) + 2e^- \rightleftharpoons 2H_2O(l) \quad E^o = +1.78\,V$$

The overall redox process is:

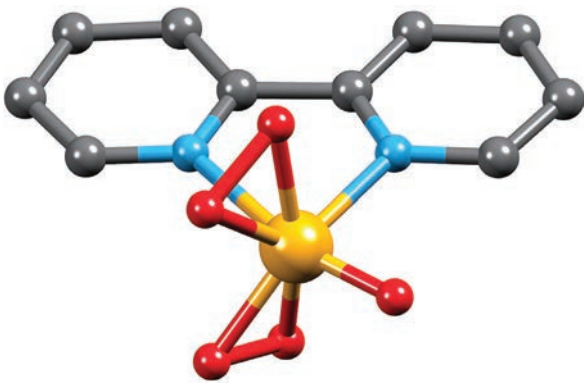
$$2[Fe(CN)_6]^{4-}(aq) + H_2O_2(aq) + 2H^+(aq) \longrightarrow 2[Fe(CN)_6]^{3-}(aq) + 2H_2O(l)$$

$$E^o_{cell} = 1.78 - 0.36 = 1.42\,V$$

$$\Delta G^o(298\,K) = -zFE^o_{cell}$$
$$= -2 \times 96\,485 \times 1.42 \times 10^{-3}$$
$$= -274\,kJ\,mol^{-1}$$

The value of ΔG^o is large and negative showing that the reaction is spontaneous and will go to completion.

Self-study exercises



1. In aqueous solution at pH 14, $[Fe(CN)_6]^{3-}$ is reduced by H_2O_2. Find the relevant half-equations in Appendix 11 and calculate $\Delta G^o(298\,K)$ for the overall reaction.
[*Ans.* −98 kJ per mole of H_2O_2]

2. At pH 0, H_2O_2 oxidizes aqueous sulfurous acid. Find the appropriate half-equations in Appendix 11 and determine $\Delta G^o(298\,K)$ for the overall reaction.
[*Ans.* −311 kJ per mole of H_2O_2]

3. Is the oxidation of Fe^{2+} to Fe^{3+} by aqueous H_2O_2 (at pH 0) thermodynamically more or less favoured when the Fe^{2+} ions are in the form of $[Fe(bpy)_3]^{2+}$ or $[Fe(OH_2)_6]^{2+}$? Quantify your answer by determining $\Delta G^o(298\,K)$ for each reduction.
[*Ans.* Less favoured for $[Fe(bpy)_3]^{2+}$; $\Delta G^o = -145$; −195 kJ per mole of H_2O_2]

See also end-of-chapter problem 8.8.

Deprotonation of H_2O_2 gives $[OOH]^-$ (eq. 16.31) and loss of a second proton yields the peroxide ion, $[O_2]^{2-}$. In addition to peroxide salts such as those of the alkali metals (see Section 11.6), many peroxido complexes are known. Figure 16.12 shows two such complexes, one of which also contains the $[OOH]^-$ ion in a bridging mode. Typical O–O bond distances for coordinated peroxido groups are ≈140–148 pm. Further peroxido complexes are described elsewhere in this book (e.g. Fig. 21.13 and accompanying discussion) and include models for the active centre in cytochrome *c* oxidase (see the end of Section 29.4).

∠H−E−H / deg	92	91	90

[†] The IUPAC names of sulfane, selane and tellane are rarely used.

Hydrides H_2E (E = S, Se, Te)

Selected physical data for hydrogen sulfide, selenide and telluride are listed in Table 16.4 and illustrated in Figs. 10.7 and 10.8. Hydrogen sulfide is more toxic than HCN, but because H_2S has a very characteristic odour of rotten eggs, its presence is easily detected. It is a natural product of decaying S-containing matter, and is present in coal pits, gas wells and sulfur springs. Where it occurs in natural gas deposits, H_2S is removed by reversible absorption in a solution of an organic base and is converted to S by controlled oxidation. Figure 16.2 showed the increasing importance of sulfur recovery from natural gas as a source of commercial sulfur. In the laboratory, H_2S was historically prepared by reaction 16.37 in a Kipp's apparatus. The hydrolysis of calcium or barium sulfides (e.g. eq. 16.38) produces purer H_2S, but the gas is also commercially available in small cylinders.

$$FeS(s) + 2HCl(aq) \longrightarrow H_2S(g) + FeCl_2(aq) \quad (16.37)$$

$$CaS + 2H_2O \longrightarrow H_2S + Ca(OH)_2 \quad (16.38)$$

Hydrogen selenide may be prepared by reaction 16.39, and a similar reaction can be used to make H_2Te.

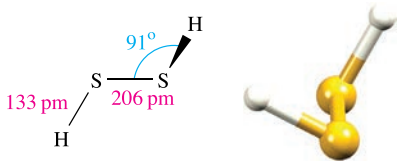
$$Al_2Se_3 + 6H_2O \longrightarrow 3H_2Se + 2Al(OH)_3 \quad (16.39)$$

The enthalpies of formation of H_2S, H_2Se and H_2Te (Table 16.4) indicate that the sulfide can be prepared by direct combination of H_2 and sulfur (boiling), and is more stable with respect to decomposition into its elements than H_2Se or H_2Te.

Like H_2O, the hydrides of the later elements in group 16 have bent structures but the angles of ≈90° (Table 16.4) are significantly less than that in H_2O (105°). This suggests that the E−H bonds (E = S, Se or Te) involve *p* character from the central atom (i.e. little or no contribution from the valence *s* orbital).

In aqueous solution, the hydrides behave as weak acids (Table 16.4 and Section 7.5). The second acid dissociation constant of H_2S is $\approx 10^{-19}$ and, thus, metal sulfides are hydrolysed in aqueous solution. The only reason that many metal sulfides can be isolated by the action of H_2S on solutions of their salts is that the sulfides are extremely insoluble. For example, a qualitative test for H_2S is its reaction with aqueous lead acetate (eq. 16.40).

$$H_2S + Pb(O_2CCH_3)_2 \longrightarrow \underset{\text{Black ppt.}}{PbS} + 2CH_3CO_2H \quad (16.40)$$



Sulfides such as CuS, PbS, HgS, CdS, Bi_2S_3, As_2S_3, Sb_2S_3 and SnS have solubility products (see Sections 7.9 and 7.10) less than $\approx 10^{-30}$ and can be precipitated by H_2S in the presence of dilute HCl. The acid suppresses ionization of H_2S, lowering the concentration of S^{2-} in solution. Sulfides such as ZnS, MnS, NiS and CoS with solubility products in the range $\approx 10^{-15}$ to 10^{-30} are precipitated only from neutral or alkaline solutions.

Protonation of H_2S to $[H_3S]^+$ can be achieved using the superacid HF/SbF_5 (see Section 9.9). The salt $[H_3S][SbF_6]$ is a white crystalline solid which reacts with quartz glass. Vibrational spectroscopic data for $[H_3S]^+$ are consistent with a trigonal pyramidal structure like that of $[H_3O]^+$. The addition of MeSCl to $[H_3S][SbF_6]$ at 77 K followed by warming of the mixture to 213 K yields $[Me_3S][SbF_6]$, which is stable below 263 K. Spectroscopic data (NMR, IR and Raman) are consistent with the presence of the trigonal pyramidal $[Me_3S]^+$ cation.

Polysulfanes

Polysulfanes are compounds of the general type H_2S_x where $x \geq 2$ (see structure **16.8**). Sulfur dissolves in aqueous solutions of group 1 or 2 metal sulfides (e.g. Na_2S) to yield polysulfide salts, (e.g. Na_2S_x). Acidification of such solutions gives a mixture of polysulfanes as a yellow oil, which can be fractionally distilled to yield H_2S_x ($x = 2$–6). An alternative method of synthesis, particularly useful for polysulfanes with $x > 6$, is by condensation reaction 16.41.

$$2H_2S + S_nCl_2 \longrightarrow H_2S_{n+2} + 2HCl \qquad (16.41)$$

(16.18)

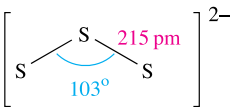
The structure of H_2S_2 (**16.18**) resembles that of H_2O_2 (Fig. 16.11) with an internal dihedral angle of 90.5° in the gas phase. All polysulfanes are thermodynamically unstable with respect to decomposition to H_2S and S. Their use in the preparation of *cyclo*-S_n species was described in Section 16.4.

16.6 Metal sulfides, polysulfides, polyselenides and polytellurides

Sulfides

Descriptions of metal sulfides already covered include:

- the zinc blende and wurtzite structures (Section 6.11, Figs. 6.21 and 6.23);
- precipitation of metal sulfides using H_2S (Section 16.5);
- sulfides of the group 14 metals (Section 14.11);
- sulfides of the group 15 elements (Section 15.14).



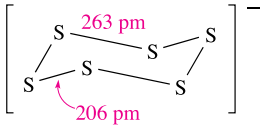
The group 1 and 2 metal sulfides possess the antifluorite and NaCl structure types respectively (see Section 6.11), and are typical ionic salts. However, the adoption of the NaCl-type structure (e.g. by PbS and MnS) cannot be regarded as a criterion for ionic character, as we discussed in Section 14.11. Most *d*-block metal monosulfides crystallize with the NiAs-type structure (e.g. FeS, CoS, NiS) (see Fig. 15.12) or the zinc blende or wurtzite structure (e.g. ZnS, CdS, HgS) (see Figs. 6.21 and 6.23). Metal disulfides may adopt the CdI_2 structure (e.g. TiS_2 and SnS_2 with metal(IV) centres), but others such as FeS_2 (iron pyrites) contain $[S_2]^{2-}$ ions. The latter are formally analogous to peroxides and may be considered to be salts of H_2S_2.

The blue paramagnetic $[S_2]^-$ ion is an analogue of the superoxide ion and has been detected in solutions of alkali metal sulfides in acetone or dimethyl sulfoxide. Simple salts containing $[S_2]^-$ are not known, but the blue colour of the aluminosilicate mineral *ultramarine* is due to the presence of the radical anions $[S_2]^-$ and $[S_3]^-$ (Box 16.4).

Polysulfides

Polysulfide ions $[S_x]^{2-}$ are not prepared by deprotonation of the corresponding polysulfanes. Instead, methods of synthesis include reactions 16.19 and 16.42, and the reaction of H_2S with S suspended in NH_4OH solution which yields a mixture of $[NH_4]_2[S_4]$ and $[NH_4]_2[S_5]$.

$$2Cs_2S + S_8 \xrightarrow{\text{aq medium}} 2Cs_2[S_5] \qquad (16.42)$$



(16.19)

Polysulfides of the *s*-block metals are well established. The $[S_3]^{2-}$ ion is bent (**16.19**), but as the chain length increases, it develops a helical twist, making it chiral (Fig. 16.13a). The coordination chemistry of these anions leads to some complexes such as those in Figs. 16.13 and 22.27b. For chains containing four or more S atoms, the $[S_x]^{2-}$ ligand often chelates to one metal centre or bridges between two centres. The structure of $[AuS_9]^-$ (Fig. 16.13d) illustrates a case where a long chain is required to satisfy the fact that the Au(I) centre favours a linear arrangement of donor atoms. The structures in Fig. 16.13 emphasize the helical twist that is a characteristic of an S_n-chain.

The cyclic $[S_6]^-$ radical has been prepared by reaction 16.43. In $[Ph_4P][S_6]$, the anion adopts a chair conformation, with two S–S bonds significantly longer than the other four (structure **16.20**).

$$2[Ph_4P][N_3] + 22H_2S + 20Me_3SiN_3 \longrightarrow 2[Ph_4P][S_6] + 10(Me_3Si)_2S + 11[NH_4][N_3] + 11N_2 \qquad (16.43)$$

(16.20)

ENVIRONMENT

Box 16.4 Ultramarine blues

The death mask of Tutankhamen, Cairo Museum, Egypt.

The soft, metamorphic mineral *lapis lazuli* (or *lazurite*) is a natural resource that was prized by ancient Egyptians for its blue colour and was cut, carved and polished for ornamental uses. The photograph above illustrates its use in the elaborate decoration of Tutankhamen's death mask. Natural deposits of lapis lazuli occur in, for example, Afghanistan, Iran and Siberia. Powdered lapis lazuli is a natural source of the blue pigment *ultramarine*. Lapis lazuli is related to the aluminosilicate mineral *sodalite*, $Na_8[Al_6Si_6O_{24}]Cl_2$, whose structure is shown opposite. The cavities in the aluminosilicate framework contain Na^+ cations and Cl^- anions. Partial or full replacement of Cl^- by the radical anions $[S_2]^-$ and $[S_3]^-$ results in the formation of $Na_8[Al_6Si_6O_{24}][Cl,S_n]_2$. Additional replacement of ions (e.g. $2Na^+$ for Ca^{2+}) may also occur. The presence of the chalcogenide ions gives rise to the blue pigmentation. The relative amounts of $[S_2]^-$ and $[S_3]^-$ present determine the colour of the pigment: in the UV–VIS spectrum, $[S_2]^-$ absorbs at 370 nm and $[S_3]^-$ at 595 nm. The $[S_2]^-$ and $[S_3]^-$ chromophores therefore give rise to yellow and blue colours, respectively. In some cases, red $[S_4]^-$ is present. In artificial ultramarines, the ratio of different $[S_n]^-$ ions can be controlled, so producing a range of colours from green to blue to violet to pink. Synthetic ultramarine is manufactured by heating together kaolinite (see Box 14.10), Na_2CO_3 and sulfur. This method means that SO_2 is produced, and desulfurization of the waste gases must be carried out to meet legislative requirements. More environmentally friendly methods of production are being sought (see the reading list below).

Polyselenides and polytellurides

Although Se and Te analogues of polysulfanes do not extend beyond the poorly characterized H_2Se_2 and H_2Te_2, the chemistries of polyselenides, polytellurides and their metal complexes are well established. Equations 16.44–16.47 illustrate preparations of salts of $[Se_x]^{2-}$ and $[Te_x]^{2-}$; see Section 11.8 for details of crown ethers and cryptands. Solvothermal conditions may also be used for the synthesis of $[Se_x]^{2-}$ and $[Te_x]^{2-}$ anions. For example, when Cs_2CO_3 and Se react in superheated MeOH solution, the Cs_2CO_3 facilitates the disproportionation of Se to $[Se_x]^{2-}$ and oxoanions. An example of this type of approach is given in self-study exercise 3 on p. 584.

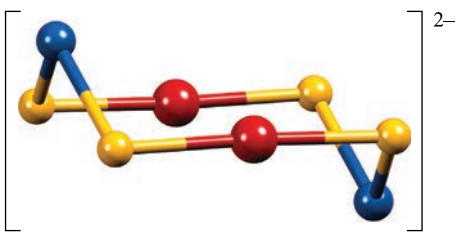
$$3Se + K_2Se_2 \xrightarrow{DMF} K_2[Se_5] \qquad (16.44)$$

$$4Se + K_2Se_2 + 2[Ph_4P]Br \longrightarrow [Ph_4P]_2[Se_6] + 2KBr \qquad (16.45)$$

Ed.*, vol. 23, p. 632]. Colour code: S, yellow.

$$3Se + K_2Se_2 \xrightarrow{\text{DMF, 15-crown-5}} [K(15\text{-crown-5})]_2[Se_5] \quad (16.46)$$

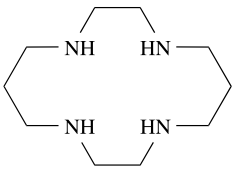
$$2K + 3Te \xrightarrow{\text{1,2-diaminoethane, crypt-222}} [K(\text{crypt-222})]_2[Te_3] \quad (16.47)$$



(16.21)

(16.22)

Structurally, the smaller polyselenide and polytelluride ions resemble their polysulfide analogues, e.g. $[Te_5]^{2-}$ has structure **16.21** with a helically twisted chain. The structures of higher anions are less simple, e.g. $[Te_8]^{2-}$ (**16.22**) can be considered in terms of $[Te_4]^{2-}$ and $[Te_3]^{2-}$ ligands bound to a Te^{2+} centre. Similarly, $[Se_{11}]^{2-}$ can be described in terms of two $[Se_5]^{2-}$ ligands chelating to an Se^{2+} centre. The coordination chemistry of the $[Se_x]^{2-}$ and $[Te_x]^{2-}$ chain anions has developed significantly since 1990.† Examples include $[(Te_4)Cu(\mu\text{-}Te_4)Cu(Te_4)]^{4-}$ and $[(Se_4)_2In(\mu\text{-}Se_5)In(Se_4)_2]^{4-}$ (both of which have bridging and chelating ligands), octahedral $[Pt(Se_4)_3]^{2-}$ with chelating $[Se_4]^{2-}$ ligands, $[Zn(Te_3)(Te_4)]^{2-}$, $[Cr(Te_4)_3]^{3-}$ and $[Au_2(TeSe_2)_2]^{2-}$ (**16.23**) which contains an example of a metal-coordinated, mixed Se/Te polychalcogenide anion.



Colour code: Au, red; Te, blue; Se, yellow.

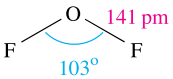
(16.23)

† For reviews on polychalcogenide anions as ligands, see: W.S. Sheldrick (2012) *Z. Anorg. Allg. Chem.*, vol. 638, p. 2401; M. Ruck and F. Locherer (2013) *Coord. Chem. Rev.*, vol. 285, p. 1.

Self-study exercises

1. $[TeSe_2]^{2-}$ and $[TeSe_3]^{2-}$ possess bent and trigonal pyramidal structures, respectively. Rationalize these structures in terms of the available valence electrons, and draw a set of resonance structures for $[TeSe_3]^{2-}$. Ensure that each atom obeys the octet rule.
2. The $[Te(Se_5)_2]^{2-}$ ion contains two $[Se_2]^{2-}$ bidentate ligands coordinated to a square planar tellurium centre. (i) What is the oxidation state of Te in $[Te(Se_5)_2]^{2-}$? (ii) Each $TeSe_6$-ring has a chair-conformation. Draw the structure of $[Te(Se_5)_2]^{2-}$, given that the Te atom lies on an inversion centre.
3. $[MnCl_2(cyclam)]Cl$ was reacted with elemental selenium in the presence of Cs_2CO_3 in MeOH at 150 °C in a sealed glass tube for 20 h. After this period, the mixture was cooled slowly to room temperature, and crystals of product **X** formed. **X** is a manganese(II) complex and contains 21.03% C, 4.24% H and 9.81% N. (a) Suggest how the cyclam ligand coordinates to a metal ion. (b) Suggest a molecular formula and possible structure for **X**.

cyclam



[*Ans.* See A. Kromm *et al.* (2008) *Z. Anorg. Allg. Chem.*, vol. 634, p. 2191]

16.7 Halides, oxohalides and complex halides

In contrast to the trend found in earlier groups, the stability of the lowest oxidation state (+2) of the central atom in the halides of the group 16 elements *decreases* down the group. This is well exemplified in the halides discussed in this section. Our discussion is confined to the fluorides of O, and the fluorides and chlorides of S, Se and Te. The bromides and iodides of the later elements are similar to their chloride analogues. Compounds of O with Cl, Br and I are described in Section 17.8.

Oxygen fluorides

Oxygen difluoride, OF_2 (**16.24**), is highly toxic and may be prepared by reaction 16.48. Selected properties are given in Table 16.5. Although OF_2 is formally the anhydride of hypofluorous acid, HOF, only reaction 16.49 occurs with water and this is very slow at 298 K. With concentrated alkali, decomposition is much faster, and with steam, it is explosive.

(16.24)

$$2NaOH + 2F_2 \longrightarrow OF_2 + 2NaF + H_2O \quad (16.48)$$

$$H_2O + OF_2 \longrightarrow O_2 + 2HF \quad (16.49)$$

Pure OF_2 can be heated to 470 K without decomposition, but it reacts with many elements (to form fluorides and oxides) at, or slightly above, room temperature. When subjected to UV radiation in an argon matrix at 4 K, the $OF^{\bullet}$ radical is formed (eq. 16.50) and on warming, the radicals combine to give dioxygen difluoride, O_2F_2.

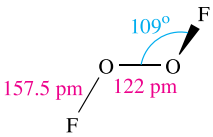
$$OF_2 \xrightarrow{\text{UV radiation}} OF^{\bullet} + F^{\bullet} \quad (16.50)$$

Dioxygen difluoride may also be made by the action of a high-voltage discharge on a mixture of O_2 and F_2 at 77–90 K and 1–3 kPa pressure. Selected properties of O_2F_2 are listed in Table 16.5. The low-temperature decomposition of O_2F_2 initially yields $O_2F^{\bullet}$ radicals. Even at low temperatures, O_2F_2 is an extremely powerful fluorinating agent, e.g. it inflames with S at 93 K, and reacts with BF_3 (eq. 16.8) and SbF_5 (eq. 16.51). O_2F_2 is one of the most powerful oxidative fluorinating agents known, and this is well exemplified by reactions with oxides and fluorides of uranium, plutonium and neptunium (e.g. reactions 16.52 and 16.53). These reactions occur at or below ambient temperatures, in contrast to the high temperatures required to form UF_6, PuF_6 and NpF_6 using F_2 or halogen fluorides as fluorinating agents. However, because of the high reactivity of O_2F_2, choosing appropriate reaction conditions is crucial to being able to control the reaction.

$$2O_2F_2 + 2SbF_5 \longrightarrow 2[O_2]^+[SbF_6]^- + F_2 \quad (16.51)$$

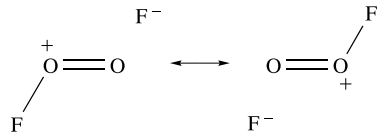
$$NpF_4 + O_2F_2 \longrightarrow NpF_6 + O_2 \quad (16.52)$$

$$NpO_2 + 3O_2F_2 \longrightarrow NpF_6 + 4O_2 \quad (16.53)$$



The molecular shape of O_2F_2 (**16.25**) resembles that of H_2O_2 (Fig. 16.10) although the internal dihedral angle is smaller (87°). The very long O–F bond probably accounts for the ease of dissociation into $O_2F^{\bullet}$ and $F^{\bullet}$. Structures **16.26** show valence bond representations which reflect the long O–F and short O–O bonds; compare the O–O bond

Table 16.5 Selected physical properties of oxygen and sulfur fluorides.



Property	OF_2	O_2F_2	S_2F_2	$F_2S{=}S$	SF_4	SF_6	S_2F_{10}
Physical appearance and general characteristics	Colourless (very pale yellow) gas; explosive and toxic	Yellow solid below 119 K; decomposes above 223 K	Colourless gas; extremely toxic	Colourless gas	Colourless gas; toxic; reacts violently with water	Colourless gas; highly stable	Colourless liquid; extremely toxic

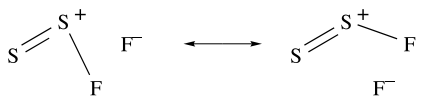
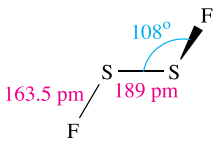
distance with those for O_2 and derived ions (Section 16.4) and H_2O_2 (Table 16.3).



(16.25)



(16.26)

Sulfur fluorides and oxofluorides

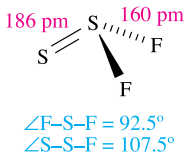


Table 16.5 lists some properties of the most stable fluorides of sulfur. The fluorides SF_4 and S_2F_2 can be prepared from the reaction of SCl_2 and HgF_2 at elevated temperatures. Both fluorides are highly unstable. Disulfur difluoride exists as two isomers: S_2F_2 (**16.27**) and $F_2S{=}S$ (**16.28**), with S_2F_2 (made from AgF and S at 398 K) readily isomerizing to $F_2S{=}S$. The structure of S_2F_2 is like that of O_2F_2, with an internal dihedral angle of 88°. The S−S bond distances in both isomers are very short and imply multiple bond character (compare ≈206 pm for a single S−S bond, and 184 pm in $[S_2I_4]^{2+}$, Fig. 16.7). For S_2F_2, contributions from resonance structures analogous to those shown for O_2F_2 are important, while for $S{=}SF_2$, we may write:

Both isomers are unstable with respect to disproportionation into SF_4 and S, and are extremely reactive, attacking glass and being rapidly hydrolysed by water and alkali (e.g. eq. 16.54).

(16.27)

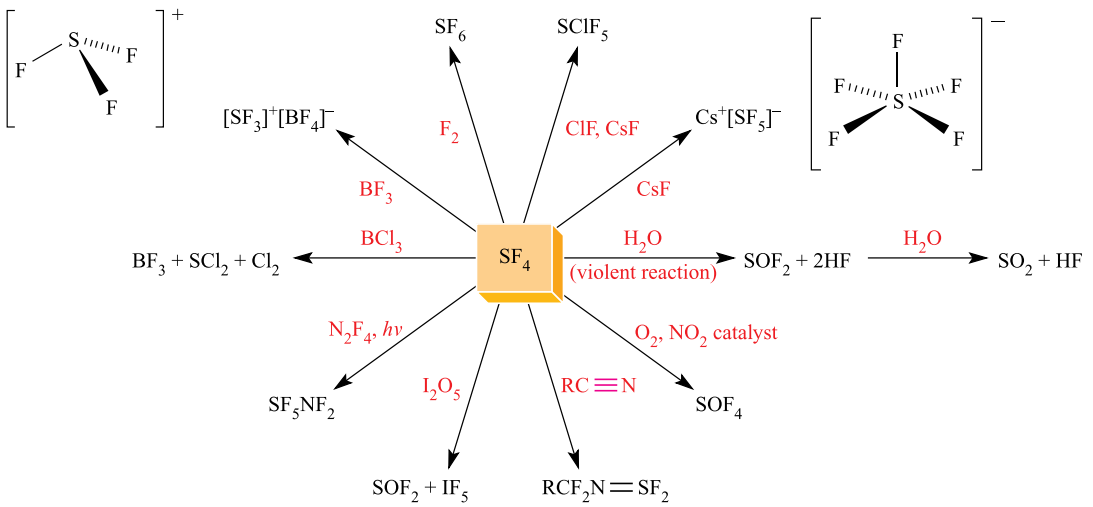
(16.28)

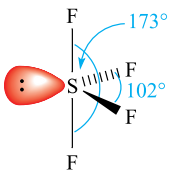
$$2S{=}SF_2 + 2[OH]^- + H_2O \longrightarrow \tfrac{1}{4}S_8 + [S_2O_3]^{2-} + 4HF \quad (16.54)$$

Sulfur tetrafluoride, SF_4, is best prepared by reaction 16.55. It is commercially available and is used as a selective fluorinating agent, e.g. it converts carbonyl groups into CF_2 groups without destroying any unsaturation in the molecule. Representative reactions are shown in Fig. 16.14. SF_4 hydrolyses rapidly and must be handled in moisture-free conditions.

$$3SCl_2 + 4NaF \xrightarrow{MeCN,\ 350\,K} SF_4 + S_2Cl_2 + 4NaCl \quad (16.55)$$

In the gas-phase, SF_4 has a see-saw structure (**16.29**) derived from a trigonal bipyramid that can be rationalized using the VSEPR model. The S−F_{ax} bonds are longer than the S−F_{eq} bonds (Table 16.5), consistent with more ionic character in the axial bonds. The low melting point of SF_4 (Table 16.5) has made it difficult to obtain single crystals





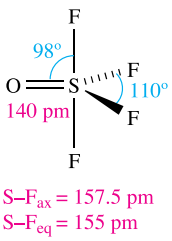


Fig. 16.14. Selected reactions of sulfur tetrafluoride.

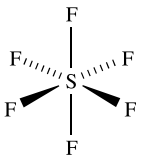
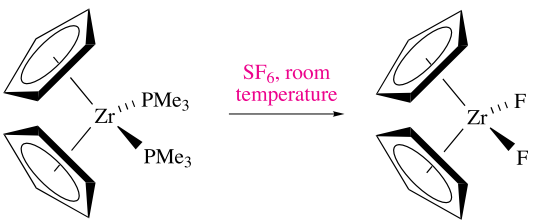


of the compound.† Discrete SF_4 molecules, structurally similar to those in the gas phase, are present in the solid state (at 128 K). However, short S−F_{ax}···S contacts (295.4 pm) lead to a description of the structure as a 3-dimensional network of SF_4 molecules. Oxidation of SF_4 by O_2 in the absence of a catalyst to form SOF_4 is slow. The structure of SOF_4, **16.30**, is related to that of SF_4, but with S−F_{ax} and S−F_{eq} bond distances that are close in value.

(16.29)

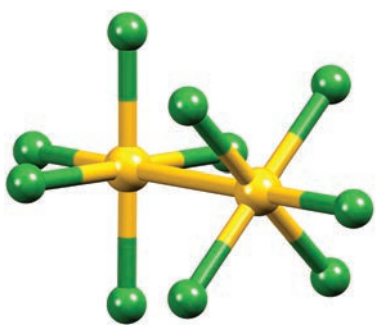
(16.30)



(16.31)

Among the sulfur fluorides, SF_6, **16.31**, stands out for its high stability and chemical inertness. Its bonding was discussed in Section 5.8. SF_6 is commercially available and is manufactured by burning sulfur in F_2. It has a high dielectric constant and its main use is as an electrical insulator. However, SF_6 that enters the atmosphere is long-lived, and emissions are controlled under the Kyoto Protocol (see Box 14.7). Its lack of reactivity (e.g. it is unaffected by steam at 770 K or molten alkalis) is kinetic rather than thermodynamic in origin. The value of Δ_rG^o for reaction 16.56 certainly indicates thermodynamic spontaneity. Rather surprisingly, SF_6 has been shown to be a reactive fluorinating agent towards low-valent organometallic Ti and Zr compounds (e.g. reaction 16.57 which involves cyclopentadienyl derivatives).

† See: J.T. Goettel, N. Kostiuk and M. Gerken (2013) *Angew. Chem. Int. Ed.*, vol. 52, p. 8037 – 'The solid-state structure of SF_4: The final piece of the puzzle'.



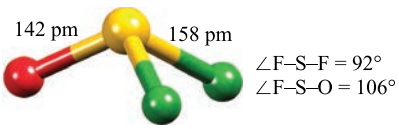
$$SF_6 + 3H_2O \longrightarrow SO_3 + 6HF$$
$$\Delta_rG^o(298\,K) = -221\,kJ\,mol^{-1} \qquad (16.56)$$

(16.57)

The preparation of SF_6 from S and F_2 produces small amounts of S_2F_{10} and the yield can be optimized by controlling the reaction conditions. An alternative route is reaction 16.58. Selected properties of S_2F_{10} are given in Table 16.5.

$$2SF_5Cl + H_2 \xrightarrow{h\nu} S_2F_{10} + 2HCl \qquad (16.58)$$

(16.32)



Molecules of S_2F_{10} have the staggered structure **16.32**. The S−S bond length of 221 pm is significantly longer than the single bonds in elemental S (206 pm). It disproportionates

when heated (eq. 16.59) and is a powerful oxidizing agent. An interesting reaction is that with NH_3 to yield $N{\equiv}SF_3$ (see structure **16.68**).

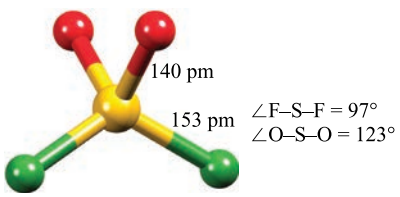
$$S_2F_{10} \xrightarrow{420\,K} SF_4 + SF_6 \qquad (16.59)$$

Many compounds containing SF_5 groups are known, including $SClF_5$ and SF_5NF_2 (Fig. 16.14). In accord with the relative strengths of the S−Cl and S−F bonds (Table 16.2), reactions of $SClF_5$ usually involve cleavage of the S−Cl bond (e.g. reaction 16.60).

$$2SClF_5 + O_2 \xrightarrow{h\nu} F_5SOOSF_5 + Cl_2 \qquad (16.60)$$

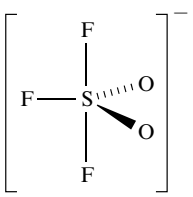
(16.33)

Sulfur forms several oxofluorides, and we have already mentioned SOF_4. Thionyl difluoride, SOF_2 (**16.33**), is a colourless gas (bp 229 K), prepared by fluorinating $SOCl_2$ using SbF_3. It reacts with F_2 to give SOF_4, and is slowly hydrolysed by water (see Fig. 16.14). The reaction of SOF_2 and $[Me_4N]F$ at 77 K followed by warming to 298 K produces $[Me_4N][SOF_3]$, the first example of a salt containing $[SOF_3]^-$. The anion rapidly hydrolyses (reaction 16.61 followed by reaction 16.62 depending on conditions) and reacts with SO_2 to give SOF_2 and $[SO_2F]^-$.



$$3[SOF_3]^- + H_2O \longrightarrow 2[HF_2]^- + [SO_2F]^- + 2SOF_2 \qquad (16.61)$$

$$4[SO_2F]^- + H_2O \longrightarrow 2[HF_2]^- + [S_2O_5]^{2-} + 2SO_2 \qquad (16.62)$$

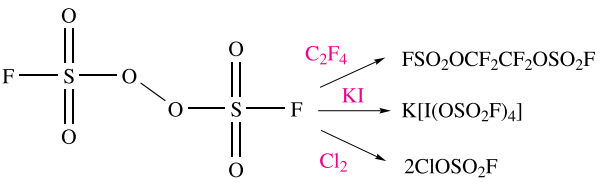


Sulfuryl difluoride,† SO_2F_2 (**16.34**), is a colourless gas (bp 218 K) which is made by reaction 16.63 or 16.64.

$$SO_2Cl_2 + 2NaF \longrightarrow SO_2F_2 + 2NaCl \qquad (16.63)$$

$$Ba(SO_3F)_2 \xrightarrow{\Delta} SO_2F_2 + BaSO_4 \qquad (16.64)$$

(16.34)



(16.35)

† Sulfuryl difluoride is also called sulfonyl difluoride or sulfonyl fluoride.

Although unaffected by water, SO_2F_2 is hydrolysed by concentrated aqueous alkali. Like SOF_2, SO_2F_2 accepts F^- when reacted with $[Me_4N]F$; the reaction must be carried out in MeCN and the product, $[SO_2F_3]^-$, reacts rapidly with H_2O (see self-study exercise 4 below). $[SO_2F_3]^-$ is isoelectronic with SOF_4 (**16.30**) and vibrational spectroscopic data are consistent with structure **16.35**. A series of sulfuryl fluorides is known, including FSO_2OSO_2F and FSO_2OOSO_2F. The latter compound is prepared by reaction **16.65**; fluorosulfonic acid (see Section 9.8) is related to the intermediate in this reaction.

$$SO_3 + F_2 \xrightarrow{AgF_2,\ 450\,K} FSO_2OF \xrightarrow{SO_3} FSO_2OOSO_2F \qquad (16.65)$$

The dissociation of FSO_2OOSO_2F at 393 K produces the brown paramagnetic radical $FSO_2O^{\bullet}$, selected reactions of which are shown in scheme 16.66.

(16.66)

The reaction of F_2 with sulfate ion yields $[FSO_4]^-$ which can be isolated as the caesium salt and is an extremely powerful oxidizing agent (eq. 16.67).

$$[FSO_4]^- + 2H^+ + 2e^- \rightleftharpoons [HSO_4]^- + HF \quad E^\circ \approx +2.5\,V \qquad (16.67)$$

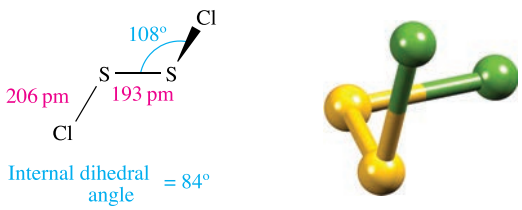
Self-study exercises

1. Consider structure **16.33**. Draw a set of resonance structures for SOF_2 that maintains an octet of electrons around the S atom. Comment on the structures that you have drawn, given that values of r_{cov} of S, O and F are 103, 73 and 71 pm, respectively.
2. Show that SO_2F_2 belongs to the C_{2v} point group.
3. SF_6 is a greenhouse gas. In the upper stratosphere, photolysis to SF_5 is possible. Combination of SF_5 with O_2 gives the radical F_5SO_2. Draw Lewis structures for SF_5 and F_5SO_2 showing which atom formally carries the unpaired electron in each species.
4. The solution ^{19}F NMR spectrum of freshly prepared $[Me_4N][SO_2F_3]$ contains a singlet at δ +79 ppm as well as lower-intensity signals: a doublet at δ −148.5 ppm (J = 120 Hz) and singlet at δ +46 ppm. Rationalize

these data in terms of the rapid hydrolysis of $[SO_2F_3]^-$, and write a balanced equation for the reaction.

[*Ans.* See: C. Hohenstein *et al.* (2011) *Chem. Eur. J.*, vol. 17, p. 925]

5. Explain why both SOF_4 and $[SO_2F_3]^-$ have C_{2v} symmetry.



Sulfur chlorides and oxochlorides

The range of sulfur chlorides and oxochlorides (which are all hydrolysed by water) is more restricted than that of the corresponding fluorides. There are no stable chloro analogues of SF_4, SF_6 and S_2F_{10}. One example of a high oxidation state chloride is $SClF_5$, prepared as shown in Fig. 16.14.

Disulfur dichloride, S_2Cl_2, is a fuming orange liquid (mp 193 K, bp 409 K) which is toxic and has a repulsive smell. It is manufactured by passing Cl_2 through molten S, and further chlorination yields SCl_2 (a dark-red liquid, mp 195 K, dec. 332 K). Both are used industrially for the manufacture of $SOCl_2$ (scheme 16.68) and S_2Cl_2 for the vulcanization of rubber. Pure SCl_2 is unstable with respect to equilibrium 16.69.

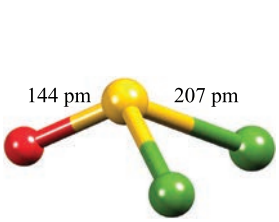
$$\left.\begin{aligned} 2SO_2 + S_2Cl_2 + 3Cl_2 &\longrightarrow 4SOCl_2 \\ SO_3 + SCl_2 &\longrightarrow SOCl_2 + SO_2 \end{aligned}\right\} \quad (16.68)$$

$$2SCl_2 \rightleftharpoons S_2Cl_2 + Cl_2 \quad (16.69)$$

(16.36)

The structure of S_2Cl_2, **16.36**, resembles that of S_2F_2. SCl_2 is a bent molecule (S–Cl = 201 pm, ∠Cl–S–Cl = 103°). Decomposition of both chlorides by water yields a complicated mixture containing S, SO_2, $H_2S_5O_6$ and HCl. Equation 16.18 showed the use of S_2Cl_2 in the formation of an S_n ring. Condensation of S_2Cl_2 with polysulfanes (eq. 16.70) gives rise to chlorosulfanes that can be used, for example, in the formation of various sulfur rings (see structures **16.8** and **16.9** and discussion).

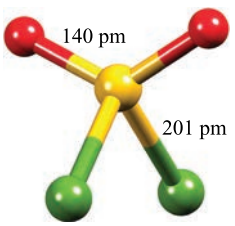
$$ClS{-}SCl + H{-}(S)_x{-}H + ClS{-}SCl \longrightarrow ClS_{x+4}Cl + 2HCl \quad (16.70)$$



Thionyl dichloride, $SOCl_2$ (prepared, for example, by reaction 16.68 or 16.71), and sulfuryl dichloride,† SO_2Cl_2 (prepared by reaction 16.72), are colourless, fuming liquids: $SOCl_2$, bp 351 K; SO_2Cl_2, bp 342 K. Their ease of hydrolysis accounts for their fuming nature, e.g. eq. 16.73.

$$SO_2 + PCl_5 \longrightarrow SOCl_2 + POCl_3 \quad (16.71)$$

$$SO_2 + Cl_2 \xrightarrow{\text{activated charcoal}} SO_2Cl_2 \quad (16.72)$$



$$SOCl_2 + H_2O \longrightarrow SO_2 + 2HCl \quad (16.73)$$

The structural parameters shown for $SOCl_2$, **16.37**, and SO_2Cl_2, **16.38**, are for the gas-phase molecules.

∠Cl–S–Cl = 97°
∠Cl–S–O = 108°

(16.37)

∠Cl–S–Cl = 100°
∠O–S–O = 123.5°

(16.38)

Both $SOCl_2$ and SO_2Cl_2 are available commercially. Thionyl dichloride is used to prepare acyl chlorides (eq. 16.74) and anhydrous metal chlorides (i.e. removing water of crystallization by reaction 16.73), while SO_2Cl_2 is a chlorinating agent.

$$RCO_2H + SOCl_2 \xrightarrow{\Delta} RC(O)Cl + SO_2 + HCl \quad (16.74)$$

Self-study exercises

1. Show that SCl_2 belongs to the C_{2v} point group.
2. Does SCl_2 possess $(3n - 5)$ or $(3n - 6)$ degrees of vibrational freedom? Rationalize your answer.

[*Ans.* See eqs. 3.5 and 3.6]

3. By using the C_{2v} character table (Appendix 3), show that an SCl_2 molecule has A_1 and B_2 normal modes of vibration. Draw diagrams to illustrate these modes of vibration. Confirm that each mode is both IR and Raman active.

[*Ans.* Refer to Fig. 3.12 (SCl_2 is like SO_2) and related discussion]

4. Show that S_2Cl_2 has C_2 symmetry.

† Sulfuryl dichloride is also called sulfonyl dichloride or sulfonyl chloride.

[†] For other structural data, see text.

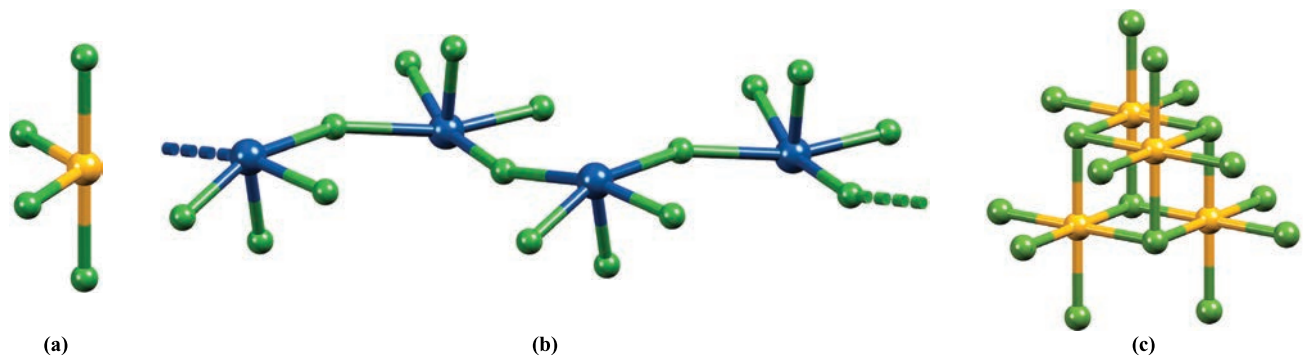
Halides of selenium and tellurium

In contrast to sulfur chemistry where dihalides are well established, the isolation of dihalides of selenium and tellurium has only been achieved for $SeCl_2$ and $SeBr_2$ (reactions 16.75 and 16.76). Selenium dichloride is a thermally unstable red oil; $SeBr_2$ is a red-brown solid.

$$\underset{\text{powder}}{Se} + SO_2Cl_2 \xrightarrow{296\,K} SeCl_2 + SO_2 \qquad (16.75)$$

$$SeCl_2 + 2Me_3SiBr \xrightarrow{296\,K,\ THF} SeBr_2 + 2Me_3SiCl \qquad (16.76)$$

Table 16.6 lists selected properties of SeF_4, SeF_6, TeF_4 and TeF_6. Selenium tetrafluoride is a good fluorinating agent. It is a liquid at 298 K and (compared with SF_4) is relatively convenient to handle. It is prepared by reacting SeO_2 with SF_4. Combination of F_2 and Se yields SeF_6 which is thermally stable and relatively inert. The tellurium fluorides are similarly prepared, TeF_4 from TeO_2 and SF_4 (or SeF_4), and TeF_6 from the elements. In the liquid and gas phases, SeF_4 contains discrete molecules (Fig. 16.15a) but in the solid state, significant intermolecular interactions are present. These are considerably weaker than in TeF_4, in which the formation of asymmetrical Te−F−Te bridges leads to a polymeric structure in the crystal (Fig. 16.15b). ^{19}F NMR spectroscopic studies of liquid SeF_4 have shown that the molecules are stereochemically non-rigid (see Section 4.8). The structures of SeF_6 and TeF_6 are regular octahedra. SeF_4 fumes in moist air, whereas SeF_6 resists hydrolysis. SeF_4 reacts with CsF to give $Cs^+[SeF_5]^-$. Further reaction with fluoride ion to give $[SeF_6]^{2-}$ can be achieved only by using a highly active fluoride source (the so-called 'naked' fluoride ion, accessed by using anhydrous $[Me_4N]F$ or organic fluorides containing large counterions). Thus, the reaction of **16.39** with $[SeF_5]^-$ gives the hexamethylpiperidinium salt of $[SeF_6]^{2-}$. In the solid state, the $[SeF_6]^{2-}$ ion in this salt has a distorted octahedral structure (its symmetry lies between C_{3v} and C_{2v}). The distortion away from O_h symmetry has been attributed to the presence of a stereochemically active lone pair of electrons, but the fact that there are C–H···F hydrogen bonds between cations and anions means that the $[SeF_6]^{2-}$ ion cannot be considered to be in an isolated environment.



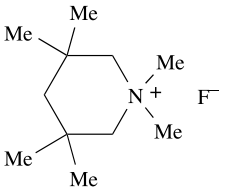


Fig. 16.15. (a) The structure of SeF_4 in the gas and liquid phases. (b) In the solid state, TeF_4 consists of polymeric chains; the Te−F−Te bridges are asymmetrical (Te−F = 208 and 228 pm). (c) The structure of the molecular Se_4Cl_{16}-unit present in crystalline $SeCl_4$. Colour code: Se, yellow; Te, blue; F and Cl, green.

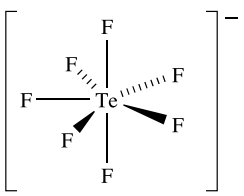
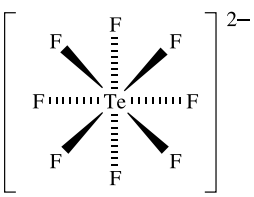
1,1,3,3,5,5-hexamethylpiperidinium fluoride
(a source of 'naked' fluoride ion)



(16.39)

Tellurium hexafluoride is hydrolysed by water to telluric acid, H_6TeO_6 (see **16.64**), and undergoes a number of exchange reactions such as reaction 16.77. It is also a fluoride acceptor, reacting with alkali metal fluorides and $[Me_4N]F$ under anhydrous conditions (eq. 16.78).

$$TeF_6 + Me_3SiNMe_2 \longrightarrow Me_2NTeF_5 + Me_3SiF \qquad (16.77)$$



$$\left.\begin{aligned} TeF_6 + [Me_4N]F &\xrightarrow{MeCN,\ 233\ K} [Me_4N][TeF_7] \\ [Me_4N][TeF_7] + [Me_4N]F &\xrightarrow{MeCN,\ 273\ K} [Me_4N]_2[TeF_8] \end{aligned}\right\} \qquad (16.78)$$

The $[TeF_7]^-$ ion has a pentagonal bipyramidal structure (**16.40**) although in the solid state, the equatorial F atoms deviate slightly from the mean equatorial plane. In $[TeF_8]^{2-}$, **16.41**, vibrational spectroscopic data are consistent with the Te centre being in a square-antiprismatic environment.

$Te–F_{ax}$ = 179 pm
$Te–F_{eq}$ = 183-190 pm

(16.40)

(16.41)

In contrast to sulfur, Se and Te form stable tetrachlorides, made by direct combination of the elements. At 298 K, both tetrachlorides are solids ($SeCl_4$, colourless, subl. 469 K; $TeCl_4$, yellow, mp 497 K, bp 653 K) which contain tetrameric units, depicted in Fig. 16.15c for $SeCl_4$. The E−Cl (E = Se or Te) bonds within the cubane core are significantly longer than the terminal E−Cl bonds: e.g. Te−Cl = 293 (core) and 231 (terminal) pm. Thus, the structure may also be described in terms of $[ECl_3]^+$ and Cl^- ions. Stepwise removal of $[ECl_3]^+$ from the tetramers E_4Cl_{16} (E = Se, Te) occurs in the presence of chloride ion in non-polar solvents, e.g. for the first step:

$$Te_4Cl_{16} + R^+Cl^- \longrightarrow R^+[Te_3Cl_{13}]^- + TeCl_4$$

in which R^+ is a large, organic cation, or overall:

$$Te_4Cl_{16} \longrightarrow [Te_3Cl_{13}]^- \longrightarrow [Te_2Cl_{10}]^{2-} \longrightarrow [TeCl_6]^{2-}$$

A ***cubane*** contains a central cubic (or near-cubic) arrangement of atoms.

The $[SeCl_3]^+$ and $[TeCl_3]^+$ cations are also formed in reactions with Cl^- acceptors, e.g. reaction 16.79.

$$SeCl_4 + AlCl_3 \longrightarrow [SeCl_3]^+ + [AlCl_4]^- \qquad (16.79)$$

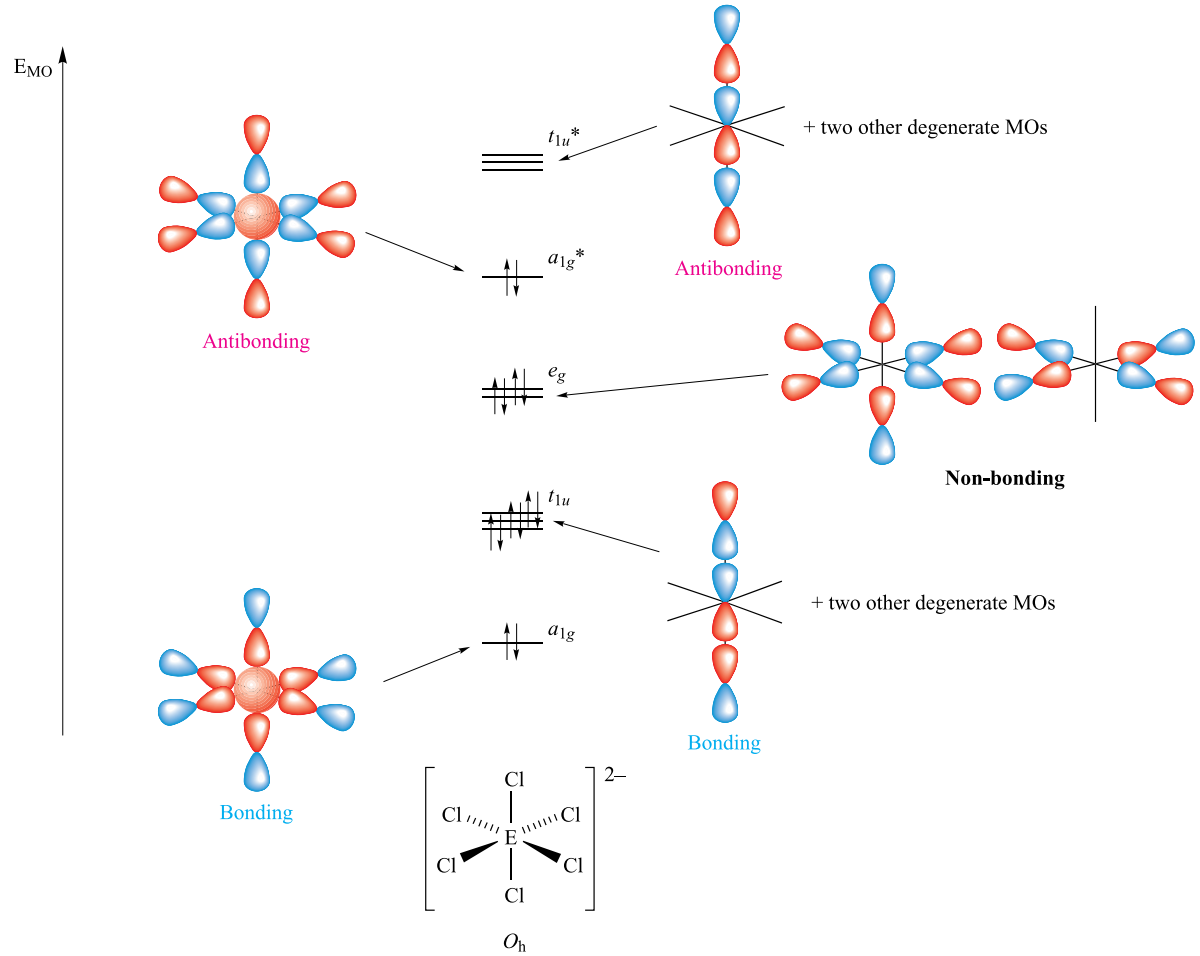
Both $SeCl_4$ and $TeCl_4$ are readily hydrolysed by water, but with group 1 metal chlorides in the presence of concentrated HCl, yellow complexes such as $K_2[SeCl_6]$ and $K_2[TeCl_6]$ are formed. Reaction 16.80 is an alternative route to $[TeCl_6]^{2-}$, while $[SeCl_6]^{2-}$ is formed when $SeCl_4$ is dissolved in molten $SbCl_3$ (eq. 16.81).

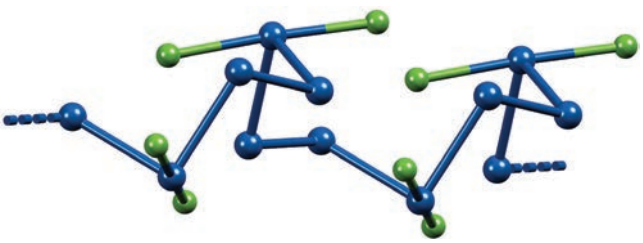
$$TeCl_4 + 2^tBuNH_2 + 2HCl \longrightarrow 2[^tBuNH_3]^+ + [TeCl_6]^{2-} \qquad (16.80)$$

$$2SbCl_3 + SeCl_4 \rightleftharpoons 2[SbCl_2]^+ + [SeCl_6]^{2-} \qquad (16.81)$$

The $[SeCl_6]^{2-}$ and $[TeCl_6]^{2-}$ ions usually (see below) possess *regular octahedral* structures (O_h symmetry), rather than the distorted structure (with a stereochemically active lone pair) that would be expected on the basis of the VSEPR model. It may be argued that a change from a distorted to a regular octahedral structure arises from a decrease in stereochemical activity of the lone pair as the steric crowding of the ligands increases,[†] e.g. on going from $[SeF_6]^{2-}$ to $[SeCl_6]^{2-}$. However, as we have already noted, the origins of the distortion in $[SeF_6]^{2-}$ in the solid state are not unambiguous because of the presence of cation–anion hydrogen-bonded interactions. This word of caution extends to other examples where the nature of the cation influences the structure of the anion in the *solid state*. For example, in $[H_3N(CH_2)_3NH_3][TeCl_6]$, the $[TeCl_6]^{2-}$ ion has approximately C_{2v} symmetry, and in $[^tBuNH_3]_2[TeBr_6]$, the $[TeBr_6]^{2-}$ ion has approximately C_{3v} symmetry. For the octahedral anions, a molecular orbital scheme can be developed (Fig. 16.16) that uses only the valence shell 4*s* and 4*p* (Se) or 5*s* and 5*p* (Te) orbitals. Combined with six Cl 3*p* orbitals, this leads to seven occupied MOs in $[ECl_6]^{2-}$ (E = Se, Te), of which four have bonding character, two have non-bonding character, and one has antibonding character. The net number of bonding MOs is therefore three, and the net E−Cl bond order is 0.5.

[†] For a fuller discussion of these ideas, see: R.J. Gillespie and P.L.A. Popelier (2001) *Chemical Bonding and Molecular Geometry*, OUP, Oxford, Chapter 9. For a theoretical investigation of $[EX_6]^{n-}$ species, see: M. Atanasov and D. Reinen (2005) *Inorg. Chem.*, vol. 44, p. 5092.





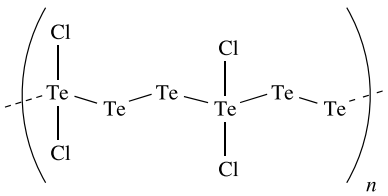


Fig. 16.16. An MO diagram for octahedral $[ECl_6]^{2-}$ (E = Se or Te) using a valence set of 4*s* and 4*p* orbitals for Se or 5*s* and 5*p* orbitals for Te. These orbitals overlap with Cl 3*p* orbitals. The diagram can be derived from that for SF_6 described in Figs. 5.27 and 5.28.

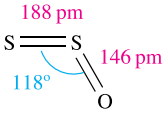
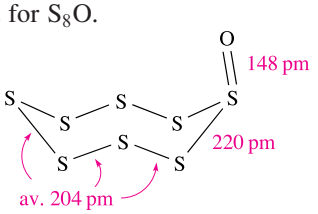
Tellurium forms a series of subhalides, e.g. Te_3Cl_2 and Te_2Cl, the structures of which can be related to the helical chains in elemental Te. When Te is oxidized to Te_3Cl_2, oxidation of one in three Te atoms occurs to give polymer **16.42**.



(16.42)



16.8 Oxides

Oxides of sulfur

The most important oxides of sulfur are SO_2 and SO_3, but there are also a number of unstable oxides. Among these are S_2O (**16.43**) and S_8O (**16.44**), made by reactions 16.82 and 16.83. The oxides S_nO (n = 6–10) can be prepared by reaction 16.84, exemplified for S_8O.

(16.43)

(16.44)

$$SOCl_2 + Ag_2S \xrightarrow{430\ K} S_2O + 2AgCl \qquad (16.82)$$

$$HS_7H + SOCl_2 \longrightarrow S_8O + 2HCl \qquad (16.83)$$

$$S_8 \xrightarrow{CF_3C(O)OOH} S_8O \qquad (16.84)$$

Table 16.7 Selected physical properties of SO_2 and SO_3.

Property	SO_2	SO_3
Physical appearance and general characteristics	Colourless, dense gas; pungent smell	Volatile white solid, or a liquid
Melting point / K	197.5	290
Boiling point / K	263.0	318
$\Delta_{vap}H^{\circ}$(bp) / kJ mol^{-1}	24.9	40.7
$\Delta_f H^{\circ}$(298 K) / kJ mol^{-1}	−296.8 (SO_2, g)	−441.0 (SO_3, l)
Dipole moment / D	1.63	0
S−O bond distance / pm *	143	142
∠O−S−O / deg *	119.5	120

* Gas phase parameters; for SO_3, data refer to the monomer.

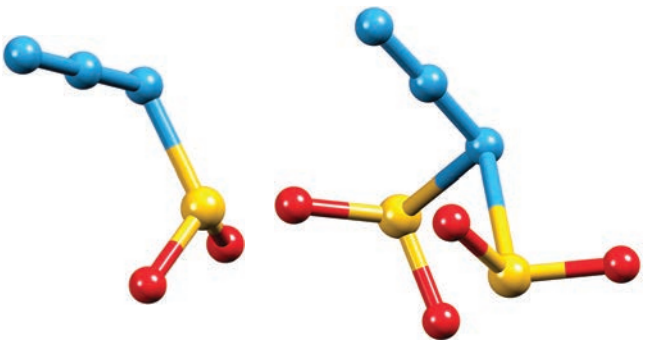
Sulfur dioxide is manufactured on a large scale by burning sulfur (the most important process) or H_2S, by roasting sulfide ores (e.g. eq. 16.85), or reducing $CaSO_4$ (eq. 16.86). Desulfurization processes to limit SO_2 emissions (see Box 12.2) and reduce acid rain (see Box 16.5) are now in use. In the laboratory, SO_2 may be prepared by reaction 16.87, and it is commercially available in cylinders. Selected physical properties of SO_2 are listed in Table 16.7.

$$4FeS_2 + 11O_2 \xrightarrow{\Delta} 2Fe_2O_3 + 8SO_2 \qquad (16.85)$$

$$CaSO_4 + C \xrightarrow{>1620\,K} CaO + SO_2 + CO \qquad (16.86)$$

$$Na_2SO_3 + 2HCl \xrightarrow[conc]{} SO_2 + 2NaCl + H_2O \qquad (16.87)$$

The boiling point of SO_2 is 263 K, but it can be safely handled in a sealed tube at room temperature under its own vapour pressure. It is a good solvent with a wide range of uses (see Section 9.8). Sulfur dioxide has a molecular structure. A bent molecule is consistent with the VSEPR model; bond parameters for gas phase SO_2 are given in structure **16.45**, along with resonance structures.



S–O = 143 pm
∠O–S–O = 119.5°

(16.45)

Sulfur dioxide reacts with O_2 (see below), F_2 and Cl_2 (eq. 16.88). It also reacts with the heavier alkali metal fluorides to give metal fluorosulfites (eq. 16.89), and with CsN_3 to give the Cs^+ salts of $[SO_2N_3]^-$ (Fig. 16.17a) and $[(SO_2)_2N_3]^-$ (Fig. 16.17b). The latter is formed when CsN_3 dissolves in liquid SO_2 at 209 K. On raising the temperature to 243 K, $[(SO_2)_2N_3]^-$ loses one equivalent of SO_2 to yield $[SO_2N_3]^-$. The highly explosive diazide $SO_2(N_3)_2$ is formed by reacting SO_2Cl_2 with NaN_3 in MeCN (the solvent is critical).† The structure of $SO_2(N_3)_2$ is analogous to that of SO_2Cl_2 (**16.38**).

ENVIRONMENT

Box 16.5 The contribution of SO_2 to acid rain

Despite being recognized as far back as the 1870s, the environmental problems associated with 'acid rain' came to the fore in the 1960s with the decline of fish stocks in European and North American lakes. Two of the major contributors towards acid rain are SO_2 and NO_x. (In Section 25.8, we discuss the use of catalytic converters to combat pollution due to nitrogen oxides, NO_x.) Although SO_2 emissions arise from natural sources such as volcanic eruptions, artificial sources contribute ≈90% of the sulfur in the atmosphere. Fossil fuels such as coal contain ≈2–3% sulfur and combustion produces SO_2. This is being countered by the recovery of sulfur from petroleum (Fig. 16.2). Sulfur dioxide is released when metal sulfide ores are roasted in the production of metals such as Co, Ni, Cu and Zn, for example:

$$Cu_2S + O_2 \xrightarrow{\Delta} 2Cu + SO_2$$

However, this source of SO_2 is now utilized for the production of sulfuric acid (see Fig. 16.2 and accompanying text). Once released into the atmosphere, SO_2 dissolves in water vapour, forming H_2SO_3 and H_2SO_4. Acid formation may take several days and involves multi-stage reactions, the outcome of which is:

$$2SO_2 + O_2 + 2H_2O \longrightarrow 2H_2SO_4$$

By the time acid rain falls to the Earth's surface, the pollutants may have travelled long distances from their industrial sources. For example, prevailing winds in Europe may carry SO_2 from the UK, France and Germany to Scandinavia.

The effects of acid rain can be devastating. The pH of lakes and streams is lowered, although the composition of the bedrock is significant, and in some cases provides a natural buffering effect. A second effect is that acid rain penetrating the bedrock can react with aluminosilicate minerals, or can leach heavy metal ions from the bedrock. As the acid rain makes its way through the bedrock and into waterways, it carries with it the metal pollutants. Acidified and polluted waters not only kill fish, but also affect the food chain. Acid rain falling on soils may be neutralized if the soil is alkaline, but otherwise the lowering of the pH and the leaching of plant nutrients has devastating effects on vegetation. The effects of acid rain on some building materials are all around us: crumbling gargoyles on ancient churches are a sad reminder of pollution by acid rain. The photograph illustrates the damage caused by acid rain to one of the limestone gargoyles on Notre Dame Cathedral in Paris. The cathedral was completed in 1345, and photographic records in the 20th century show that fine detail in the stone carving was still present in 1920. Between 1920 and ≈1990, coincident with the growth of industrialized nations, significant corrosion occurred, caused predominantly by acid rain.

International legislation to reduce acidic gas emissions has been in operation since the 1980s. Emissions of SO_2 and NO_2 in Europe climbed steadily after 1920. Maximum emissions of 62 Mt of SO_2 were recorded in 1980, while emissions of NO_2 peaked at 29 Mt in 1990. The effects of legislation have been significant reductions in both SO_2 and NO_2 emissions with projected values of 18 and 15 Mt per year, respectively, by 2020. Recent environmental studies indicate some improvement in the state of Western European and North American streams and lakes.

A gargoyle on Notre Dame Cathedral, Paris, photographed in 2012. The damage to the limestone has been caused mainly by acid rain.

For related information: see Box 12.2: Desulfurization processes to limit SO_2 emissions; Box 16.6: Volcanic emissions.

In aqueous solution, SO_2 is converted to only a small extent to sulfurous acid. Aqueous solutions of H_2SO_3 contain significant amounts of dissolved SO_2 (see eqs. 7.18–7.20). Sulfur dioxide is a weak reducing agent in acidic solution, and a slightly stronger one in basic media (eqs. 16.90 and 16.91).

$$[SO_4]^{2-}(aq) + 4H^+(aq) + 2e^- \rightleftharpoons H_2SO_3(aq) + H_2O(l) \qquad E^\circ = +0.17\,V \qquad (16.90)$$

$$[SO_4]^{2-}(aq) + H_2O(l) + 2e^- \rightleftharpoons [SO_3]^{2-}(aq) + 2[OH]^-(aq) \qquad E^\circ_{[OH^-]=1} = -0.93\,V \qquad (16.91)$$

Thus, aqueous solutions of SO_2 are oxidized to sulfate by many oxidizing agents (e.g. I_2, $[MnO_4]^-$, $[Cr_2O_7]^{2-}$ and Fe^{3+} in acidic solutions). However, if the concentration of H^+ is very high, $[SO_4]^{2-}$ can be reduced to SO_2 as in, for example, reaction 16.92; the dependence of E on $[H^+]$ is detailed in Section 8.2.

$$Cu + \underset{\text{conc}}{2H_2SO_4} \longrightarrow SO_2 + CuSO_4 + 2H_2O \qquad (16.92)$$

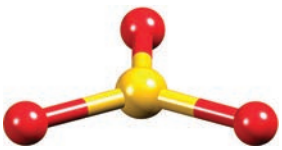
In the presence of concentrated HCl, SO_2 will itself act as an oxidizing agent; in reaction 16.93, the Fe(III) produced is then complexed by Cl^-.

$$\left.\begin{aligned} SO_2 + 4H^+ + 4Fe^{2+} &\longrightarrow S + 4Fe^{3+} + 2H_2O \\ Fe^{3+} + 4Cl^- &\longrightarrow [FeCl_4]^- \end{aligned}\right\} \qquad (16.93)$$

The oxidation of SO_2 by atmospheric O_2 (eq. 16.94) is very slow, but is catalysed by V_2O_5 (see Section 25.8). This is the first step in the *Contact process* for the manufacture of sulfuric acid. Operating conditions are crucial since equilibrium 16.94 shifts further towards the left-hand side as the temperature is raised, although the yield can be increased somewhat by use of high pressures of air. In practice, the industrial catalytic process operates at ≈750 K and achieves conversion factors of >98%.

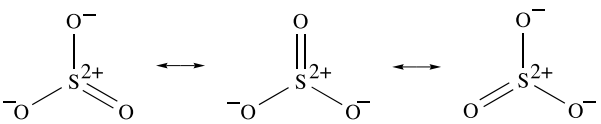
$$2SO_2 + O_2 \rightleftharpoons 2SO_3 \quad \Delta_r H^\circ = -96\,kJ \text{ per mole of } SO_2 \qquad (16.94)$$

Self-study exercise



For the equilibrium:

$$SO_2(g) + \tfrac{1}{2}O_2(g) \rightleftharpoons SO_3(g)$$



values of $\ln K$ are 8.04 and −1.20 at 1073 and 1373 K respectively. Determine ΔG° at each of these temperatures and comment on the significance of the data with respect to the application of this equilibrium in the first step in the manufacture of H_2SO_4.

[*Ans.* $\Delta G^\circ(1073\,K) = -71.7\,kJ\,mol^{-1}$; $\Delta G^\circ(1373\,K) = +13.7\,kJ\,mol^{-1}$]

In the manufacture of sulfuric acid, gaseous SO_3 is removed from the reaction mixture by passage through concentrated H_2SO_4, in which it dissolves to form *oleum* (see Section 16.9). Absorption into water to yield H_2SO_4 directly is not a viable option because SO_3 reacts vigorously and very exothermically with H_2O, forming a thick mist. On a small scale, SO_3 can be prepared by heating oleum.

(16.46)

(16.47)

Table 16.7 lists selected physical properties of SO_3. In the gas phase, it is an equilibrium mixture of monomer (planar

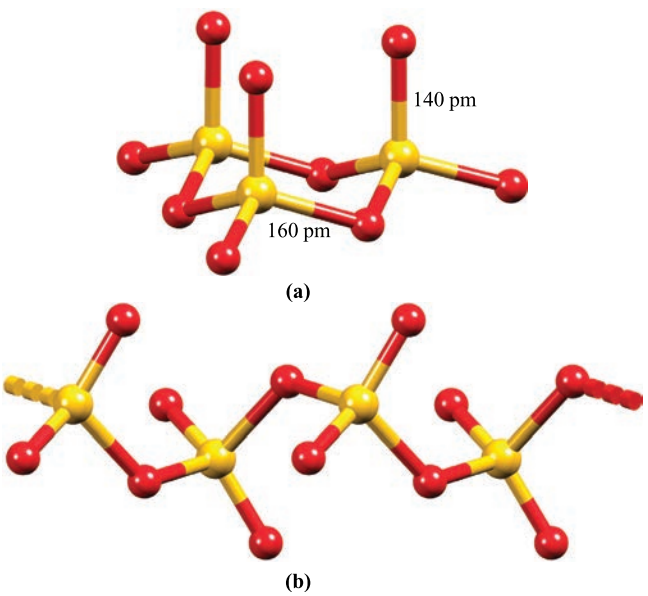


Fig. 16.18. The structures of solid state polymorphs of sulfur trioxide contain tetrahedral SO_4 units: (a) γ-SO_3 consists of trimeric units and (b) α- and β-SO_3 contain polymeric chains. Colour code: S, yellow; O, red.

ENVIRONMENT

Box 16.6 Volcanic emissions

The eruption of a volcano is accompanied by emissions of water vapour (>70% of the volcanic gases), CO_2 and SO_2 plus lower levels of CO, sulfur vapour and Cl_2. Carbon dioxide contributes to the 'greenhouse' effect, and it has been estimated that volcanic eruptions produce ≈112 million tonnes of CO_2 per year. Levels of CO_2 in the plume of a volcano can be monitored by IR spectroscopy (the asymmetric stretching mode of the linear CO_2 molecule is observed at 2349 cm^{-1}). Ultraviolet spectroscopy is used to monitor SO_2 (it absorbs at ≈300 nm).

Mount Etna in southern Italy is classed as a 'continuously degassing' volcano and its emissions of SO_2 are among the largest of any volcano. In 1991, its SO_2 emission rate of ≈4000–5000 Mg day^{-1} was estimated to be similar to the total industrial sulfur emissions from France. Sulfur dioxide emissions are particularly damaging to the environment, since they result in the formation of acid rain. Sulfuric acid aerosols persist as suspensions in the atmosphere for long periods after an eruption. The Mount St Helens eruption occurred in May 1980. Towards the end of the eruption, the level of SO_2 in the volcanic plume was ≈2800 tonnes per day, and an emission rate of ≈1600 tonnes per day was measured in July 1980. Emissions of SO_2 (diminishing with time after the major eruption) continued for over two years, being boosted periodically by further volcanic activity.

Related discussions: see Box 12.2; Box 14.7; Box 16.5.

Explosive eruption of Mount St Helens, Washington, US on 22 July 1980.

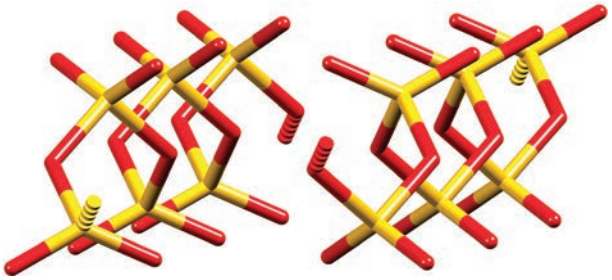
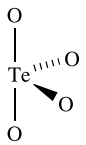
molecules, **16.46**, S−O = 142 pm) and trimer. Resonance structures **16.47** are consistent with three equivalent S−O bonds, and with the S atom possessing an octet of electrons. Solid SO_3 is polymorphic, with all forms containing SO_4-tetrahedra sharing two oxygen atoms. Condensation of the vapour at low temperatures yields γ-SO_3 which contains trimers (Fig. 16.18a); crystals of γ-SO_3 have an ice-like appearance. In the presence of traces of water, white crystals of β-SO_3 form; β-SO_3 consists of polymeric chains (Fig. 16.18b), as does α-SO_3 in which the chains are arranged into layers in the solid state. Differences in the thermodynamic properties of the different polymorphs are very small, although they do react with water at different rates. Sulfur trioxide is very reactive and representative reactions are given in scheme 16.95.



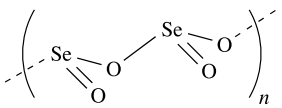
(16.95)

Self-study exercise

The diagram on the next page shows parts of two adjacent chains in the solid state structure of β-SO_3. (a) Explain why each chain is chiral. (b) What is the relationship between the structures of the two chains? (c) The crystal

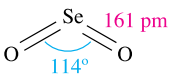


lattice of β-SO_3 contains equal numbers of the two chains shown below. Why is the overall structure achiral?



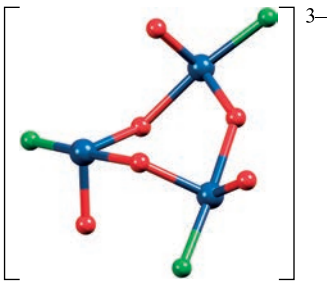
[*Ans.* See Section 3.8; the backbone of the chain in β-SO_3 is helical]

Oxides of selenium and tellurium

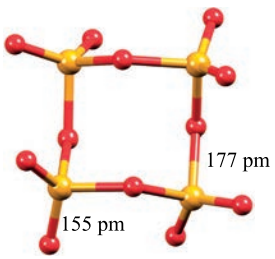


Selenium and tellurium dioxides are white solids obtained by direct combination of the elements. The reaction of Te with O_2 gives α-TeO_2, whereas a second polymorph, β-TeO_2, occurs naturally as the mineral *tellurite*. Both forms of TeO_2 contain structural units **16.48** which are connected by shared O atoms into a 3-dimensional lattice in α-TeO_2, and into a sheet structure in the β-form. The structure of SeO_2 consists of chains (**16.49**) in which the Se centres are in trigonal pyramidal environments. Whereas SeO_2 sublimes at 588 K, TeO_2 is an involatile solid (mp 1006 K). In the gas phase, SeO_2 is monomeric with structure **16.50**. Resonance structures for SeO_2 can be drawn as for SO_2 (structure **16.45**). The trends in structures of the dioxides of S, Se and Te and their associated properties (e.g. mp, volatility) reflect the increase in metallic character on descending group 16.

(16.48)



(16.49)



(16.50)

Selenium dioxide is very toxic and is readily soluble in water to give selenous acid, H_2SeO_3. It is readily reduced, e.g. by hydrazine, and is used as an oxidizing agent in organic reactions. The α-form of TeO_2 is sparingly soluble in water, giving H_2TeO_3, but is soluble in aqueous HCl and alkali. Like SeO_2, TeO_2 is a good oxidizing agent. Like SO_2, SeO_2 and TeO_2 react with KF (see eq. 16.89). In solid $K[SeO_2F]$, weak fluoride bridges link the $[SeO_2F]^-$ ions into chains. In contrast, the tellurium analogue contains trimeric anions (structure **16.51**, see worked example 16.4). Selenium trioxide is a white, hygroscopic solid. It is difficult to prepare, being thermodynamically unstable with respect to SeO_2 and O_2 ($\Delta_f H^o$(298 K): $SeO_2 = -225$; $SeO_3 = -184\,kJ\,mol^{-1}$). It may be made by reaction of SO_3 with K_2SeO_4 (a salt of selenic acid). Selenium trioxide decomposes at 438 K, is soluble in water, and is a stronger oxidizing agent than SO_3. In the solid state, tetramers (**16.52**) are present.

(16.51)

(16.52)

Tellurium trioxide (the α-form) is formed by dehydrating telluric acid (eq. 16.96). It is an orange solid which is insoluble in water but dissolves in aqueous alkali, and is a very powerful oxidizing agent. On heating above 670 K, TeO_3 decomposes to TeO_2 and O_2. Solid TeO_3 has a 3-dimensional structure in which each Te(VI) centre is octahedrally sited and connected by bridging O atoms.

$$H_6TeO_6 \longrightarrow TeO_3 + 3H_2O \qquad (16.96)$$

Worked example 16.4 Selenium and tellurium oxides and their derivatives

Structure 16.51 shows a representation of $[Te_3O_6F_3]^{3-}$. Rationalize why the coordination environment of the Te atom is *not* tetrahedral.

Apply the VSEPR model to structure **16.51**:

Te is in group 16 and has six valence electrons.

The formation of Te−F and three Te−O bonds (terminal and two bridging O atoms) adds four more electrons to the valence shell of Te.

In $[Te_3O_6F_3]^{3-}$, each Te centre is surrounded by five electron pairs, of which one is a lone pair.

Within the VSEPR model, a trigonal bipyramidal coordination environment is expected.

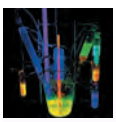
Self-study exercises

1. Draw a resonance structure for Se_4O_{12} (**16.52**) that is consistent with selenium retaining an octet of electrons. [*Hint*: See structure **16.47**]
2. Explain what is meant by the phrase 'TeO_2 is dimorphic'.

3. SeO_2 is soluble in aqueous NaOH. Suggest what species are formed in solution, and write equations for their formation. [*Ans.* $[SeO_3]^{2-}$ and $[HSeO_3]^-$]

4. 'TeO_2 is amphoteric'. Explain what this statement means. [*Ans.* See Section 7.8]

16.9 Oxoacids and their salts



By way of an introduction to oxoacids, we note some generalities:

- oxoacid chemistry of sulfur resembles the complicated system of phosphorus;
- there are structural analogies between sulfates and phosphates, although fewer condensed sulfates are known;
- redox processes involving sulfur oxoanions are often slow, and thermodynamic data alone do not give a very good picture of their chemistry (compare similar situations for nitrogen- and phosphorus-containing oxoanions);
- selenium and tellurium have a relatively simple oxoacid chemistry.

Structures and pK_a values for important sulfur oxoacids are given in Table 16.8.

Dithionous acid, $H_2S_2O_4$

Although we show the structure of dithionous acid in Table 16.8, only its salts are known and these are powerful

APPLICATIONS

Box 16.7 SO_2 and sulfites in wine

During the fermentation process in the manufacture of wine, SO_2 or $K_2S_2O_5$ is added to the initial wine pressings to kill microorganisms, the presence of which results in spoilage of the wine. Molecular SO_2 is only used for large-scale wine production, while $K_2S_2O_5$ is the common additive in small-scale production. In acidic solution, $[S_2O_5]^{2-}$ undergoes the following reactions:

$$[S_2O_5]^{2-} + H_2O \rightleftharpoons 2[HSO_3]^-$$

$$[HSO_3]^- + H^+ \rightleftharpoons SO_2 + H_2O$$

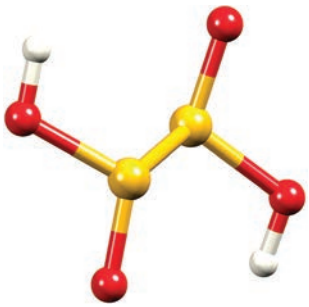
The overall equilibrium system for aqueous SO_2 is:

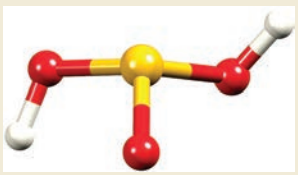
$$SO_2 + H_2O \rightleftharpoons H^+ + [HSO_3]^- \rightleftharpoons 2H^+ + [SO_3]^{2-}$$

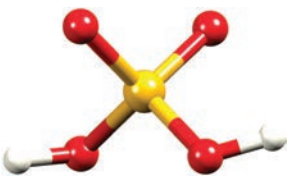
(These equilibria are discussed more fully with eqs. 7.18–7.20.) The position of equilibrium is pH-dependent; for the fermentation process, the pH is in the range 2.9–3.6. Only *molecular* SO_2 is active against microorganisms.

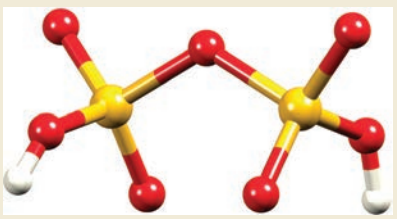
The first (i.e. yeast) fermentation step is followed by a bacterial fermentation step (malolactic fermentation) in which malic acid is converted to lactic acid. After this stage, SO_2 is added to stabilize the wine against oxidation. Adding SO_2 too early destroys the bacteria that facilitate malolactic fermentation. Malolactic fermentation is usually only important in red wine production.

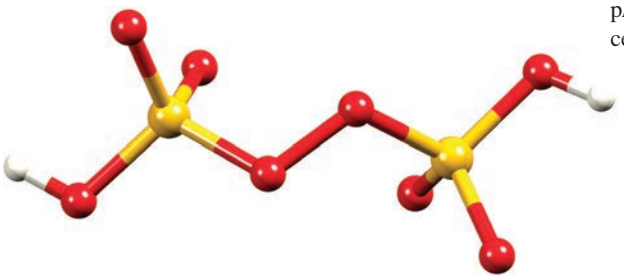
The addition of SO_2 to white and red wines is handled differently. Red wines contain anthocyanin pigments, and these react with $[HSO_3]^-$ or $[SO_3]^{2-}$, resulting in a partial loss of the red coloration. Clearly, this must be avoided and means that addition of SO_2 to red wine must be carefully controlled. On the other hand, significantly more SO_2 can be added to white wine. Red wine, therefore, is less well protected by SO_2 against oxidation and spoilage by microorganisms than white wine, and it is essential to ensure that sugar and malic acid (food for the microbes) are removed from red wine before bottling. Red wine does possess a higher phenolic content than white wine, and this acts as a built-in anti-oxidant.

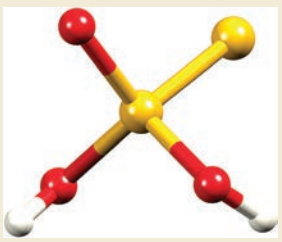






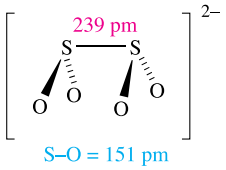






Red wine contains anthocyanin pigments which react with $[SO_3]^{2-}$ and $[HSO_3]^-$.

Wines manufactured in the US carry a '*contains sulfites*' statement on the label. Some people are allergic to sulfites, and one possible substitute for SO_2 is the enzyme lysozyme. Lysozyme attacks lactic bacteria, and is used in cheese manufacture. However, it is not able to act as an anti-oxidant. A possible solution (not yet adopted by the wine industry) would be to mount a combined offensive: adding lysozyme and a reduced level of SO_2.



[Dr Paul Bowyer is acknowledged for assistance with the content of this box.]

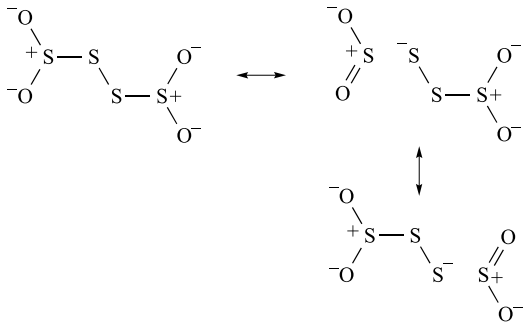
Table 16.8 Selected oxoacids of sulfur.[†]

Formula	Name	Structure[‡]	pK_a values (298 K)
$H_2S_2O_4$	Dithionous acid		$pK_a(1) = 0.35$; $pK_a(2) = 2.45$
H_2SO_3	Sulfurous acid*		$pK_a(1) = 1.82$; $pK_a(2) = 6.92$
H_2SO_4	Sulfuric acid		$pK_a(2) = 1.92$
$H_2S_2O_7$	Disulfuric acid		$pK_a(1) = 3.1$
$H_2S_2O_8$	Peroxydisulfuric acid		pK_a values not known with certainty.
$H_2S_2O_3$	Thiosulfuric acid		$pK_a(1) = 0.6$; $pK_a(2) = 1.74$

[†] Commonly used names have been included in this table; for systematic additive names and comments on uses of traditional names, see: *IUPAC*: *Nomenclature of Inorganic Chemistry* (*Recommendations 2005*), senior eds N.G. Connelly and T. Damhus, RSC Publishing, Cambridge.
[‡] See text; not all the acids can be isolated.
* See text for comment on structure of conjugate base.

reducing agents. Dithionite is prepared by reduction of sulfite in aqueous solution (eq. 16.97) by Zn or Na amalgam and possesses eclipsed structure **16.53**.

(16.53)



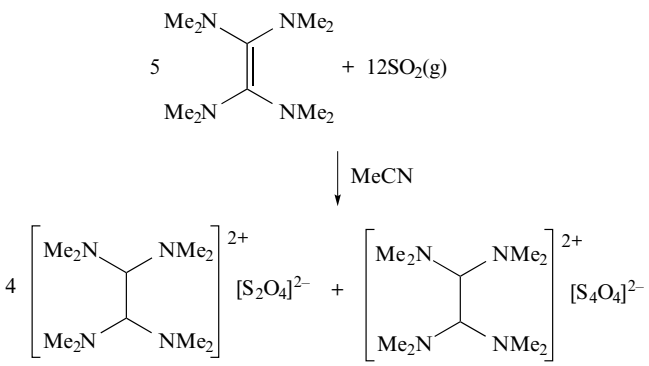
$$2[SO_3]^{2-} + 2H_2O + 2e^- \rightleftharpoons 4[OH]^- + [S_2O_4]^{2-}$$

$$E^\circ = -1.12\,V \qquad (16.97)$$

The very long S–S bond in $[S_2O_4]^{2-}$ (compare $2 \times r_{cov}(S) = 206$ pm) shows it to be particularly weak and this is consistent with the observation that ^{35}S undergoes rapid exchange between $[S_2O_4]^{2-}$ and SO_2 in neutral or acidic solution. The presence of the $[SO_2]^-$ radical anion in solutions of $Na_2S_2O_4$ has been demonstrated by EPR spectroscopy. In aqueous solutions, $[S_2O_4]^{2-}$ is oxidized by air but in the absence of air, it undergoes reaction 16.98.

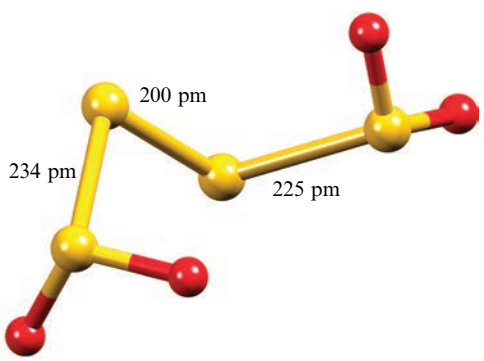
$$2[S_2O_4]^{2-} + H_2O \longrightarrow [S_2O_3]^{2-} + 2[HSO_3]^- \qquad (16.98)$$

The first polythionite $[S_4O_4]^{4-}$ salt was isolated in 2013 by using a large organic counterion (Fig. 16.19a). The alternation in S–S bond distances observed in the solid state structure (Fig. 16.19b) is consistent with contributions from the resonance structures **16.54**.



(16.54)

Sulfurous and disulfurous acids, H_2SO_3 and $H_2S_2O_5$

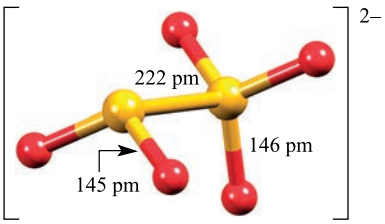


Neither 'sulfurous acid' (see also Section 16.8) nor 'disulfurous acid' has been isolated as a free acid. Salts containing the sulfite ion, $[SO_3]^{2-}$, are well established (e.g. Na_2SO_3 and K_2SO_3 are commercially available) and are quite good reducing agents (eq. 16.91). Applications of sulfites include those as food preservatives, e.g. an additive in wines (see Box 16.7). The $[SO_3]^{2-}$ ion has a trigonal pyramidal structure with delocalized bonding (S–O = 151 pm, ∠O–S–O = 106°). There is evidence from ^{17}O NMR spectroscopic data that protonation of $[SO_3]^{2-}$ occurs to give a mixture of isomers as shown in equilibrium 16.99.

(16.99)

Although the $[HSO_3]^-$ ion exists in solution, and salts such as $NaHSO_3$ (used as a bleaching agent) may be isolated,

(a)



(b)

Fig. 16.19. (a) The use of a bulky cation to stabilize the polythionite $[S_4O_4]^{4-}$ anion and (b) the structure of $[S_4O_4]^{4-}$ (X-ray diffraction) showing alternating S–S bond lengths [P. Bruna *et al.* (2013) *Inorg. Chem.*, vol. 52, p. 13651].

evaporation of a solution of $NaHSO_3$ which has been saturated with SO_2 yields $Na_2S_2O_5$ (eq. 16.100).

$$2[HSO_3]^- \rightleftharpoons H_2O + [S_2O_5]^{2-} \qquad (16.100)$$

The $[S_2O_5]^{2-}$ ion is the only known derived anion of disulfurous acid and possesses structure **16.55** with a long, weak S−S bond. The bond distances given in structure **16.55** are for the K^+ salt.

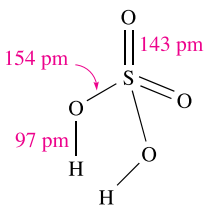
(16.55)

Dithionic acid, $H_2S_2O_6$

Dithionic acid is another sulfur oxoacid that is only known in aqueous solution (in which it behaves as a strong acid) or in the form of salts containing the dithionate, $[S_2O_6]^{2-}$, ion. Such salts can be isolated as crystalline solids and Fig. 16.20a shows the presence of a long S−S bond; the anion possesses a staggered conformation in the solid state. The dithionate ion can be prepared by controlled oxidation of $[SO_3]^{2-}$ (eqs. 16.101 and 16.102), but *not* by the reduction of $[SO_4]^{2-}$ (eq. 16.103). $[S_2O_6]^{2-}$ can be isolated as the soluble salt BaS_2O_6, which is easily converted into salts of other cations.

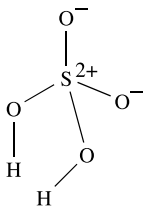
$$[S_2O_6]^{2-} + 4H^+ + 2e^- \rightleftharpoons 2H_2SO_3 \quad E^\circ = +0.56\,V \qquad (16.101)$$

$$MnO_2 + 2[SO_3]^{2-} + 4H^+ \longrightarrow Mn^{2+} + [S_2O_6]^{2-} + 2H_2O \qquad (16.102)$$



$$2[SO_4]^{2-} + 4H^+ + 2e^- \rightleftharpoons [S_2O_6]^{2-} + 2H_2O \quad E^\circ = -0.22\,V \qquad (16.103)$$

The $[S_2O_6]^{2-}$ ion is not easily oxidized or reduced, but in acidic solution it slowly decomposes according to eq. 16.104, consistent with there being a weak S−S bond.



$$[S_2O_6]^{2-} \longrightarrow SO_2 + [SO_4]^{2-} \qquad (16.104)$$

Sulfuric acid, H_2SO_4

Sulfuric acid is the most important of the oxoacids of sulfur and is manufactured by the *Contact process*. The first stages of this process (conversion of SO_2 to SO_3 and formation of oleum) were described in Section 16.8. The oleum is finally diluted with water to give H_2SO_4. Pure H_2SO_4 is a colourless liquid with a high viscosity caused by extensive intermolecular hydrogen bonding. Its self-ionization and use as a non-aqueous solvent were described in Section 9.8, and selected properties given in Table 9.6. Gas-phase H_2SO_4 molecules have C_2 symmetry (Fig. 16.20b) with S−O bond distances (157 and 142 pm) that reflect two different types of S−O bond. In the solid state, hydrogen bonding between adjacent H_2SO_4 molecules results in the formation of a 3-dimensional network (Fig. 16.21). Diagram **16.56** shows a hypervalent structure for H_2SO_4, and **16.57** gives a bonding scheme in which the S atom obeys the octet rule (refer back to the discussion of bonding in Section 16.3). In the sulfate ion, all four S−O bond distances are equal (149 pm) because of charge delocalization, and in $[HSO_4]^-$, the S−OH bond distance is 156 pm and the remaining S−O bonds are of equal length (147 pm).

(16.56)

(16.57)

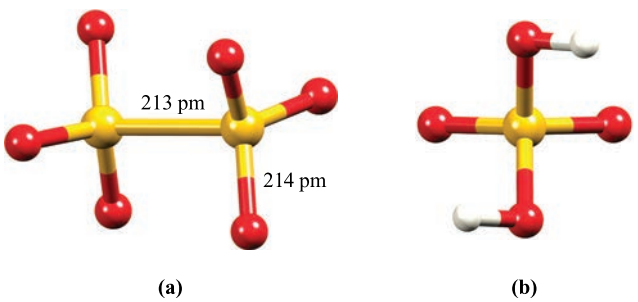


Fig. 16.20. (a) The structure of $[S_2O_6]^{2-}$ showing the staggered conformation; from the salt $[Zn\{H_2NNHC(O)Me\}_3][S_2O_6]\cdot 2.5H_2O$ [I.A. Krol *et al.* (1981) *Koord. Khim.*, vol. 7, p. 800]; (b) the C_2 structure of gas-phase H_2SO_4. Colour code: S, yellow; O, red; H, white.

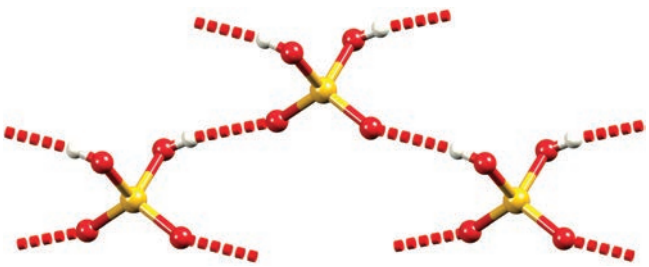

Fig. 16.21. Part of the 3-dimensional, hydrogen-bonded network of H_2SO_4 molecules in crystalline sulfuric acid. The structure was determined by X-ray diffraction at 113 K [E. Kemnitz *et al.* (1996) *Acta Crystallogr., Sect. C*, vol. 52, p. 2665]. Colour code: S, yellow; O, red; H, white.

In aqueous solution, H_2SO_4 acts as a strong acid (eq. 16.105) but the $[HSO_4]^-$ ion is a fairly weak acid (eq. 16.106 and Table 16.8). Two series of salts are formed and can be isolated, e.g. $KHSO_4$ and K_2SO_4.

$$H_2SO_4 + H_2O \longrightarrow [H_3O]^+ + [HSO_4]^- \quad (16.105)$$

$$[HSO_4]^- + H_2O \rightleftharpoons [H_3O]^+ + [SO_4]^{2-} \quad (16.106)$$

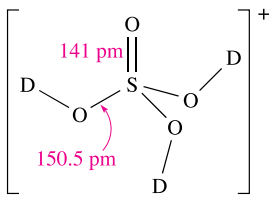
Dilute aqueous H_2SO_4 (typically 2 M) neutralizes bases (e.g. eq. 16.107), and reacts with electropositive metals, liberating H_2, and metal carbonates (eq. 16.108).

$$H_2SO_4(aq) + 2KOH(aq) \longrightarrow K_2SO_4(aq) + 2H_2O(l) \quad (16.107)$$

$$H_2SO_4(aq) + CuCO_3(s) \longrightarrow CuSO_4(aq) + H_2O(l) + CO_2(g) \quad (16.108)$$

Commercial applications of sulfate salts are numerous, e.g. $(NH_4)_2SO_4$ as a fertilizer, $CuSO_4$ in fungicides, $MgSO_4{\cdot}7H_2O$ (Epsom salt) as a laxative, and hydrated $CaSO_4$ (see Boxes 12.2 and 12.6). Uses of H_2SO_4 were included in Fig. 16.3.

Concentrated H_2SO_4 is a good oxidizing agent (e.g. reaction 16.92) and a powerful dehydrating agent (see Box 12.3). Its reaction with HNO_3 is important for organic nitrations (eq. 16.109).



$$HNO_3 + 2H_2SO_4 \longrightarrow [NO_2]^+ + [H_3O]^+ + 2[HSO_4]^- \quad (16.109)$$

Although HF/SbF_5 is a superacid, attempts to use it to protonate pure H_2SO_4 are affected by the fact that pure sulfuric acid undergoes reaction 16.110 to a small extent. The presence of the $[H_3O]^+$ ions in the HF/SbF_5 system prevents complete conversion of H_2SO_4 to $[H_3SO_4]^+$ (see worked example 16.5).

$$2H_2SO_4 \rightleftharpoons [H_3O]^+ + [HS_2O_7]^- \quad (16.110)$$

An ingenious method of preparing a salt of $[H_3SO_4]^+$ is to use reaction 16.111 which is thermodynamically driven by the high Si–F bond enthalpy term in Me_3SiF (see Table 14.2). In the solid state structure of $[D_3SO_4]^+[SbF_6]^-$ (made by using DF in place of HF), the cation has structure **16.58** and there are extensive O–D···F interactions between cations and anions.

$$\underset{\text{a silyl ester of } H_2SO_4}{(Me_3SiO)_2SO_2} + 3HF + SbF_5 \xrightarrow{\text{liquid HF}} [H_3SO_4]^+[SbF_6]^- + 2Me_3SiF \quad (16.111)$$

(16.58)

Worked example 16.5 Protonation of sulfuric acid

Reaction of HF/SbF_5 with H_2SO_4 does not result in complete protonation of sulfuric acid because of the presence of the $[H_3O]^+$ ions. (a) Explain the origin of the $[H_3O]^+$ ions and (b) explain how $[H_3O]^+$ interferes with attempts to use HF/SbF_5 to protonate H_2SO_4.

(a) Pure sulfuric acid undergoes self-ionization processes. The most important is:

$$2H_2SO_4 \rightleftharpoons [H_3SO_4]^+ + [HSO_4]^-$$

and the following dehydration process also occurs:

$$2H_2SO_4 \rightleftharpoons [H_3O]^+ + [HS_2O_7]^-$$

The equilibrium constants for these processes are 2.7×10^{-4} and 5.1×10^{-5} respectively (see eqs. 9.46 and 9.47).

(b) The equilibrium for the superacid system in the absence of pure H_2SO_4 is:

$$2HF + SbF_5 \rightleftharpoons [H_2F]^+ + [SbF_6]^-$$

$[H_2F]^+$ is a stronger acid than H_2SO_4 and, in theory, the following equilibrium should lie to the right:

$$H_2SO_4 + [H_2F]^+ \rightleftharpoons [H_3SO_4]^+ + HF$$

However, a competing equilibrium is established which arises from the self-ionization process of H_2SO_4 described in part (a):

$$HF + SbF_5 + 2H_2SO_4 \rightleftharpoons [H_3O]^+ + [SbF_6]^- + H_2S_2O_7$$

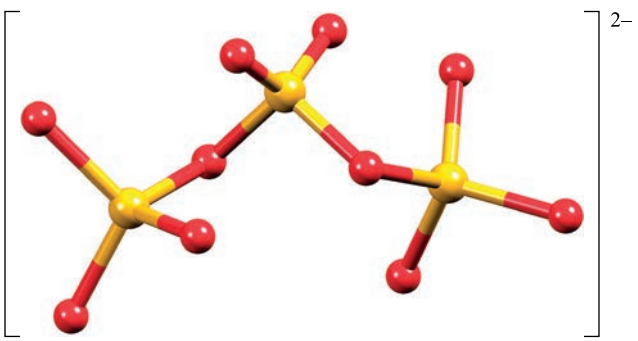
Since H_2O is a stronger base than H_2SO_4, protonation of H_2O is favoured over protonation of H_2SO_4.

Self-study exercises

1. The $[H_3SO_4]^+$ ion is formed when boric acid is dissolved in oleum. Draw the structure of the anion that is produced, and write a balanced equation for the reaction.

[*Ans.* See eq. 9.51]

2. The preparation of $[D_3SO_4]^+$ requires the use of DF. Suggest a method of preparing DF.
[*Ans.* See eq. 17.1]



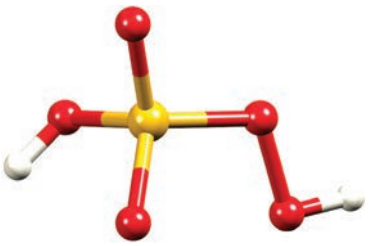
3. The methodology of reaction 16.111 has been used to protonate H_2O_2 and H_2CO_3. Write equations for these reactions and suggest structures for the protonated acids. [*Ans.* See R. Minkwitz *et al.* (1998, 1999) *Angew. Chem. Int. Ed.*, vol. 37, p. 1681; vol. 38, p. 714]

Fluoro- and chlorosulfonic acids, HSO_3F and HSO_3Cl

Fluoro- and chlorosulfonic acids, HSO_3F and HSO_3Cl, are obtained as shown in scheme 16.95, and their structures are related to that of H_2SO_4 with one OH group replaced by F or Cl. Both are colourless liquids at 298 K, and fume in moist air. HSO_3Cl reacts explosively with water. Both acids are commercially available. HSO_3F has wide applications in *superacid* systems (see Section 9.9) and as a fluorinating agent, while HSO_3Cl is used as a chlorosulfonating agent.

Polyoxoacids with S–O–S units

Although K^+ salts of the polysulfuric acids $HO_3S(OSO_2)_nOSO_3H$ ($n = 2, 3, 5, 6$) have been obtained by the reaction of SO_3 with K_2SO_4, the free acids cannot be isolated. Disulfuric and trisulfuric acids are present in oleum, i.e. when SO_3 is dissolved in concentrated H_2SO_4. The salts $[NO_2]_2[S_3O_{10}]$, $Pb[S_3O_{10}]$, $[NO_2]_2[S_4O_{13}]$[†] and $K_2[S_5O_{16}]$ have been prepared and structurally characterized. Structure **16.59** shows $[S_3O_{10}]^{2-}$ as a representative example of this group of polyoxoanions.



(16.59)

[†] For a discussion of the anions, see: C. Logemann *et al.* (2012) *Angew. Chem. Int. Ed.*, vol. 51, p. 4997; C. Logemann *et al.* (2012) *Z. Anorg. Allg. Chem.*, vol. 638, p. 758; J. Bruns *et al.* (2015) *Inorg. Chem.*, vol. 54, p. 5681.

Peroxysulfuric acids, $H_2S_2O_8$ and H_2SO_5

The reaction between cold, anhydrous H_2O_2 and chlorosulfonic acid yields peroxysulfuric acid, H_2SO_5, and peroxydisulfuric acid, $H_2S_2O_8$ (eq. 16.112). However, $H_2S_2O_8$ (Table 16.8) is readily hydrolysed to H_2SO_5 (**16.60**) (eq. 16.113).

(16.60)

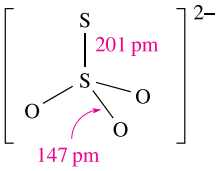
$$H_2O_2 \xrightarrow[-HCl]{ClSO_3H} H_2SO_5 \xrightarrow[-HCl]{ClSO_3H} H_2S_2O_8 \qquad (16.112)$$

$$H_2S_2O_8 + H_2O \xrightarrow{273\,K} H_2SO_5 + H_2SO_4 \qquad (16.113)$$

Both H_2SO_5 and $H_2S_2O_8$ are crystalline solids at 298 K. Few salts of H_2SO_5 are known, but those of $H_2S_2O_8$ are easily made by anodic oxidation of the corresponding sulfates in acidic solution at low temperatures and high current densities. Peroxydisulfates are strong oxidizing agents (eq. 16.114), and oxidations are often catalysed by Ag^+, with Ag(II) species being formed as intermediates. In acidic solutions, $[S_2O_8]^{2-}$ oxidizes Mn^{2+} to $[MnO_4]^-$, and Cr^{3+} to $[Cr_2O_7]^{2-}$.

$$[S_2O_8]^{2-} + 2e^- \rightleftharpoons 2[SO_4]^{2-} \qquad E^o = +2.01\,V \qquad (16.114)$$

Peroxydisulfuric acid smells of ozone, and when $K_2S_2O_8$ is heated, a mixture of O_2 and O_3 is produced.



Thiosulfuric acid, $H_2S_2O_3$, and polythionates

Thiosulfuric acid may be prepared under *anhydrous* conditions by reaction 16.115, or by treatment of lead thiosulfate (PbS_2O_3) with H_2S, or sodium thiosulfate with HCl. The free acid is very unstable, decomposing at 243 K or upon contact with water.

$$H_2S + HSO_3Cl \xrightarrow{\text{low temp}} H_2S_2O_3 + HCl \qquad (16.115)$$

A representation of the structure of thiosulfuric acid is given in Table 16.8, but the conditions of reaction 16.115 may suggest protonation at sulfur, i.e. $(HO)(HS)SO_2$. Thiosulfate salts are far more important than the acid. Crystallization of the aqueous solution from reaction 16.116 yields $Na_2S_2O_3{\cdot}5H_2O$.

$$Na_2SO_3 + S \xrightarrow{\text{in aqueous solution}} Na_2S_2O_3 \qquad (16.116)$$

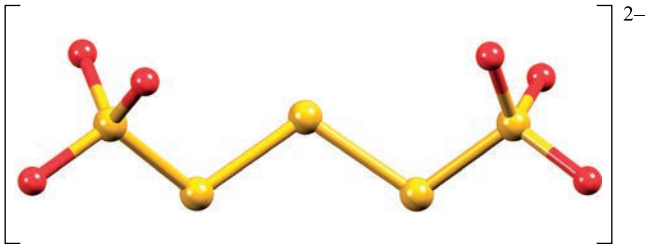
(16.61)

The thiosulfate ion, **16.61**, is a very good complexing agent for Ag^+, and $Na_2S_2O_3$ is used in photography for removing unchanged AgBr from exposed photographic film (eq. 16.117) although this use has declined dramatically as a result of the huge growth in digital photography. In $[Ag(S_2O_3)_3]^{5-}$, each thiosulfate ion coordinates to Ag^+ through a sulfur donor atom.

$$AgBr + 3Na_2S_2O_3 \longrightarrow Na_5[Ag(S_2O_3)_3] + NaBr \qquad (16.117)$$

Most oxidizing agents (including Cl_2 and Br_2) slowly oxidize $[S_2O_3]^{2-}$ to $[SO_4]^{2-}$, and $Na_2S_2O_3$ is used to remove excess Cl_2 in bleaching processes. In contrast, I_2 rapidly oxidizes $[S_2O_3]^{2-}$ to tetrathionate; reaction 16.118 is of importance in titrimetric analysis.

$$2[S_2O_3]^{2-} + I_2 \longrightarrow [S_4O_6]^{2-} + 2I^- \qquad (16.118)$$

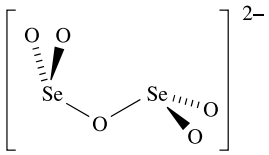


$$[S_4O_6]^{2-} + 2e^- \rightleftharpoons 2[S_2O_3]^{2-} \qquad E^\circ = +0.08\,V$$

$$I_2 + 2e^- \rightleftharpoons 2I^- \qquad E^\circ = +0.54\,V$$

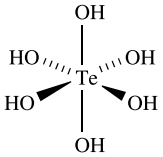
Polythionates contain ions of type $[S_nO_6]^{2-}$ and may be prepared by condensation reactions such as those in scheme 16.119, but some ions must be made by specific routes. Polythionate ions are structurally similar and have two $\{SO_3\}^-$ groups connected by a sulfur chain (**16.62** shows $[S_5O_6]^{2-}$). Solid state structures for a number of salts show chain conformations are variable. In aqueous solution, polythionates slowly decompose to H_2SO_4, SO_2 and sulfur.

$$\left.\begin{aligned} SCl_2 + 2[HSO_3]^- &\longrightarrow [S_3O_6]^{2-} + 2HCl \\ S_2Cl_2 + 2[HSO_3]^- &\longrightarrow [S_4O_6]^{2-} + 2HCl \end{aligned}\right\} \qquad (16.119)$$



Some compounds are known in which S atoms in a polythionate are replaced by Se or Te, e.g. $Ba[Se(SSO_3)_2]$ and $Ba[Te(SSO_3)_2]$. Significantly, Se and Te cannot replace the terminal S atoms, presumably because in their highest oxidation states they are too powerfully oxidizing and attack the remainder of the chain.

(16.62)



Oxoacids of selenium and tellurium

Selenous acid, H_2SeO_3, may be crystallized from aqueous solutions of SeO_2 and gives rise to two series of salts containing the $[HSeO_3]^-$ and $[SeO_3]^{2-}$ ions. In aqueous solution, it behaves as a weak acid: $pK_a(1) \approx 2.46$, $pK_a(2) \approx 7.31$. Heating salts of $[HSeO_3]^-$ generates diselenites containing ion **16.63**. Tellurous acid, H_2TeO_3, is not as stable as H_2SeO_3 and is usually prepared in aqueous solution where it acts as a weak acid: $pK_a(1) \approx 2.48$, $pK_a(2) \approx 7.70$. Most tellurite salts contain the $[TeO_3]^{2-}$ ion.

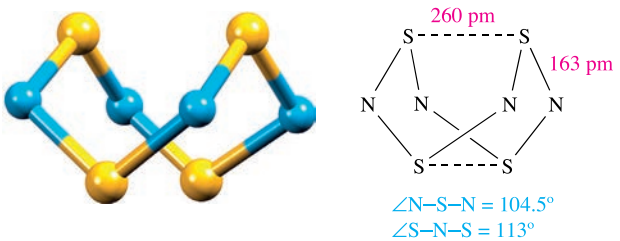
(16.63)

Oxidation of H_2SeO_3 with 30% aqueous H_2O_2 yields selenic acid, H_2SeO_4, which may be crystallized from the solution. In some ways it resembles H_2SO_4, being fully dissociated in aqueous solution with respect to loss of the first proton. For the second step, $pK_a = 1.92$. It is a more powerful oxidant than H_2SO_4, e.g. it liberates Cl_2 from concentrated HCl. Selenic acid dissolves gold metal, oxidizing it to Au(III). When the reaction is carried out at 520 K, the product is $Au_2(SeO_3)_2(SeO_4)$ which contains both tetrahedral $[SeO_4]^{2-}$ and trigonal pyramidal $[SeO_3]^{2-}$ ions. Reaction in the solid state between Na_2SeO_4 and Na_2O (2:1 molar equivalents) leads to $Na_6Se_2O_9$. This formula is more usefully written as $Na_{12}(SeO_6)(SeO_4)_3$, showing the presence of the octahedral $[SeO_6]^{6-}$ ion which is stabilized in the crystalline lattice by interaction with eight Na^+ ions. The $[SeO_5]^{4-}$ ion has been established in Li_4SeO_5 and Na_4SeO_5. The formula, H_6TeO_6 or $Te(OH)_6$, and properties of telluric acid contrast with those of selenic acid. In the solid, octahedral molecules (**16.64**) are present and in solution, it behaves as a weak acid: $pK_a(1) = 7.68$, $pK_a(2) = 11.29$. Typical salts include those containing $[Te(O)(OH)_5]^-$ and $[Te(O)_2(OH)_4]^{2-}$ and the presence of the $[TeO_4]^{2-}$ ion has been confirmed in the solid state structure of $Rb_6[TeO_5][TeO_4]$.

(16.64)

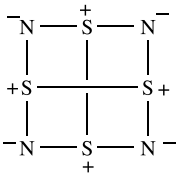
16.10 Compounds of sulfur and selenium with nitrogen

Sulfur–nitrogen compounds



Sulfur–nitrogen chemistry is an area that has seen major developments over the last few decades, in part because of the conductivity of the polymer $(SN)_x$. The following discussion is necessarily selective, and more detailed accounts are listed at the end of the chapter. Probably the best known of the sulfur–nitrogen compounds is tetrasulfur tetranitride, S_4N_4. It has traditionally been obtained using reaction 16.120, but a more convenient method is reaction 16.121. Tetrasulfur tetranitride is a diamagnetic orange solid (mp 451 K) which explodes when heated or struck. Pure samples are very sensitive (see exercise 1 at the end of the section). It is hydrolysed slowly by water (in which it is insoluble) and rapidly by warm alkali (eq. 16.122).

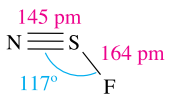
$$6S_2Cl_2 + 16NH_3 \xrightarrow{CCl_4,\ 320\ K} S_4N_4 + 12NH_4Cl + S_8 \qquad (16.120)$$



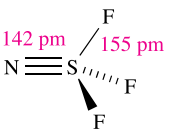
$$2\{(Me_3Si)_2N\}_2S + 2SCl_2 + 2SO_2Cl_2 \longrightarrow S_4N_4 + 8Me_3SiCl + 2SO_2 \qquad (16.121)$$

$$S_4N_4 + 6[OH]^- + 3H_2O \longrightarrow [S_2O_3]^{2-} + 2[SO_3]^{2-} + 4NH_3 \qquad (16.122)$$

The structure of S_4N_4, **16.65**, is a cradle-like ring in which pairs of S atoms are brought within weak bonding distance of one another (compare with $[S_8]^{2+}$, Fig. 16.8). The S−N bond distances in S_4N_4 indicate delocalized bonding with π-contributions (compare the S−N distances of 163 pm with the sum of the S and N covalent radii of 178 pm). Transfer of charge from S to N occurs giving $S^{\delta+}-N^{\delta-}$ polar bonds. A resonance structure for S_4N_4 that illustrates the cross-cage S−S bonding interactions is shown in **16.66**.



(16.65)



(16.66)

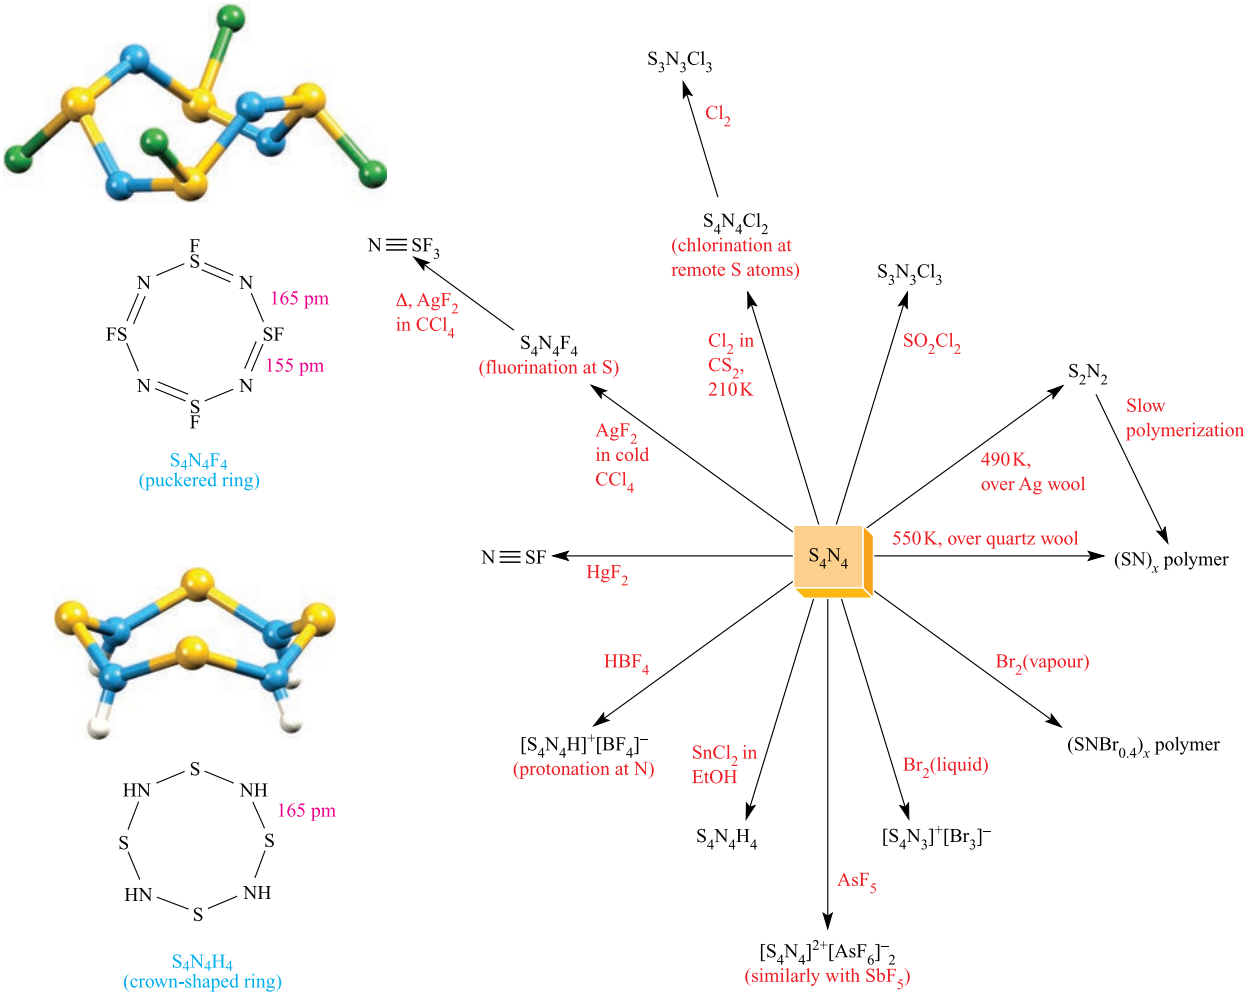
Figure 16.22 gives selected reactions of S_4N_4. Some lead to products containing S−N rings in which the cross-cage interactions of S_4N_4 are lost. Reduction (at N) gives tetrasulfur tetraimide, $S_4N_4H_4$, which has a crown-shaped ring with equal S−N bond lengths. Tetrasulfur tetraimide is one of a number of compounds in which S atoms in S_8 are formally replaced by NH groups with retention of the crown conformation; S_7NH, $S_6N_2H_2$, $S_5N_3H_3$ (along with S_4N_4 and S_8) are all obtained by treating S_2Cl_2 with NH_3. No members of this family with adjacent NH groups in the ring are known.

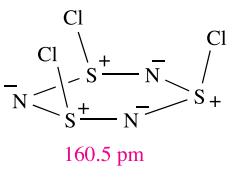
(16.67)

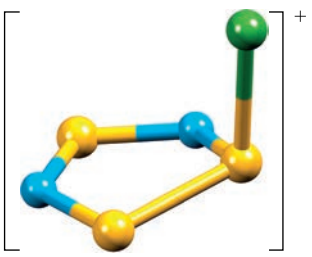
∠F–S–F = 94°
∠N–S–F = 122°

(16.68)

Halogenation of S_4N_4 (at S) may degrade the ring depending on X_2 or the conditions (Fig. 16.22). The ring in $S_4N_4F_4$ has a puckered conformation quite different from that in $S_4N_4H_4$. Fluorination of S_4N_4 under appropriate conditions (Fig. 16.22) yields thiazyl fluoride, NSF, **16.67**, or thiazyl trifluoride NSF_3, **16.68**, which contain S≡N triple bonds (see end-of-chapter problem 16.29a). Both are pungent gases at room temperature, and NSF slowly trimerizes to $S_3N_3F_3$; note that $S_4N_4F_4$ is not made from the monomer. The structures of $S_3N_3Cl_3$ (**16.69**) and $S_3N_3F_3$ are similar. The rings exhibit only slight puckering and the S−N bond distances are equal in $S_3N_3Cl_3$ and approximately equal in the fluoro analogue. The salt $[S_3N_2Cl]^+Cl^-$ (made by heating a mixture of S_2Cl_2, sulfur and NH_4Cl) contains cation **16.70**. Oxidation of S_4N_4 with AsF_5 or SbF_5 gives $[S_4N_4][EF_6]_2$ (E = As or Sb) containing $[S_4N_4]^{2+}$. This has the planar structure **16.71** in many of its salts, but $[S_4N_4]^{2+}$ can also adopt a planar structure with alternating bond distances, or a puckered conformation. The $[S_4N_3]^+$ cation (prepared as shown in Fig. 16.22) has the planar structure **16.72** with delocalized bonding.







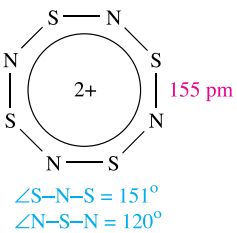


Fig. 16.22. Selected reactions of S_4N_4; the rings in $S_4N_4H_4$ and $S_4N_4F_4$ are non-planar.

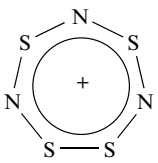
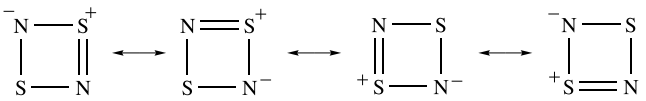
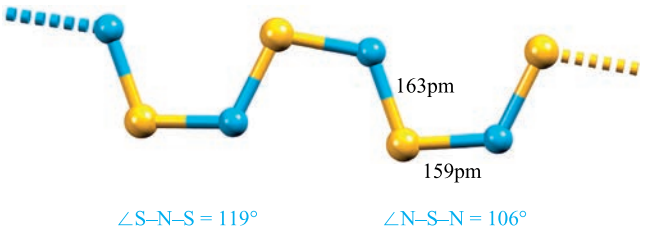


(16.69)

(16.70)



(16.71)

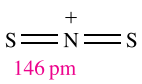


(16.72)

The S_4N_4 cage can be degraded to S_2N_2 (Fig. 16.22) which is isoelectronic with $[S_4]^{2+}$ (see Section 16.4). S_2N_2 is planar with delocalized bonding (S–N = 165 pm), and resonance structures are shown in **16.73**. At room temperature, this converts to the lustrous golden-yellow, fibrous polymer $(SN)_x$, which can also be prepared from S_4N_4. The polymer decomposes explosively at 520 K, but can be sublimed *in vacuo* at ≈410 K. It is a remarkable material, being covalently bonded but showing metallic properties: a 1-dimensional pseudo-metal. It has an electrical conductance about one-quarter of that of mercury in the direction of the polymer chains, and at 0.3 K it becomes a

superconductor. However, the explosive nature of S_4N_4 and S_2N_2 limits commercial production of $(SN)_x$. In the solid state, X-ray diffraction data indicate that the S−N bond lengths in $(SN)_x$ alternate (159 and 163 pm) but highly precise data are still not available; the closest interchain distances are non-bonding S−S contacts of 350 pm. Structure **16.74** gives a representation of the polymer chain and the conductivity can be considered to arise from the unpaired electrons on sulfur occupying a half-filled conduction band (see Section 6.8).

(16.73)



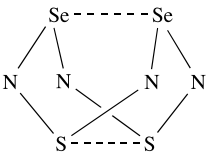
Colour code: S, yellow; N blue

(16.74)

Equations 16.123 and 16.124 show convenient routes to $[NS_2][SbF_6]$. This product is soluble in liquid SO_2 and is readily separated from AgCl which precipitates out of solution. The $[NS_2]^+$ ion (**16.75**) is isoelectronic (in terms of valence electrons) with $[NO_2]^+$ (see structure **15.50**). The $[NS_2]^+$ ion is a useful synthon, undergoing cycloaddition reactions with, for example, alkynes, nitriles and alkenes.

$$S_3N_3Cl_3 + \tfrac{3}{8}S_8 + 3AgSbF_6 \xrightarrow{\text{liquid } SO_2} 3[NS_2][SbF_6] + 3AgCl \quad (16.123)$$

$$[S_3N_2Cl]Cl + \tfrac{1}{8}S_8 + 2AgSbF_6 \xrightarrow{\text{liquid } SO_2} 2[NS_2][SbF_6] + 2AgCl \quad (16.124)$$



(16.75)

Tetraselenium tetranitride

Among the compounds formed by Se and N, we mention only Se analogues of S_4N_4. Selenium tetranitride, Se_4N_4, can be prepared by reacting $SeCl_4$ with $\{(Me_3Si)_2N\}_2Se$. It forms orange, hygroscopic crystals and is highly explosive. The structure of Se_4N_4 is like that of S_4N_4 (**16.65**) with Se−N bond lengths of 180 pm and cross-cage Se···Se separations of 276 pm (compare with $r_{cov}(Se) = 117$ pm). The reactivity of Se_4N_4 has not been as fully explored as that of S_4N_4. Reaction 16.125 is an adaptation of the synthesis of Se_4N_4 and leads to the 1,5-isomer of $Se_2S_2N_4$ (**16.76**). In the solid state structure, the S and Se atoms are disordered (see Box 15.5), making it difficult to tell whether the crystalline sample is $Se_2S_2N_4$ or a solid solution of S_4N_4 and Se_4N_4. Mass spectrometric data are consistent with the presence of $Se_2S_2N_4$, and the appearance of only one signal in the ^{14}N NMR spectrum confirms the 1,5- rather than 1,3-isomer.

$$2\{(Me_3Si)_2N\}_2S + 2SeCl_4 \longrightarrow Se_2S_2N_4 + 8Me_3SiCl \quad (16.125)$$

(16.76)

Self-study exercises

1. Although $\Delta_fH^o(S_4N_4, s, 298\,K) = +460\,kJ\,mol^{-1}$, S_4N_4 is kinetically stable under ambient conditions with respect to decomposition to the elements. (a) What is meant by 'kinetically stable'? (b) An electrically heated Pt wire can be used to initiate the explosive decomposition of S_4N_4 under a pressure of N_2. Write an equation for what happens during the reaction, and determine the enthalpy change, $\Delta_rH^o(298\,K)$.
2. Theoretical calculations suggest that the $S_3N_3^{\bullet}$ radical has D_{3h} symmetry. Deduce, with reasoning, whether the ring is planar or puckered.
3. Suggest products for the reactions of S_4N_4 with the following reagents: (a) SO_2Cl_2; (b) AsF_5; (c) $SnCl_2$ in EtOH; (d) HgF_2; (e) liquid Br_2.

[*Ans.* See Fig. 16.22]

16.11 Aqueous solution chemistry of sulfur, selenium and tellurium

As we saw earlier in the chapter, the redox reactions between compounds of S in different oxidation states are often slow, and values of E^o for half-reactions are invariably obtained from thermochemical information or estimated on the basis of observed chemistry. The data in Fig. 16.23 illustrate the relative redox properties of some S-, Se- and Te-containing species. Points to note are:

- the greater oxidizing powers of selenate and tellurate than of sulfate;
- the similarities between the oxidizing powers of sulfate, selenite and tellurite;
- the instabilities in aqueous solution of H_2Se and H_2Te.

There is little difference in energy between the various oxidation state species of sulfur, a fact that is doubtless involved in

the complicated oxoacid and oxoanion chemistry of sulfur. We have already discussed some aspects of the aqueous solution chemistry of the group 16 elements:

- the ionization of the hydrides (Sections 7.5 and 16.5);
- formation of metal sulfides (Section 16.6);
- formation of polysulfide ions, e.g. $[S_5]^{2-}$ (eq. 16.42);
- oxoacids and their salts (Section 16.9);
- the oxidizing power of $[S_2O_8]^{2-}$ (eq. 16.114).

There is no cation chemistry in aqueous solution for the group 16 elements. The coordination to metal ions of oxoanions such as $[SO_4]^{2-}$ and $[S_2O_3]^{2-}$ is well established (e.g. see eq. 16.117).

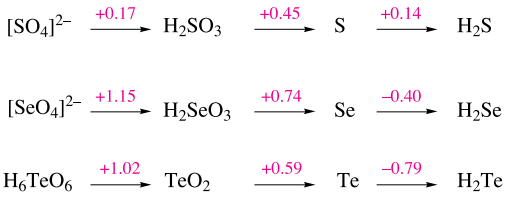


Fig. 16.23. Potential diagrams (values in V) for sulfur, selenium and tellurium at pH = 0.

KEY TERMS

The following terms were introduced in this chapter. Do you know what they mean?

- ❑ annular
- ❑ transannular interaction
- ❑ cubane

PROBLEMS

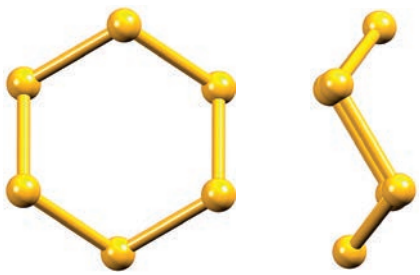
16.1 (a) Write down, in order, the names and symbols of the elements in group 16; check your answer by reference to the first page of this chapter. (b) Give a *general* notation showing the ground state electronic configuration of each element.

16.2 Write an equation to represent the formation of ^{210}Po from ^{209}Bi.

16.3 Write half-equations to show the reactions involved during the electrolysis of aqueous alkali.

16.4 By considering the reactions $8E(g) \longrightarrow 4E_2(g)$ and $8E(g) \longrightarrow E_8(g)$ for E = O and E = S, show that the formation of diatomic molecules is favoured for oxygen, whereas ring formation is favoured for sulfur. [Data: see Table 16.2.]

16.5 (a) Draw diagrams to show the occupancies of the π_g^* level in the ground state and first two excited states of O_2. Does the formal bond order change upon excitation from the ground to the first excited state ($^1\Delta_g$) of O_2? (b) The $^1\Delta_g$ state of O_2 lies 94.7 kJ mol^{-1} above the ground state. Show that the simultaneous excitation of two O_2 molecules from their ground to $^1\Delta_g$ states corresponds to an absorption of light of wavelength 631 nm.



16.6 (a) Use the values of E^o for reactions 16.32 and 16.33 to show that H_2O_2 is thermodynamically unstable with respect to decomposition into H_2O and O_2. (b) '20 Volume' H_2O_2 is so called because 1 volume of the solution liberates 20 volumes of O_2 when it decomposes. If the volumes are measured at 273 K and 1 bar pressure, what is the concentration of the solution expressed in grams of H_2O_2 per dm^3?

16.7 Suggest products for the following reactions: (a) H_2O_2 and Ce^{4+} in acidic solution; (b) H_2O_2 and I^- in acidic solution. [Data needed: see Appendix 11.]

16.8 Hydrogen peroxide oxidizes $Mn(OH)_2$ to MnO_2. (a) Write an equation for this reaction. (b) What secondary reaction will occur?

16.9 Explain why *catena*-Se_∞ is chiral.

16.10 The diagrams below show two views of S_6. Confirm that this molecule has D_{3d} symmetry.

16.11 Predict the structures of (a) H_2Se; (b) $[H_3S]^+$; (c) SO_2; (d) SF_4; (e) SF_6; (f) S_2F_2.

16.12 (a) Explain why the reaction of SF_4 with BF_3 yields $[SF_3]^+$, whereas the reaction with CsF gives $Cs[SF_5]$. (b) Suggest how SF_4 might react with a carboxylic acid, RCO_2H.

16.13 The Raman spectrum of solid $[SeI_3][AsF_6]$ contains absorptions at 227, 216, 99 and 80 cm^{-1} assigned to the vibrational modes of the $[SeI_3]^+$ ion. Explain the origins of the four absorptions. Draw diagrams to represent the modes of vibration, and assign a symmetry label to each mode.

16.14 Discuss the trends in (a) the O–O bond lengths in O_2 (121 pm), $[O_2]^+$ (112 pm), H_2O_2 (147.5 pm), $[O_2]^{2-}$ (149 pm) and O_2F_2 (122 pm), and (b) the S–S bond distances in S_6 (206 pm), S_2 (189 pm), $[S_4]^{2+}$ (198 pm), H_2S_2 (206 pm), S_2F_2 (189 pm), S_2F_{10} (221 pm) and S_2Cl_2 (193 pm). [Data: $r_{cov}(S) = 103$ pm.]

16.15 Comment on the following values of gas-phase dipole moments: SeF_6, 0 D; SeF_4, 1.78 D; SF_4, 0.64 D; SCl_2, 0.36 D; $SOCl_2$, 1.45 D; SO_2Cl_2, 1.81 D.

16.16 The ^{125}Te NMR spectrum of $[Me_4N][TeF_7]$ (298 K in MeCN) consists of a binomial octet ($J = 2876$ Hz), while the ^{19}F NMR spectrum exhibits a singlet with two (superimposed over the singlet), very low-intensity doublets ($J = 2876$ and 2385 Hz respectively). Rationalize these observations. [Data: see Table 16.1; ^{19}F, 100%, $I = \frac{1}{2}$.]

16.17 In each of the following series of compounds or ions, identify those that are isoelectronic (with respect to the valence electrons) and those that are also isostructural: (a) $[SiO_4]^{4-}$, $[PO_4]^{3-}$, $[SO_4]^{2-}$; (b) CO_2, SiO_2, SO_2, TeO_2, $[NO_2]^+$; (c) SO_3, $[PO_3]^-$, SeO_3; (d) $[P_4O_{12}]^{4-}$, Se_4O_{12}, $[Si_4O_{12}]^{8-}$.

16.18 (a) Give the structures of SO_3 and $[SO_3]^{2-}$ and rationalize the difference between them. (b) Outline the properties of aqueous solutions of SO_2 and discuss the species that can be derived from them.

16.19 (a) Draw the structures of S_7NH, $S_6N_2H_2$, $S_5N_3H_3$ and $S_4N_4H_4$, illustrating isomerism where appropriate. (The structures of hypothetical isomers with two or more adjacent NH groups should be ignored.) (b) Write a brief account of the preparation and reactivity of S_4N_4, giving the structures of the products formed in the reactions described.

16.20 Discuss the interpretation of each of the following observations.

(a) When metallic Cu is heated with concentrated H_2SO_4, in addition to $CuSO_4$ and SO_2, some CuS is formed.

(b) The $[TeF_5]^-$ ion is square pyramidal.

(c) Silver nitrate gives a white precipitate with aqueous sodium thiosulfate; the precipitate dissolves in an excess of $[S_2O_3]^{2-}$. If the precipitate is heated with water, it turns black, and the supernatant liquid then gives a white precipitate with acidified aqueous $Ba(NO_3)_2$.

16.21 Interpret the following experimental results.

(a) Sodium dithionite, $Na_2S_2O_4$ (0.0261 g) was added to an excess of ammoniacal $AgNO_3$ solution; the

precipitated silver was removed by filtration, and dissolved in nitric acid. The resulting solution was found to be equivalent to 30.0 cm^3 0.10 M thiocyanate solution.

(b) A solution containing 0.0725 g of $Na_2S_2O_4$ was treated with 50.0 cm^3 0.0500 M iodine solution and acetic acid. After completion of the reaction, the residual I_2 was equivalent to 23.75 cm^3 0.1050 M thiosulfate.

16.22 The action of concentrated H_2SO_4 on urea, $(H_2N)_2CO$, results in the production of a white crystalline solid **X** of formula H_3NO_3S. This is a monobasic acid. On treatment with sodium nitrite and dilute hydrochloric acid at 273 K, one mole of **X** liberates one mole of N_2, and on addition of aqueous $BaCl_2$, the resulting solution yields one mole of $BaSO_4$ per mole of **X** taken initially. Deduce the structure of **X**.

16.23 Write a brief account of the oxoacids of sulfur, paying attention to which species are isolable.

16.24 Give the structures of S_2O, $[S_2O_3]^{2-}$, NSF, NSF_3, $[NS_2]^+$ and S_2N_2 and rationalize their shapes.

16.25 $[NS_2][SbF_6]$ reacts with nitriles, RC≡N, to give $[\mathbf{X}][SbF_6]$ where $[\mathbf{X}]^+$ is a cycloaddition product. Propose a structure for $[\mathbf{X}]^+$ and show that it is a 6π-electron system. Do you expect the ring to be planar or puckered? Give reasons for your answer.

OVERVIEW PROBLEMS

16.26 Which description in the second list below can be correctly matched to each element or compound in the first list? There is only one match for each pair.

List 1	List 2
S_∞	A toxic gas
$[S_2O_8]^{2-}$	Readily disproportionates in the presence of Mn^{2+}
$[S_2]^-$	Reacts explosively with H_2O
S_2F_2	Exists as a tetramer in the solid state
Na_2O	A strong reducing agent, oxidized to $[S_4O_6]^{2-}$
$[S_2O_6]^{2-}$	A blue, paramagnetic species
PbS	Exists as two monomeric isomers
H_2O_2	A chiral polymer
HSO_3Cl	Crystallizes with an antifluorite structure
$[S_2O_3]^{2-}$	A black, insoluble solid
H_2S	A strong oxidizing agent, reduced to $[SO_4]^{2-}$
SeO_3	Contains a weak S–S bond, readily cleaved in acidic solution

16.27 (a) A black precipitate forms when H_2S is added to an aqueous solution of a Cu(II) salt. The precipitate redissolves when Na_2S is added to the solution. Suggest a reason for this observation.

(b) In the presence of small amounts of water, the reaction of SO_2 with CsN_3 leads to $Cs_2S_2O_5$ as a by-product in the formation of $Cs[SO_2N_3]$. Suggest how the formation of $Cs_2S_2O_5$ arises.

(c) The complex ion $[Cr(Te_4)_3]^{3-}$ possesses a $\Delta\lambda\lambda\lambda$-conformation. Using the information in Box 19.3, explain (i) to what the symbols Δ and λ refer, and (ii) how the $\Delta\lambda\lambda\lambda$-conformation arises.

16.28 Suggest products for the following reactions; the equations are not necessarily balanced on the left-hand sides. Draw the structures of the sulfur-containing products.

(a) $SF_4 + SbF_5 \xrightarrow{\text{liq HF}}$

(b) $SO_3 + HF \longrightarrow$

(c) $Na_2S_4 + HCl \longrightarrow$

(d) $[HSO_3]^- + I_2 + H_2O \longrightarrow$

(e) $[SN][AsF_6] + CsF \xrightarrow{\Delta}$

(f) HSO_3Cl + anhydrous $H_2O_2 \longrightarrow$

(g) $[S_2O_6]^{2-} \xrightarrow{\text{in acidic solution}}$

16.29 (a) Structures **16.67** and **16.68** show hypervalent sulfur in NSF and NSF_3. Draw resonance structures for each molecule that retains an octet of electrons around the S atoms, and account for the three equivalent S–F bonds in NSF_3.

(b) The enthalpies of vaporization (at the boiling point) of H_2O, H_2S, H_2Se and H_2Te are 40.6, 18.7, 19.7 and 19.2 $kJ\,mol^{-1}$. Give an explanation for the trend in these values.

(c) Which of the following compounds undergoes significant reaction when they dissolve in water under ambient conditions: Al_2Se_3, HgS, SF_6, SF_4, SeO_2, FeS_2 and As_2S_3? Give equations to show the reactions that occur. Which of these compounds is kinetically, but not thermodynamically, stable with respect to hydrolysis?

16.30 The $[Se_4]^{2+}$ ion has D_{4h} symmetry and the Se−Se bond lengths are equal (228 pm).

(a) Is the ring in $[Se_4]^{2+}$ planar or puckered?
(b) Look up a value of r_{cov} for Se. What can you deduce about the Se−Se bonding?
(c) Draw a set of resonance structures for $[Se_4]^{2+}$.
(d) Construct an MO diagram that describes the π-bonding in $[Se_4]^{2+}$. What is the π-bond order?

16.31 (a) S_8O can be prepared by treating S_8 with CF_3CO_3H. The structure of S_8O is shown below. Explain why the addition of one O atom to the S_8 ring reduces the molecular symmetry from D_{4d} to C_1.

(b) The reaction between TeF_4 and Me_3SiCN leads to the formation of Me_3SiF and substitution products $TeF_{4-n}(CN)_n$. When the ^{125}Te NMR spectrum of a mixture of TeF_4 and less than four equivalents of Me_3SiCN is recorded at 173 K, three signals are observed: δ 1236 ppm (quintet, J 2012 Hz), δ 816 ppm (triplet, J 187 Hz), δ 332 ppm (doublet, J 200 Hz). The ^{19}F NMR spectrum of the same mixture at 173 K exhibits three signals, each with ^{125}Te satellites. Rationalize the observed spectra (including comments on fluxional species where appropriate), and suggest structures for the products.

16.32 The reaction of $TeCl_4$ with PPh_3 in THF solution in air leads to the formation of the salt $[(Ph_3PO)_2H]_2[Te_2Cl_{10}]$. Structural data reveal that each Te centre in the anion is in an approximately octahedral environment. (a) Suggest a structure for $[Te_2Cl_{10}]^{2-}$. (b) The cation $[(Ph_3PO)_2H]^+$ is derived from the phosphine oxide Ph_3PO. Suggest a structure for the cation and comment on its bonding.

INORGANIC CHEMISTRY MATTERS

16.33 HSO is an intermediate in the atmospheric oxidation of H_2S, and it has been implicated in ozone depletion. Calculated wavenumbers for the fundamental modes of vibration of HSO are 2335, 1077 and 1002 cm^{-1}. These are assigned to stretching, bending and stretching modes, respectively. Deuteration causes the fundamental modes of vibration to shift to 1704, 772 and 1041 cm^{-1}. (a) Is the HSO molecule linear or bent? (b) Draw one or more resonance structures to describe the bonding in HSO. (c) How many of the fundamental modes of vibration are IR active? (d) Which of the modes of vibration (2335, 1077 or 1002 cm^{-1}) arises from the S–H stretch? Use the deuteration data to confirm your assignment. (e) Suggest why HSO is associated with ozone depletion.

16.34 (a) North African desert dusts contain particles of calcite and dolomite. Why are these dusts important in counteracting acid rain in the Eastern Mediterranean? Give equations to illustrate your answer.

(b) Crystalline $CaC_2O_4{\cdot}H_2O$ (log K_{sp} = −8.6) and $CaC_2O_4{\cdot}2H_2O$ (log $K_{sp} \approx -8.2$) accumulate on the surfaces of some lichens. This is thought to be in response to high levels of calcium ions. Zones of $CaC_2O_4{\cdot}H_2O$ and $CaC_2O_4{\cdot}2H_2O$ crystals on lichens exposed to SO_2 emissions or acid rain are interrupted by growths of gypsum crystals. (i) Why are $CaC_2O_4{\cdot}H_2O$ and $CaC_2O_4{\cdot}2H_2O$ suited to immobilizing excess Ca^{2+} ions? (ii) What is the origin of the gypsum crystals on lichens. Include appropriate equations for their formation.

16.35 Comment on the relevance of homonuclear bond formation between group 16 elements to the following:

(a) ozone and dioxygen;
(b) iron pyrites (fool's gold);
(c) the blue gemstone lapis lazuli;
(d) elemental Te, used as an additive in low-carbon steels.

17.1 Introduction

The group 17 elements are called the ***halogens***.

Fluorine, chlorine, bromine and iodine

The chemistry of fluorine, chlorine, bromine and iodine is probably better understood than that of any other group of elements except the alkali metals. This is partly because much of the chemistry of the halogens is that of singly bonded atoms or singly charged anions, and partly because of the wealth of structural and physicochemical data available for most of their compounds. The fundamental principles of inorganic chemistry are often illustrated by discussing properties of the halogens and halide compounds, and topics already discussed include:

- electron affinities of the halogens (Section 1.10);
- valence bond theory for F_2 (Section 2.2);
- molecular orbital theory for F_2 (Section 2.3);
- electronegativities of the halogens (Section 2.5);
- dipole moments of hydrogen halides (Section 2.6);
- bonding in HF by molecular orbital theory (Section 2.7);
- VSEPR model (which works well for many halide compounds, Section 2.8);
- application of the packing-of-spheres model, solid state structure of F_2 (Section 6.3);
- ionic radii (Section 6.10);
- ionic structure types: NaCl, CsCl, CaF_2, antifluorite, CdI_2 (Section 6.11);
- lattice energies: comparisons of experimental and calculated values for metal halides (Section 6.15);
- estimation of fluoride ion affinities (Section 6.17);
- estimation of standard enthalpies of formation and disproportionation, illustrated using halide compounds (Section 6.17);
- hydrogen halides as Brønsted acids (Section 7.4);
- energetics of hydrogen halide dissociation in aqueous solution (Section 7.5);
- solubilities of metal halides (Section 7.9);
- common-ion effect, exemplified by AgCl (Section 7.10);
- stability of complexes containing hard and soft metal ions and ligands, illustrated with halides of Fe(III) and Hg(II) (Section 7.13);
- redox half-cells involving silver halides (Section 8.3);
- non-aqueous solvents: liquid HF (Section 9.7);
- non-aqueous solvents: BrF_3 (Section 9.10);
- reactions of halogens with H_2 (Section 10.4);
- hydrogen bonding involving halogens (Section 10.6).

In Sections 11.5, 12.5, 13.6, 14.8, 15.7 and 16.7 we have discussed the halides of the group 1, 2, 13, 14, 15 and 16 elements respectively. Fluorides of the noble gases are discussed in Sections 18.4 and 18.5, and of the *d*- and *f*-block metals in Chapters 21, 22 and 27. In this chapter, we discuss the halogens themselves, their oxides and oxoacids, interhalogen compounds and polyhalide ions.

Astatine and tennessine

Astatine is the heaviest member of group 17 and is known only in the form of radioactive isotopes, all of which have short half-lives. The longest lived isotope is ^{210}At ($t_{\frac{1}{2}} = 8.1$ h). Several isotopes are present naturally as transient products of the decay of uranium and thorium minerals; ^{218}At is formed from the β-decay of ^{218}Po, but the path competes with decay to ^{214}Pb (the dominant decay, see Fig. 27.3). Other isotopes are artificially prepared, e.g. ^{211}At (an α-emitter) from the nuclear reaction:

$$^{209}_{83}\text{Bi} + {}^{4}_{2}\text{He} \longrightarrow {}^{211}_{85}\text{At} + 2{}^{1}_{0}\text{n}.$$

The ^{211}At isotope may be separated by vacuum distillation. In general, At is chemically similar to iodine. Tracer studies (which are the only sources of information about the element) show that At_2 is less volatile than I_2, is soluble in organic solvents, and is reduced by SO_2 to At^- which can be coprecipitated with AgI or TlI. Hypochlorite, $[ClO]^-$, or peroxydisulfate, $[S_2O_8]^{2-}$, oxidizes astatine to an anion that is carried by $[IO_3]^-$ (e.g. coprecipitation with $AgIO_3$) and is therefore probably $[AtO_3]^-$. Less powerful oxidizing agents such as Br_2 also oxidize astatine, probably to $[AtO]^-$ or $[AtO_2]^-$.

Tennessine (Ts, $Z = 117$) is one of the artificially produced 'superheavy' elements (see Section 27.5) and its discovery and name were confirmed by the IUPAC in 2015[†] and 2016, respectively. Like the other *p*-block elements with quantum number $n = 7$, Ts is radioactive and the most stable isotope ^{294}Ts has a half-life of <100 ms. Since the element is made on an 'atom-at-a-time' scale (see Section 27.5), little is known about its properties.

Self-study exercises

1. The preparation of ^{211}At can be described by the abbreviated nuclear reaction $^{209}_{83}\text{Bi}(\alpha,2n)^{211}_{85}\text{At}$. Explain what this means.

2. Explain what happens when $^{218}_{84}$Po loses a β-particle. [*Ans.* See Section 10.3]

17.2 Occurrence, extraction and uses

Occurrence

Figure 17.1 shows the relative abundances of the group 17 elements in the Earth's crust and in seawater. The major natural sources of fluorine are the minerals *fluorspar* (*fluorite*, CaF_2), *cryolite* ($Na_3[AlF_6]$) and *fluorapatite*, ($Ca_5F(PO_4)_3$) (see Section 15.2 and Box 15.11). The importance of cryolite lies in its being an *aluminium* ore (see Section 13.2). Sources of chlorine are closely linked to those of Na and K (see Section 11.2): *rock salt* (NaCl), *sylvite* (KCl) and *carnallite* ($KCl{\cdot}MgCl_2{\cdot}6H_2O$). Seawater is one source of Br_2 (Fig. 17.1), but significantly higher concentrations of Br^- are present in salt lakes and natural brine wells (see Box 17.3). The natural abundance of iodine is less than that of the lighter halogens. It occurs as iodide ion in seawater and is taken up by seaweed, from which it may be extracted. Impure Chile saltpetre (*caliche*) contains up to 1% sodium iodate and this has become an important source of I_2. Brines associated with oil and salt wells are of increasing importance.

Extraction

Most fluorine-containing compounds are made using HF, the latter being prepared from fluorite (CaF_2) by reaction 17.1. Hydrogen fluoride is also recycled from Al manufacturing processes and from petroleum alkylation processes, and re-enters the supply chain. Difluorine is strongly oxidizing and must be prepared industrially by electrolytic oxidation of F^- ion. The electrolyte is a

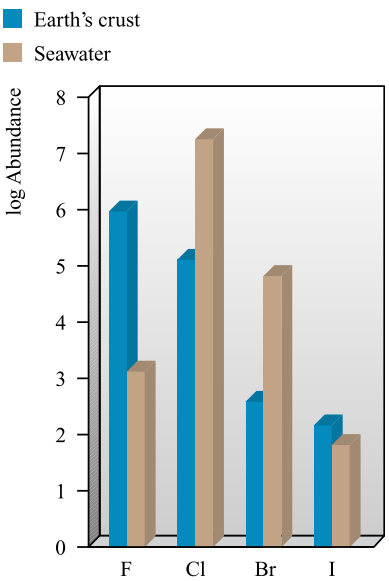

Fig. 17.1. Relative abundances of the halogens (excluding astatine) in the Earth's crust and seawater. The data are plotted on a logarithmic scale. The units of abundance are parts per billion (1 billion = 10^9).

mixture of anhydrous molten KF and HF, and the electrolysis cell contains a steel or copper cathode, ungraphitized carbon anode, and a Monel metal (Cu/Ni) diaphragm which is perforated below the surface of the electrolyte, but not above it, thus preventing the H_2 and F_2 products from recombining. As electrolysis proceeds, the HF content of the melt is renewed by adding dry gas from cylinders.

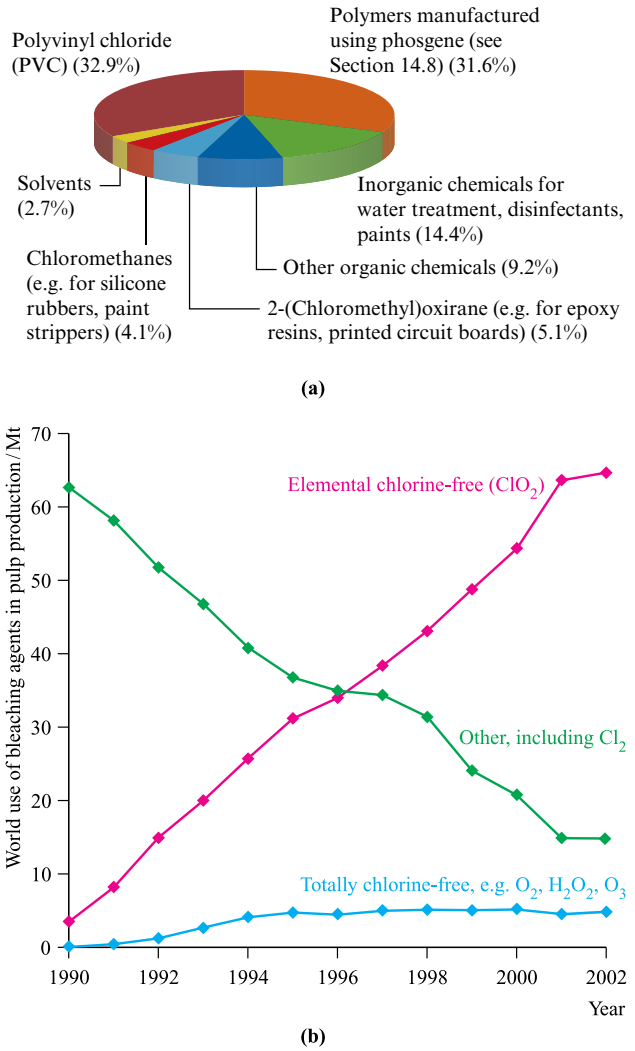
$$CaF_2 + \underset{\text{conc}}{H_2SO_4} \longrightarrow CaSO_4 + 2HF \qquad (17.1)$$

Dichlorine is one of the most important industrial chemicals in the world, and is manufactured by the chlor-alkali process (≈95% of the world's supply, see Box 11.4) and by the Downs process (see Fig. 11.2). High global demand for Cl_2 is associated with its use in the manufacture of polymers such as polyvinyl chloride (PVC). The manufacture of Br_2 involves oxidation of Br^- by Cl_2, with air being swept through the system to remove Br_2. Similarly, I^- in brines is oxidized to I_2. The extraction of I_2 from $NaIO_3$ involves controlled reduction by SO_2; complete reduction yields NaI.

Uses

The nuclear fuel industry uses large quantities of F_2 in the production of UF_6 for fuel enrichment processes and this is the major use of F_2. Reprocessing of spent nuclear fuels involves both recovery of uranium and separation of ^{235}U from fission products. Short-lived radionuclides decay during a period of fuel storage (*pond storage*). After this, uranium is converted in the soluble salt $[UO_2][NO_3]_2$, and then into UF_6 (see Box 7.3).

Industrially, the most important F-containing compounds are HF, BF_3, CaF_2 (as a flux in metallurgy), synthetic cryolite (see reaction 13.46) and chlorofluorocarbons (CFCs, see Box 14.6). Water fluoridation was introduced in many developed countries during the mid-20th century, in order to reduce occurrences of dental caries, especially in children. The fluoridation agents are H_2SiF_6 and Na_2SiF_6, the former being a by-product of the manufacture of phosphoric acid from phosphate rock (see eq. 15.3). Phosphate rock contains fluoride impurities and, in the presence of SiO_2, phosphoric acid production results in the formation of gaseous HF and SiF_4. Scrubbing these emissions with water yields H_2SiF_6. Since the 1990s, there have been concerns that long-term uptake of fluoridated water may be linked to higher cancer risks.[†] Although the fluoridation of many water supplies continues, the introduction of toothpastes containing NaF or sodium monofluorophosphate,



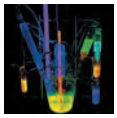


Fig. 17.2. (a) Industrial uses of Cl_2 in Europe in 2013 [data: www.eurochlor.org]. (b) The trends in uses of bleaching agents in the pulp industry between 1990 and 2002; ClO_2 has replaced Cl_2. Both elemental chlorine-free and totally chlorine-free agents comply with environmental legislations [data: Alliance for Environmental Technology].

and the use of fluoridized salt (in Germany, France and Switzerland), provide other means of fighting tooth decay.

Figure 17.2a summarizes the major uses of chlorine. Chlorinated organic compounds, including 1,2-dichloroethene and vinyl chloride for the polymer industry, are hugely important. Dichlorine was widely used as a bleach in the paper and pulp industry, but environmental legislations have resulted in changes (Fig. 17.2b). Chlorine dioxide, ClO_2 (an 'elemental chlorine-free' bleaching agent) is favoured over Cl_2 because it does not produce toxic effluents; ClO_2 now accounts for >80% of the bleaching agents used globally in the pulp industry. In addition to pulp bleaching, ClO_2 is increasingly used for the treatment of drinking water. However, because ClO_2 is unstable as a compressed gas, it must be produced

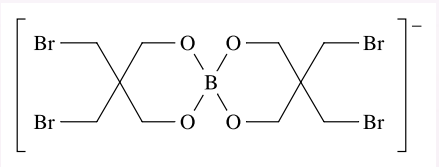
APPLICATIONS

Box 17.1 Flame retardants

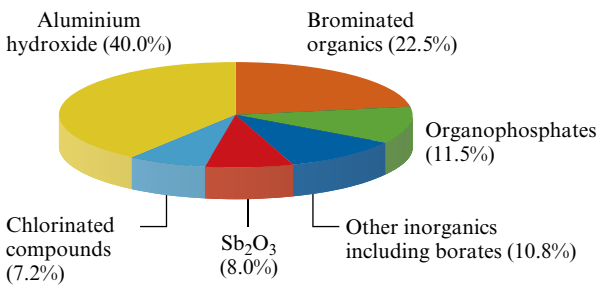
The incorporation of flame retardants into plastics, textiles, electronic equipment (e.g. printed circuit boards) and other materials is big business. First-generation halogenated fire retardants were polychlorinated biphenyls (PCBs), but their high toxicity led to their replacement in the 1970s by polybrominated biphenyls (PBBs) followed by a range of other brominated organics:

- the perbrominated diphenyl ether $(C_6Br_5)_2O$ (abbreviated as deca-BDE in the commercial market);
- octabromodiphenyl ether (octa-BDE);
- pentabromodiphenyl ether (penta-BDE);
- 1,2,5,6,9,10-hexabromocyclododecane (HBCDD);
- tetrabromobisphenol A (TBBPA, see below);
- brominated polymers (e.g. epoxy resins, polycarbonates).



TBBPA

However, growing awareness of the bioaccumulation of bromine-containing fire retardants and their side-effects (including hormone-related effects and the production of bromodioxins) has led to legislative controls and changes in policy. In the EU, the production of PBBs has been banned since 2000, and from 2006, the use of penta-BDE and octa-DBE in new electrical and electronic equipment was prohibited; PBBs, penta-BDE and octa-DBE are also banned in the US. Following EU risk assessment of TBBPA in 2008, no restrictions in its use as a flame retardant have been put in place and it is widely used in epoxy resins and polycarbonates. HBCDD continues to be used as a fire retardant in polystyrene foam for building insulation and in textiles. The chart on the right shows the split between the main categories of flame retardants in the US, Asia and Europe in 2008; the use of borates is growing in importance.



Phosphorus-based flame retardants include tris(1,3-dichloroisopropyl) phosphate, used in polyurethane foams and polyester resins. Once again, there is debate concerning toxic side-effects of such products: although these flame retardants may save lives, they produce noxious fumes during a fire.

Many inorganic compounds are used as flame retardants; for example:

- aluminium hydroxide;
- Sb_2O_3 is used in PVC, and in aircraft and motor vehicles; scares that Sb_2O_3 in cot mattresses may be the cause of 'cot deaths' appear to have subsided;
- $Ph_3Sb(OC_6Cl_5)_2$ is added to polypropene;
- borates, exemplified by:

  are used in polyurethane foams, polyesters and polyester resins;
- $ZnSnO_3$ has applications in PVC, thermoplastics, polyester resins and certain resin-based gloss paints.

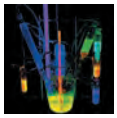
$$2NaClO_3 + 2NaCl + 2H_2SO_4 \longrightarrow 2ClO_2 + Cl_2 + 2Na_2SO_4 + 2H_2O \quad (17.2)$$

$$5NaClO_2 + 4HCl \longrightarrow 4ClO_2 + 5NaCl + 2H_2O \quad (17.3)$$

The manufacture of bromine- and iodine-containing organic compounds is a primary application of these halogens. Other uses include those of iodide salts (e.g. KI) and silver bromide in the photographic industry (although this has diminished with the use of digital cameras), and bromine-based organic compounds as flame retardants (Box 17.1). Applications of iodine and its compounds are described in Box 17.2.

† See: G. Gordon and A.A. Rosenblatt (2005) *Ozone: Science and Engineering*, vol. 27, p. 203 – 'Chlorine dioxide: the current state of the art'; W. Gan, H. Huang, X. Yang, Z. Peng and G. Chen (2016) *Environ. Sci.: Water Res. Technol.*, vol. 2, p. 838 – 'Emerging investigators series: disinfection by-products in mixed chlorine dioxide and chlorine water treatment'.



Iodine is essential for life and a deficiency results in a swollen thyroid gland; 'iodized salt' (NaCl with added I^-) provides us with iodine supplement.

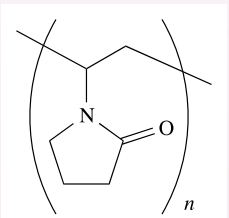
17.3 Physical properties and bonding considerations

Table 17.1 lists selected physical properties of the group 17 elements (excluding astatine). Most of the differences between fluorine and the later halogens can be attributed to the:

- inability of F to exhibit any oxidation state other than −1 in its compounds, formally, an exception is $[F_3]^-$;
- relatively small size of the F atom and F^- ion;
- low dissociation energy of F_2 (Figs. 15.2 and 17.3);
- higher oxidizing power of F_2;
- high electronegativity of fluorine.

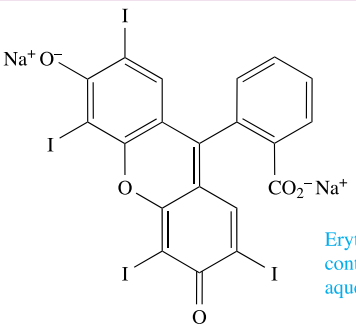
The last factor is *not* a rigidly defined quantity. However, it is useful in rationalizing such observations as the

APPLICATIONS



Box 17.2 Iodine: from X-ray contrast agents to disinfectants and catalytic uses

The annual output of iodine is significantly lower than that of chlorine or bromine, but, nonetheless, it has a wide range of important applications. Determining accurate data for end-uses of iodine is difficult because many iodine-containing intermediate compounds are marketed before the final application is reached. One major application of certain iodine-containing compounds is as X-ray contrast agents. Such agents are radio-opaque (i.e. they prevent X-rays from penetrating) and are used to assist the diagnosis of disorders of the heart, central nervous system, gall bladder, urinary tract and other organs. For example, following an injection of an iodine-based radio-opaque contrast agent, an X-ray examination of the kidneys, ureters and bladder results in an image called an intravenous pyelogram (IVP). The photograph below shows an IVP of a patient in whom a kidney stone has passed into the ureter but could not be passed into the bladder. The resulting obstruction causes dilation of the ureter and renal pelvis.



An intravenous pyelogram (IVP) imaged by using X-rays and an iodine-based contrast agent.

An important application of elemental iodine is as a biocide and disinfectant. Since I_2 is insoluble in water, solubilizing agents such as poly-*N*-vinyl-2-pyrrolidine (PVP) are required to prepare commercially useful aqueous iodine-containing solutions. PVP/I_2 antiseptic solutions are marketed under a number of trade names including Betadine. Although PVP/I_2 has been used as an antiseptic since the 1950s, the nature of the interaction between PVP and I_2 is not fully elucidated. Electronic, Raman and IR spectroscopic data are consistent with the initial formation of a charge transfer complex (see Section 17.4) followed by release of I^- ion and formation of $[I_3]^-$. When I^- is released, the formation of $[PVP{-}I]^+$ has been proposed but not proven. An alternative proposal is the formation of $[PVPH]^+[I_3]^-$ with a proton hydrogen bonded between two PVP ketone oxygen atoms in the polymer backbone. Uses of I_2 as a disinfectant range from wound antiseptics and disinfecting skin before surgery to maintaining germ-free swimming pools and water supplies.

PVP

At an industrial level, the square planar iodido-complexes *cis*-$[Rh(CO)_2I_2]^-$ and *cis*-$[Ir(CO)_2I_2]^-$ are the catalysts for the Monsanto and Cativa acetic acid and Tennessee–Eastman acetic anhydride processes, discussed in detail in Section 25.4. Application of iodine as a stabilizer includes its incorporation into nylon used in carpet and tyre manufacture. Iodized animal feed supplements are responsible for reduced instances of goitre (enlarged thyroid gland) which are otherwise prevalent in regions where the iodine content of soil and drinking water is low; iodized hen feeds increase egg production. Iodine is usually added to feeds in the form of $[H_3NCH_2CH_2NH_3]I_2$, KI, $Ca(IO_3)_2$ or $Ca(IO_4)_2$. Among dyes that have a high iodine content is erythrosine B (food red-colour additive E127) which is added to carbonated soft drinks, gelatins and cake icings. The use of ^{131}I as a medical radioisotope is described at the end of Section 17.3.

Erythrosine B
contains 58% iodine
aqueous solutions: λ_{max} = 525 nm

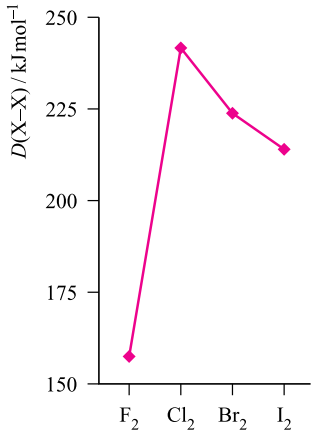


Fig. 17.3. The trend in X−X bond energies for the first four halogens.

anomalous physical properties of, for example, HF (see Section 10.6), the strength of F-substituted carboxylic acids, the deactivating effect of the CF_3 group in electrophilic aromatic substitutions, and the non-basic character of NF_3 and $(CF_3)_3N$ (see end-of-chapter problem 17.4).

Fluorine forms no high oxidation state compounds (e.g. there are no analogues of $HClO_3$ and Cl_2O_7). When F is attached to another atom, Y, the Y−F bond is usually *stronger* than the corresponding Y−Cl bond (e.g. Tables 14.2, 15.3 and 16.2). If atom Y possesses no lone pairs, or has lone pairs but a large r_{cov}, then the Y−F bond is much stronger than the corresponding Y−Cl bond (e.g. C−F versus C−Cl, Table 14.2). Consequences of the small size of the F atom are that high coordination numbers can be achieved in molecular fluorides YF_n, and good overlap of atomic orbitals between Y and F leads to short, strong bonds, reinforced by ionic contributions when the difference in electronegativities of Y and F is large. The volatility of covalent F-containing compounds (e.g. fluorocarbons, see Section 14.8) originates in the weakness of the intermolecular van der Waals or London dispersion forces. This, in turn, can be correlated with the low polarizability and small size of the F atom. The small ionic radius of F^- leads to high coordination numbers in saline fluorides, high lattice energies and highly negative values of $\Delta_f H^o$ for these compounds, as well as a large negative standard enthalpy and entropy of hydration of the ion (Table 17.1).

Worked example 17.1 Saline halides

For the process:

$$Na^+(g) + X^-(g) \longrightarrow NaX(s)$$

values of $\Delta H^o(298\,K)$ are −910, −783, −732 and −682 kJ mol^{-1} for $X^- = F^-$, Cl^-, Br^- and I^-, respectively. Account for this trend.

The process above corresponds to the formation of a crystalline lattice from gaseous ions, and $\Delta H^o(298\,K) \approx \Delta U(0\,K)$.

The Born–Landé equation gives an expression for $\Delta U(0\,K)$ assuming an electrostatic model and this is appropriate for the group 1 metal halides:

$$\Delta U(0\,K) = -\frac{LA|z_+||z_-|e^2}{4\pi\varepsilon_0 r_0}\left(1 - \frac{1}{n}\right)$$

NaF, NaCl, NaBr and NaI all adopt an NaCl structure, therefore A (the Madelung constant) is constant for this series of compounds.

The only variables in the equation are r_0 (internuclear distance) and n (Born exponent, see Table 6.3).

The term $(1 - \frac{1}{n})$ varies little since n varies only from 7 for NaF to 9.5 for NaI.

The internuclear distance $r_0 = r_{cation} + r_{anion}$ and, since the cation is constant, varies only as a function of r_{anion}.

Therefore, the trend in values of $\Delta U(0\,K)$ can be explained in terms of the trend in values of r_{anion}.

$$\Delta U(0\,K) \propto -\frac{1}{\text{constant} + r_{anion}}$$

r_{anion} follows the trend $F^- < Cl^- < Br^- < I^-$, and therefore, $\Delta U(0\,K)$ has the most negative value for NaF.

An alternative method is to use the VBT approach (see Section 6.16). The equation needed is:

$$\Delta U = -2I\left(\frac{\alpha}{\sqrt[3]{V_m}} + \beta\right)$$

where $I = 1$, $\alpha = 117$ kJ nm mol^{-1} and $\beta = 52$ kJ mol^{-1} for the 1:1 salts NaF, NaCl, NaBr and NaI. The equation becomes:

$$\Delta U = -2\left(\frac{117}{\sqrt[3]{V_m}} + 52\right)$$

As the volume of the halide ion increases from F^- to I^-, the term V_m increases, and $\frac{\alpha}{\sqrt[3]{V_m}}$ decreases. Therefore, ΔU becomes less negative on going from NaF to NaCl to NaBr to NaI.

Self-study exercises

1. What is meant by 'saline', e.g. saline fluoride?
[*Ans.* See Section 10.7]

2. The alkali metal fluorides, MgF_2 and the heavier group 2 metal fluorides adopt NaCl, rutile and fluorite structures, respectively. What are the coordination numbers of the metal ion in each case?
[*Ans.* See Figs. 6.18, 6.21a and 6.24]

3. Given the values (at 298 K) of $\Delta_f H^\circ(SrF_2, s) = -1216$ kJ mol^{-1} and $\Delta_f H^\circ(SrBr_2, s) = -718$ kJ mol^{-1}, calculate values for $\Delta_{lattice} H^\circ(298\,K)$ for these compounds using data from the Appendices. Comment on the relative magnitudes of the values.

[*Ans.* SrF_2, −2496 kJ mol^{-1}; $SrBr_2$, −2070 kJ mol^{-1}]

In Section 16.3, we pointed out the importance of anion, rather than cation, formation in group 16. As expected, this is even more true in group 17. Table 17.1 lists values of the first ionization energies simply to show the expected decrease down the group. Although none of the halogens has yet been shown to form a discrete and stable monocation X^+, complexed or solvated I^+ is established, e.g. in $[I(py)_2]^+$ (eq. 17.4, Fig. 17.4) and $[Ph_3PI]^+$ (see Section 17.4).

$$AgNO_3 \xrightarrow[2.\ I_2]{1.\ 2\ py} [I(py)_2][NO_3] + AgI \qquad (17.4)$$

The corresponding Br- and Cl-containing cationic species are less stable, though they are probably involved in aromatic bromination and chlorination reactions.

The electron affinity of F is out of line with the trend observed for the later halogens (Table 17.1). Addition of an electron to the small F atom is accompanied by greater electron–electron repulsion than is the case for Cl, Br and I, and this probably explains why the process is less exothermic than might be expected on chemical grounds. Methods of accessing 'naked' fluoride ion are of considerable current interest. Structure **16.39** showed one example and its use in the preparation of the $[SeF_6]^{2-}$ ion. Two other sources of 'naked' F^- are Me_4NF and Me_4PF, and the increased reactivity of such fluoride ions, free of interactions with other species, promises to be useful in a wide range of reactions. This has a direct parallel with use of $[K(18\text{-crown-6})][MnO_4]$ in organic chemistry as a highly reactive form of $[MnO_4]^-$ ion (see Section 11.8).

As we consider the chemistry of the halogens, it will be clear that there is an increasing trend towards higher oxidation states down the group. This is well exemplified among the interhalogen compounds (Section 17.7).

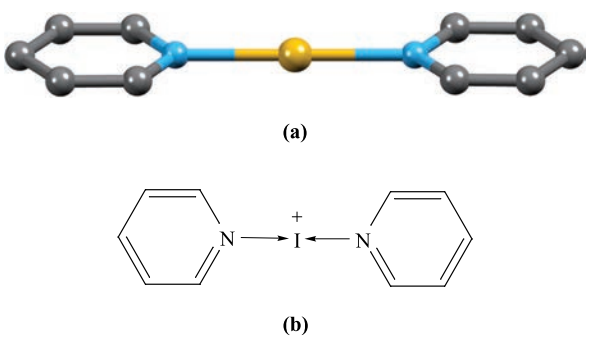

Fig. 17.4. (a) The structure of $[I(py)_2]^+$ (determined by X-ray crystallography) from the salt $[I(py)_2][I_3]\cdot 2I_2$ [O. Hassel *et al.* (1961) *Acta Chem. Scand.*, vol. 15, p. 407]; (b) A representation of the bonding in the cation. Colour code: I, gold; N, blue; C, grey.

NMR active nuclei and isotopes as tracers

Although F, Cl, Br and I all possess spin active nuclei, in practice only ^{19}F (100%, $I = \frac{1}{2}$) is used routinely. Fluorine-19 NMR spectroscopy is a valuable tool in the elucidation of structures and reaction mechanisms of F-containing compounds; see case studies 1 and 5 and the discussion of stereochemically non-rigid species in Section 4.8.

Self-study exercises

In each example, use the VSEPR model to help you.

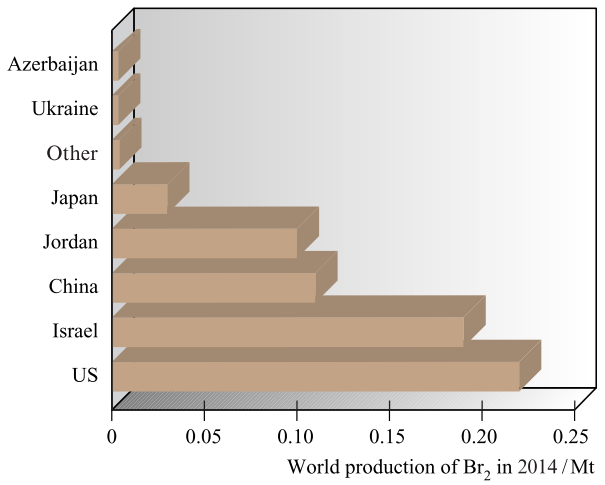
1. In the solution ^{19}F NMR spectrum (at 298 K) of $[BrF_6]^+[AsF_6]^-$, the octahedral cation gives rise to two overlapping, equal intensity 1:1:1:1 quartets ($J(^{19}F^{79}Br) = 1578$ Hz; $J(^{19}F^{80}Br) = 1700$ Hz). What can you deduce about the nuclear spins of ^{79}Br and ^{80}Br? Sketch the spectrum and indicate where you would measure the coupling constants.

[*Ans.* See R.J. Gillespie *et al.* (1974) *Inorg. Chem.*, vol. 13, p. 1230]

2. The room temperature ^{19}F NMR spectrum of $MePF_4$ shows a doublet ($J = 965$ Hz), whereas that of $[MePF_5]^-$ exhibits a doublet ($J = 829$ Hz) of doublets ($J = 33$ Hz) of quartets ($J = 9$ Hz), and a doublet ($J = 675$ Hz) of quintets ($J = 33$ Hz). Rationalize these data, and assign the coupling constants to ^{31}P–^{19}F, ^{19}F–^{19}F or ^{19}F–^{1}H spin–spin coupling.

[*Ans.* $MePF_4$, trigonal bipyramidal, fluxional; $[MePF_5]^-$, octahedral, static]

See also end-of-chapter problems 4.43, 4.45, 14.12, 15.14, 15.24b, 16.16 and 17.10, and self-study exercises after worked examples 14.1 and 16.2.



Artificial isotopes of F include ^{18}F (β^+ emitter, $t_{\frac{1}{2}} = 1.83$ h) and ^{20}F (β^- emitter, $t_{\frac{1}{2}} = 11.0$ s). The former is the longest lived radioisotope of F and is used as a radioactive tracer, for example, in *positron emission tomography* (PET). This is a medical imaging technique that uses radionuclides (e.g. ^{18}F, ^{11}C, ^{13}N, ^{15}O) which decay by loss of a positron (β^+ particle). When a positron collides with an electron, the particles are annihilated and two γ-rays of equal energy, but travelling in opposite directions, are emitted. The γ-rays

ENVIRONMENT

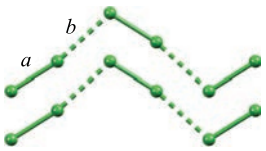
Box 17.3 Bromine: resources and commercial demand

Bromine occurs as bromide salts in seawater, salt lakes and natural brines. World reserves are plentiful. The major producers of Br_2 draw on brines from Arkansas and Michigan in the US, and from the Dead Sea in Israel, and the chart below indicates the extent to which these countries dominate the world market. The Dead Sea is the deepest saline lake in the world, containing large reserves of NaCl, $MgCl_2$ and $CaCl_2$ with smaller quantities of bromide salts.

[Data: US Geological Survey; data for the US are based on an approximate one-third contribution to world production]

Environmental issues, however, are likely to have a dramatic effect on the commercial demand for Br_2. We have already mentioned the phasing out of some bromine-based flame retardants (Box 17.1) and this significantly affects the demand for Br_2. The commercial market for Br_2 decreased with the switch from leaded to unleaded motor vehicle fuels. Leaded fuels contained 1,2-$C_2H_4Br_2$ as an additive to facilitate the release of lead (formed by decomposition of the anti-knock agent Et_4Pb) as a volatile bromide. 1,2-Dibromoethane is also used as a nematocide and fumigant, and CH_3Br is a widely applied fumigant for soil. Bromomethane, however, falls in the category of a potential ozone depleter and its use has effectively been banned by the Montreal Protocol since 2005 (2015 in developing countries). Strictly controlled 'critical exceptions' to the ban are permitted (see Box 14.6).

Crystalline salt deposits in the Dead Sea, Israel.



leaving a patient's body are detected by a PET scanner. ^{18}F-Fluorodeoxyglucose is widely used in PET to monitor glucose metabolism which is perturbed by the presence of cancerous tumours.[†] The ^{20}F isotope has application in F dating of bones and teeth; these usually contain apatite (see Section 15.2 and Box 15.11) which is slowly converted to fluorapatite when the mineral is buried in the soil. By using the technique of *neutron activation analysis*, naturally occurring ^{19}F is converted to ^{20}F by neutron bombardment; the radioactive decay of the latter is then monitored, allowing the amount of ^{19}F originally present in the sample to be determined. An alternative method of fluorine dating makes use of a fluoride ion-selective electrode.[‡]

An electrode that is sensitive to the concentration of a specific ion is called an ***ion-selective electrode***. A common example is a pH meter, the electrode in which is sensitive to H^+ ions.

The uses of radioisotopes (e.g. ^{131}I) in medicine are extremely important. Iodine-131 is a β^--emitter and also emits γ-radiation. If a patient ingests ^{131}I (usually as a solution of ^{131}I-labelled NaI), the isotope quickly accumulates in the thyroid gland. By using a γ-camera to record the emitted γ-radiation, a γ-camera scan (a *scintigram*) is recorded which reveals the size and state of the gland. The half-life of ^{131}I is 8 days, and so the dose administered decays relatively quickly. The half-life of a radionuclide used in nuclear medicine must be long enough to allow for the preparation of the radiopharmaceutical and its administration to the patient, but must be short enough so as to minimize the patient's exposure to radiation. It is also important that the radioisotope decays to a daughter nuclide that is not itself

hazardous to the patient. In the case of ^{131}I, decay is to a stable (naturally occurring) isotope of xenon:

$$^{131}_{53}I \longrightarrow {}^{131}_{54}Xe + \beta^-$$

17.4 The elements

Difluorine

Difluorine is a pale yellow gas with a characteristic smell similar to that of O_3 or Cl_2. It is extremely corrosive, being easily the most reactive element known. Difluorine is handled in Teflon or special steel vessels,[†] although glass (see below) apparatus can be used if the gas is freed of HF by passage through sodium fluoride (eq. 17.5).

$$NaF + HF \longrightarrow Na[HF_2] \qquad (17.5)$$

The synthesis of F_2 cannot be carried out in aqueous media because F_2 decomposes water, liberating ozonized oxygen (i.e. O_2 containing O_3). The oxidizing power of F_2 is apparent from the E^o value listed in Table 17.1. The decomposition of a few high oxidation state metal fluorides generates F_2, but the only efficient alternative to the electrolytic method used industrially (see Section 17.2) is reaction 17.6. Difluorine is commercially available in cylinders, making laboratory synthesis generally unnecessary.

$$K_2[MnF_6] + 2SbF_5 \xrightarrow{420\ K} 2K[SbF_6] + MnF_2 + F_2 \qquad (17.6)$$

Difluorine combines directly with all elements except O_2, N_2 and the lighter noble gases; reactions tend to be very violent. Combustion in compressed F_2 (*fluorine bomb calorimetry*) is a suitable method for determining values of $\Delta_f H^o$ for many binary metal fluorides. However, many metals are passivated by the formation of a layer of non-volatile metal fluoride. Silica is thermodynamically unstable with respect to reaction 17.7, but, unless the SiO_2 is powdered, the reaction is slow provided that HF is absent; the latter sets up chain reaction 17.8.

$$SiO_2 + 2F_2 \longrightarrow SiF_4 + O_2 \qquad (17.7)$$

$$\left.\begin{aligned} SiO_2 + 4HF &\longrightarrow SiF_4 + 2H_2O \\ 2H_2O + 2F_2 &\longrightarrow 4HF + O_2 \end{aligned}\right\} \qquad (17.8)$$

The high reactivity of F_2 arises partly from the low bond dissociation energy (Fig. 17.3) and partly from the strength of the bonds formed with other elements (see Section 17.3).

Dichlorine, dibromine and diiodine

Dichlorine is a pale green-yellow gas with a characteristic odour. Inhalation causes irritation of the respiratory system and liquid Cl_2 burns the skin. Reaction 17.9 can be used for small-scale synthesis, but, like F_2, Cl_2 may be purchased in cylinders for laboratory use.

$$MnO_2 + 4HCl \xrightarrow[\text{conc}]{} MnCl_2 + Cl_2 + 2H_2O \qquad (17.9)$$

Dibromine is a dark orange, volatile liquid (the only liquid non-metal at 298 K) but is often used as the aqueous solution 'bromine water'. Skin contact with liquid Br_2 results in burns, and Br_2 vapour has an unpleasant smell and causes eye and respiratory irritation. At 298 K, I_2 forms dark purple crystals which sublime readily at 1 bar pressure into a purple vapour.

In the crystalline state, Cl_2, Br_2 or I_2 molecules are arranged in layers (Fig. 17.5). The molecules Cl_2 and Br_2 have *intra*molecular distances which are the same as in the vapour (compare these distances with $2r_{cov}$, Table 17.1). *Inter*molecular distances for Cl_2 and Br_2 are also listed in Fig. 17.5. The distances within a layer are shorter than $2r_v$ (Table 17.1), suggesting some degree of interaction between the X_2 molecules. The shortest *inter*molecular X····X distance *between* layers is significantly longer. In solid I_2, the *intra*molecular I–I bond distance is longer

[†]See, for example, R.D. Chambers and R.C.H. Spink (1999) *Chem. Commun.*, p. 883 – 'Microreactors for elemental fluorine'.

than in a gaseous molecule, and the lowering of the bond order (i.e. decrease in intramolecular bonding) is offset by a degree of *inter*molecular bonding within each layer (Fig. 17.5). It is significant that solid I_2 possesses a metallic lustre and exhibits appreciable electrical conductivity at higher temperatures. Under very high pressure I_2 becomes a metallic conductor.

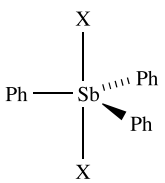
Chemical reactivity decreases steadily from Cl_2 to I_2, notably in reactions of the halogens with H_2, P_4, S_8 and most metals. The values of E^o in Table 17.1 indicate the decrease in oxidizing power along the series $Cl_2 > Br_2 > I_2$, and this trend is the basis of the methods of extraction of Br_2 and I_2 described in Section 17.2. Notable features of the chemistry of iodine which single it out among the halogens are that it is more easily:

- oxidized to high oxidation states;
- converted to stable salts containing I in the +1 oxidation state (e.g. Fig. 17.4).

Charge transfer complexes

A ***charge transfer complex*** is one in which a donor and acceptor interact *weakly* together with some transfer of electronic charge, usually facilitated by the acceptor.

The observed colours of the halogens arise from an electronic transition from the highest occupied π^* MO to the lowest unoccupied σ^* MO (see Fig. 2.10). The HOMO–LUMO energy gap decreases in the order $F_2 > Cl_2 > Br_2 > I_2$, leading to a progressive shift in the absorption maximum from the near-UV to the red region of the visible spectrum. Dichlorine, dibromine and diiodine dissolve unchanged in many organic solvents (e.g. saturated hydrocarbons, CCl_4). However in, for example, ethers, ketones and pyridine, which contain donor atoms, Br_2 and I_2 (and Cl_2 to a smaller extent) form *charge transfer complexes* with the halogen σ^* MO acting as the acceptor orbital. In the extreme, complete transfer of charge could lead to heterolytic bond fission as in the formation of $[I(py)_2]^+$ (Fig. 17.4 and eq. 17.10).



$$2py + 2I_2 \longrightarrow [I(py)_2]^+ + [I_3]^- \qquad (17.10)$$

Solutions of I_2 in donor solvents, such as pyridine, ethers or ketones, are brown or yellow. Even benzene acts as a donor, forming charge transfer complexes with I_2 and Br_2. The colours of these solutions are noticeably different from those of I_2 or Br_2 in cyclohexane (a non-donor). Whereas amines, ketones and similar compounds donate electron density through a σ lone pair, benzene uses its π-electrons. This is apparent in the relative orientations of the donor (benzene) and acceptor (Br_2) molecules in Fig. 17.6b. The fact that solutions of the charge transfer complexes are coloured means that they absorb in the visible region of the spectrum (≈400–750 nm), but the electronic spectrum also contains an intense absorption in the UV region (≈230–330 nm) arising from an electronic transition from the solvent−X_2 occupied bonding MO to a vacant antibonding MO. This is the so-called *charge transfer band*. Many charge transfer complexes can be isolated in the solid state and examples are given in Fig. 17.6. In complexes in which the donor is weak, e.g. C_6H_6, the X−X bond distance is unchanged (or nearly so) by complex formation. Elongation as in 1,2,4,5-$(EtS)_4C_6H_2\cdot(Br_2)_2$ (compare the Br−Br distance in Fig. 17.6c with that for free Br_2, in Fig. 17.5) is consistent with the involvement of a good donor. It has been estimated from theoretical calculations that −0.25 negative charges are transferred from 1,2,4,5-$(EtS)_4C_6H_2$ to Br_2. Different degrees of charge transfer are also reflected in the relative magnitudes of Δ_rH given for reactions 17.11. Further evidence for the weakening of the X−X bond comes from vibrational spectroscopic data, e.g. a shift for $\bar{\nu}$(X−X) from 215 cm^{-1} in I_2 to 204 cm^{-1} in $C_6H_6\cdot I_2$.

$$\left.\begin{aligned} C_6H_6 + I_2 &\longrightarrow C_6H_6\cdot I_2 \quad \Delta_rH = -5\ kJ\ mol^{-1} \\ C_2H_5NH_2 + I_2 &\longrightarrow C_2H_5NH_2\cdot I_2 \quad \Delta_rH = -31\ kJ\ mol^{-1} \end{aligned}\right\} \qquad (17.11)$$

Figure 17.6d shows the solid state structure of $Ph_3P\cdot Br_2$. $Ph_3P\cdot I_2$ has a similar structure (I−I = 316 pm). In CH_2Cl_2 solution, $Ph_3P\cdot Br_2$ ionizes to give $[Ph_3PBr]^+Br^-$ and, similarly, Ph_3PI_2 forms $[Ph_3PI]^+I^-$ or, in the presence of excess I_2, $[Ph_3PI]^+[I_3]^-$. The formation of complexes of this type is not easy to predict:

- the reaction of Ph_3Sb with Br_2 or I_2 is an oxidative addition yielding Ph_3SbX_2, **17.1**;
- Ph_3AsBr_2 is an As(V) compound, whereas $Ph_3As\cdot I_2$, $Me_3As\cdot I_2$ and $Me_3As\cdot Br_2$ are charge transfer complexes of the type shown in Fig. 17.6d.[†]

(17.1)

The nature of the products from reaction 17.12 depend on the solvent and the R group in R_3P. Solid state structure determinations exemplify products of type $[R_3PI]^+[I_3]^-$ (e.g. R = $^nPr_2N$, solvent = Et_2O) and $[(R_3PI)_2I_3]^+[I_3]^-$ (e.g. R = Ph, solvent = CH_2Cl_2; R = ^iPr, solvent = Et_2O).

[†] For insight into the complexity of this problem, see, for example, N. Bricklebank, S.M. Godfrey, H.P. Lane, C.A. McAuliffe, R.G. Pritchard and J.-M. Moreno (1995) *J. Chem. Soc., Dalton Trans.*, p. 3873; F.B. Alhanash *et al.* (2012) *Dalton Trans.*, vol. 41, p. 7708.

Marstokk *et al.* (1968) *Acta Crystallogr., Sect. B*, vol. 24, p. 713]; (b) schematic representation of the chain structure of $C_6H_6{\cdot}Br_2$; (c) 1,2,4,5-$(EtS)_4C_6H_2{\cdot}(Br_2)_2$ in which Br_2 molecules are sandwiched between layers of 1,2,4,5-$(EtS)_4C_6H_2$ molecules; interactions involving only one Br_2 molecule are shown and H atoms are omitted [H. Bock *et al.* (1996) *J. Chem. Soc., Chem. Commun.*, p. 1529]; (d) $Ph_3P{\cdot}Br_2$ [N. Bricklebank *et al.* (1992) *J. Chem. Soc., Chem. Commun.*, p. 355]. Colour code: Br, brown; C, grey; N, blue; S, yellow; P, orange; H, white.

Structure **17.2** shows the $[(^iPr_3PI)_2I_3]^+$ cation in $[(^iPr_3PI)_2I_3][I_3]$.

$$R_3P + 2I_2 \longrightarrow R_3PI_4 \qquad (17.12)$$

(17.2)

Although there are many examples of X_2 molecules acting as electron acceptors, the role of X_2 as a donor is less well exemplified. Two examples of I_2 acting as an electron donor towards a metal centre are $Rh_2(O_2CCF_3)_4I_2{\cdot}I_2$ and the Ag^+-containing polymer (made by reaction 17.13) shown in Fig. 17.7. The I–I bond distance of close to 267 pm indicates that the bond order is 1 (see Fig. 17.5). In the silver complex, the bonding scheme shown in Fig. 17.7 has been proposed. Charge donation from the filled π^* orbitals (the degenerate HOMO of I_2, see Fig. 2.10) to low-lying, empty 5*s* and 5*p* orbitals on the Ag^+ centre strengthens the I–I bond, while back-donation of charge from a filled Ag 4*d* orbital to the empty σ^* MO of I_2 weakens the I–I bond. In the Raman spectrum of

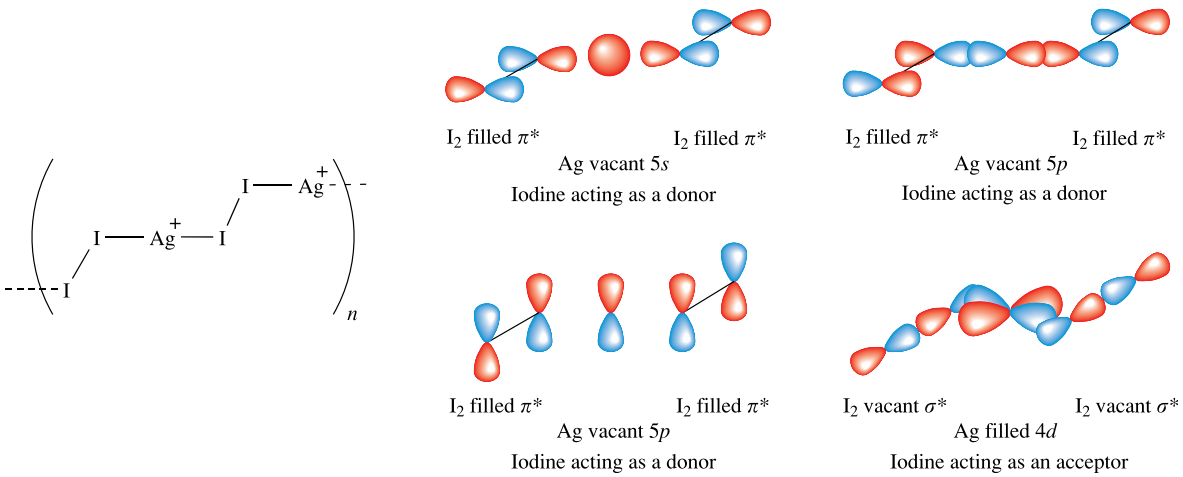


Fig. 17.7. Part of the chain structure of polymeric $[(AgI_2)_n]^{n+}$. Proposed bonding scheme for $[(AgI_2)_n]^{n+}$ illustrating the ability of I_2 to act as both a charge donor and a charge acceptor.

$[(AgI_2)_n][SbF_6]_n$, the value of 208 cm^{-1} for $\tilde{\nu}$(I–I) is slightly lower than in I_2 (215 cm^{-1}). A valence bond approach to the bonding in $[(AgI_2)_n]^{n+}$ is the subject of end-of-chapter problem 17.27.

$$AgMF_6 + I_2 \xrightarrow{\text{in liquid } SO_2} \tfrac{1}{n}[(AgI_2)_n][MF_6]_n \quad (M = As, Sb) \qquad (17.13)$$

Clathrates

Dichlorine, dibromine and diiodine are sparingly soluble in water. By freezing aqueous solutions of Cl_2 and Br_2, solid hydrates of approximate composition $X_2 \cdot 8H_2O$ may be obtained. These crystalline solids, called *clathrates* (see Section 12.8), consist of hydrogen-bonded structures with X_2 molecules occupying cavities in the 3-dimensional network. An example is $1,3,5\text{-}(HO_2C)_3C_6H_3 \cdot 0.16Br_2$ which consists of a hydrogen-bonded 3-dimensional network of benzene-1,3,5-tricarboxylic acid molecules with Br_2 molecules hosted within some of the cavities in the framework.

17.5 Hydrogen halides

All the hydrogen halides, HX, are gases at 298 K with sharp, acid smells. Selected properties are given in Table 17.2. Direct combination of H_2 and X_2 to form HX (see

Table 17.2 Selected properties of the hydrogen halides.

Property	HF	HCl	HBr	HI
Physical appearance at 298 K	Colourless gas	Colourless gas	Colourless gas	Colourless gas
Melting point / K	189	159	186	222
Boiling point / K	293	188	207	237.5
$\Delta_{fus}H^o$(mp) / kJ mol^{-1}	4.6	2.0	2.4	2.9

Bond length / pm	92	127.5	141.5	161
Dipole moment / D	1.83	1.11	0.83	0.45

eqs. 10.25–10.27 and accompanying discussion) can be used synthetically only for the chloride and bromide. Hydrogen fluoride is prepared by treating suitable metal fluorides with concentrated H_2SO_4 (e.g. reaction 17.14) and analogous reactions are also a convenient means of making HCl. Analogous reactions with bromides and iodides result in partial oxidation of HBr or HI to Br_2 or I_2 (reaction 17.15), and synthesis is thus by reaction 17.16 with PX_3 prepared *in situ*.

$$CaF_2 + 2H_2SO_4 \xrightarrow[\text{conc}]{} 2HF + Ca(HSO_4)_2 \qquad (17.14)$$

$$2HBr + H_2SO_4 \xrightarrow[\text{conc}]{} Br_2 + 2H_2O + SO_2 \qquad (17.15)$$

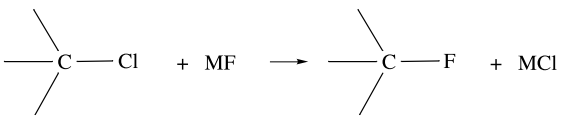
$$PX_3 + 3H_2O \longrightarrow 3HX + H_3PO_3 \qquad X = Br \text{ or } I \qquad (17.16)$$

Some aspects of the chemistry of the hydrogen halides have already been covered:

- liquid HF (Section 9.7);
- solid state structure of HF (Fig. 10.10);
- hydrogen bonding and trends in boiling points, melting points and $\Delta_{vap}H^o$ (Section 10.6);
- formation of the $[HF_2]^-$ ion (Section 9.7; eq. 10.31 and accompanying discussion);
- Brønsted acid behaviour in aqueous solution and energetics of acid dissociation (Sections 7.4 and 7.5).

Hydrogen fluoride is an important reagent for the introduction of F into organic and other compounds (e.g. reaction 14.45 in the production of CFCs). It differs from the other hydrogen halides in being a weak acid in aqueous solution ($pK_a = 3.45$). This is in part due to the high H−F bond dissociation enthalpy (Table 7.2 and Section 7.5). At high concentrations, the acid strength increases owing to the stabilization of F^- by formation of $[HF_2]^-$, **17.3** (scheme 17.17 and Table 10.4).

$$\left[F — H — F \right]^-$$



(17.3)

$$\left.\begin{aligned} &HF(aq) + H_2O(l) \rightleftharpoons [H_3O]^+(aq) + F^-(aq) \\ &F^-(aq) + HF(aq) \rightleftharpoons [HF_2]^-(aq) \quad K = \frac{[HF_2^-]}{[HF][F^-]} = 0.2 \end{aligned}\right\} \qquad (17.17)$$

The formation of $[HF_2]^-$ (see Section 9.7) is also observed when HF reacts with group 1 metal fluorides. $M[HF_2]$ salts are stable at room temperature, and structural data allow a realistic assessment of the strength of the F–H–F hydrogen-bonded interaction in the $[HF_2]^-$ ion. Analogous compounds are formed with HCl, HBr and HI only at low temperatures.

17.6 Metal halides: structures and energetics

All the halides of the alkali metals have NaCl or CsCl structures (Figs. 6.18 and 6.19) and their formation may be considered in terms of the Born–Haber cycle (see Section 6.14). In Section 11.5, we discussed trends in lattice energies of these halides, and showed that lattice energy is proportional to $1/(r_+ + r_-)$. We can apply this relationship to see why, for example, CsF is the best choice of alkali metal fluoride to effect the halogen exchange reaction 17.18.

(17.18)

In the absence of solvent, the energy change associated with reaction 17.18 involves:

- the difference between the C−Cl and C−F bond energy terms (*not* dependent on M);
- the difference between the electron affinities of F and Cl (*not* dependent on M);
- the difference in lattice energies between MF and MCl (dependent on M).

The last difference is approximately proportional to:

$$\frac{1}{(r_{M^+} + r_{Cl^-})} - \frac{1}{(r_{M^+} + r_{F^-})}$$

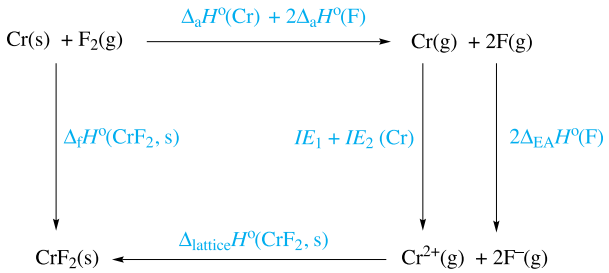
which is always negative because $r_{F^-} < r_{Cl^-}$. The term above approaches zero as r_{M^+} increases. Thus, reaction 17.18 is favoured most for $M^+ = Cs^+$.

A few other monohalides possess the NaCl or CsCl structure, e.g. AgF, AgCl, and we have already discussed (Section 6.15) that these silver(I) halides exhibit significant covalent character. The same is true for CuCl, CuBr, CuI and AgI which possess the wurtzite structure (Fig. 6.23).

Most metal difluorides crystallize with CaF_2 (Fig. 6.21) or rutile (Fig. 6.24) structures, and for most of these, a simple ionic model is appropriate (e.g. CaF_2, SrF_2, BaF_2, MgF_2, MnF_2 and ZnF_2). With slight modification, this model also holds for other *d*-block difluorides. Chromium(II)

chloride adopts a *distorted* rutile structure type, but other first row *d*-block metal dichlorides, dibromides and diiodides possess $CdCl_2$ or CdI_2 structures (see Fig. 6.25 and accompanying discussion). For these dihalides, neither purely electrostatic nor purely covalent models are satisfactory. Dihalides of the heavier *d*-block metals are considered in Chapter 22.

Metal trifluorides are crystallographically more complex than the difluorides, but symmetrical 3-dimensional structures are commonly found. Many contain octahedral (sometimes distorted) metal centres, e.g. AlF_3 (Section 13.6), VF_3 and MnF_3. For trichlorides, tribromides and triiodides, layer structures predominate. Among the tetrafluorides, a few have 3-dimensional structures, e.g. the two polymorphs of ZrF_4 possess, respectively, corner-sharing square-antiprismatic and dodecahedral ZrF_8 units. Most metal tetrahalides are either volatile molecular species (e.g. $SnCl_4$, $TiCl_4$) or contain rings or chains with M–F–M bridges (e.g. SnF_4, **14.15**). Metal–halogen bridges are longer than terminal bonds. Metal pentahalides may possess chain or ring structures (e.g. NbF_5, RuF_5, SbF_5, Fig. 15.15a) or molecular structures (e.g. $SbCl_5$), while metal hexahalides are molecular and octahedral (e.g. UF_6, MoF_6, WF_6, WCl_6). In general, an increase in oxidation state results in a structural change along the series 3-dimensional ionic ⟶ layer or polymer ⟶ molecular.



For metals exhibiting variable oxidation states, the relative thermodynamic stabilities of two ionic halides that contain a common halide ion but differ in the oxidation state of the metal (e.g. AgF and AgF_2) can be assessed using Born–Haber cycles. In such a reaction as 17.19, if the increase in ionization energies (e.g. $M \longrightarrow M^+$ versus $M \longrightarrow M^{2+}$) is approximately offset by the difference in lattice energies of the compounds, the two metal halides will be of about equal stability. This commonly happens with *d*-block metal halides.

$$MX + \tfrac{1}{2}X_2 \longrightarrow MX_2 \qquad (17.19)$$

Worked example 17.2 Thermochemistry of metal fluorides

The lattice energies of CrF_2 and CrF_3 are -2921 and $-6040\,kJ\,mol^{-1}$ respectively. (a) Calculate values of $\Delta_f H^o(298\,K)$ for $CrF_2(s)$ and $CrF_3(s)$, and comment on the stability of these compounds with respect to Cr(s) and $F_2(g)$. (b) The third ionization energy of Cr is large and positive. What factor offsets this and results in the standard enthalpies of formation of CrF_2 and CrF_3 being of the same order of magnitude?

(a) Set up a Born–Haber cycle for each compound; data needed are in the Appendices. For CrF_2 this is:

$$\begin{aligned}\Delta_f H^o(CrF_2, s) &= \Delta_a H^o(Cr) + 2\Delta_a H^o(F) + \Sigma IE(Cr) \\ &\quad + 2\Delta_{EA} H^o(F) + \Delta_{lattice} H^o(CrF_2, s) \\ &= 397 + 2(79) + 653 + 1591 + 2(-328) - 2921 \\ &= -778\,kJ\,mol^{-1}\end{aligned}$$

A similar cycle for CrF_3 gives:

$$\begin{aligned}\Delta_f H^o(CrF_3, s) &= \Delta_a H^o(Cr) + 3\Delta_a H^o(F) + \Sigma IE(Cr) \\ &\quad + 3\Delta_{EA} H^o(F) + \Delta_{lattice} H^o(CrF_3, s) \\ &= 397 + 3(79) + 653 + 1591 + 2987 \\ &\quad + 3(-328) - 6040 \\ &= -1159\,kJ\,mol^{-1}\end{aligned}$$

The large negative values of $\Delta_f H^o(298\,K)$ for both compounds show that the compounds are stable with respect to their constituent elements.

(b) $IE_3(Cr) = 2987\,kJ\,mol^{-1}$

There are two negative terms that help to offset this: $\Delta_{EA} H^o(F)$ and $\Delta_{lattice} H^o(CrF_3, s)$. Note also that:

$$\Delta_{lattice} H^o(CrF_3, s) - \Delta_{lattice} H^o(CrF_2, s) = -3119\,kJ\,mol^{-1}$$

and this term alone effectively cancels the extra energy of ionization required on going from Cr^{2+} to Cr^{3+}.

Self-study exercises

1. Values of $\Delta_{lattice} H^o$ for MnF_2 and MnF_3 (both of which are stable with respect to their elements at 298 K) are -2780 and $-6006\,kJ\,mol^{-1}$. The third ionization energy of Mn is $3248\,kJ\,mol^{-1}$. Comment on these data.
2. $\Delta_f H^o(AgF_2, s)$ and $\Delta_f H^o(AgF, s) = -360$ and $-205\,kJ\,mol^{-1}$. Calculate values of $\Delta_{lattice} H^o$ for each compound. Comment on the results in the light of the fact that the values of $\Delta_f H^o$ for AgF_2 and AgF are of the same order of magnitude.

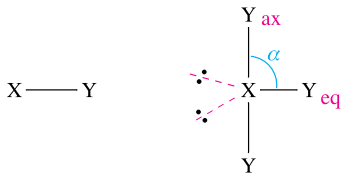
[*Ans.* AgF, $-972\,kJ\,mol^{-1}$; AgF_2, $-2951\,kJ\,mol^{-1}$]

17.7 Interhalogen compounds and polyhalogen ions

Interhalogen compounds

Properties of interhalogen compounds are listed in Table 17.3. All are prepared by direct combination of elements, and where more than one product is possible, the outcome of the reaction is controlled by temperature and relative proportions of the halogens. Reactions of F_2 with the later halogens at ambient temperature and pressure give ClF, BrF_3 or IF_5, but increased temperatures give ClF_3, ClF_5, BrF_5 and IF_7. For the formation of IF_3, the reaction between I_2 and F_2 is carried out at 228 K. Table 17.3 shows clear trends among the four families of compounds XY, XY_3, XY_5 and XY_7:

- F is always in oxidation state −1;
- highest oxidation states for X reached are Cl < Br < I;
- combination of the later halogens with *fluorine* leads to the highest oxidation state compounds.



The structural families are **17.4**–**17.7** and are consistent with the VSEPR model (see Section 2.8). Angle α in **17.5** is 87.5° in gaseous ClF_3, 86° in gaseous BrF_3 and 80.2° in crystalline IF_3 (IF_3 decomposes at 245 K). In each of ClF_5, BrF_5 and IF_5, the X atom lies just below the plane of the four F atoms. In this series of compounds, angle α in structure **17.6** lies between 90° (in ClF_5) and 81° (in IF_5). Among

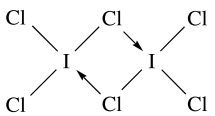
§§ Solid state (X-ray diffraction) data.



the interhalogens, ICl_3 is unusual in dimerizing. It possesses structure **17.8** and the planar I environments are rationalized in terms of the VSEPR model.

(17.4) **(17.5)**

(17.6) **(17.7)**

(17.8)

In a series of compounds XY_n in which the oxidation state of X increases, the X–Y bond enthalpy term decreases, e.g. for the Cl–F bonds in ClF, ClF_3 and ClF_5, they are 257, 172 and 153 kJ mol^{-1} respectively.

The most stable of the diatomic molecules are ClF and ICl. At 298 K, IBr dissociates somewhat into its elements, while BrCl is substantially dissociated (Table 17.3). Bromine monofluoride readily disproportionates (eq. 17.20), and IF is unstable at room temperature with respect to reaction 17.21.

$$3BrF \longrightarrow Br_2 + BrF_3 \qquad (17.20)$$

$$5IF \longrightarrow 2I_2 + IF_5 \qquad (17.21)$$

In general, the diatomic interhalogens exhibit properties intermediate between their parent halogens. However, where the electronegativities of X and Y differ significantly, the X–Y bond is stronger than the mean of the X–X and Y–Y bond strengths (see eqs. 2.10 and 2.11). Consistent with this is the observation that, if $\chi^P(X) \ll \chi^P(Y)$, the X–Y bond lengths (Table 17.3) are shorter than the mean of d(X–X) and d(Y–Y). Figure 17.5 illustrated that in the solid state, molecules of Cl_2, Br_2 and I_2 form zigzag chains which stack in layers. The structure of crystalline IBr is similar (Fig. 17.8a). Within each chain, the intermolecular

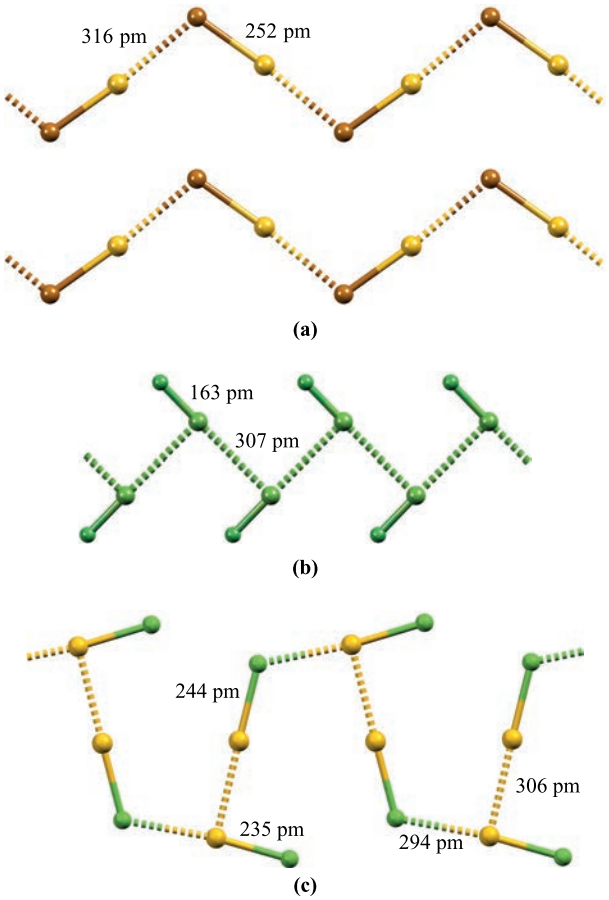


Fig. 17.8. The solid state structures (determined by X-ray diffraction) of (a) IBr [L.N. Swink *et al.* (1968) *Acta Crystallogr., Sect. B*, vol. 24, p. 429], (b) ClF (determined at 85 K) in which the chains are supported by short Cl···Cl contacts [R. Boese *et al.* (1997) *Angew. Chem. Int. Ed.*, vol. 36, p. 1489] and (c) β-ICl [G.B. Carpenter *et al.* (1962) *Acta Crystallogr.*, vol. 15, p. 360]. Colour code: F and Cl, green; Br, brown; I, gold.

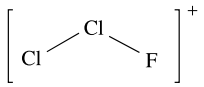
I···Br distances (316 pm) are significantly shorter than the sum of the van der Waals radii of I and Br (410 pm). In contrast, solid ClF is composed of ribbons of molecules which are supported by Cl···Cl interactions (Fig. 17.8b). The Cl···Cl distances (307 pm) are appreciably shorter than twice r_v(Cl). Two polymorphs (α- and β-forms) of crystalline ICl have been structurally characterized. Each form comprises chains of molecules, with each chain consisting of alternating non-equivalent ICl units (I–Cl = 235 and 244 pm). Figure 17.8c shows part of one chain of β-ICl and illustrates that short Cl···I and I···I interactions are present. The I···I distances of 306 pm are particularly significant, being closer to the sum of r_{cov} (266 pm) than to the sum of r_v (430 pm). This suggests that ICl tends towards forming I_2Cl_2 dimers in the solid state.



Chlorine monofluoride is commercially available and acts as a powerful fluorinating and oxidizing agent (e.g. reaction 17.22). Oxidative addition of ClF to SF_4 was shown in Fig. 16.14. It may behave as a fluoride donor

(eq. 17.23) or as a fluoride acceptor (eq. 17.24). The structures of $[Cl_2F]^+$ (**17.9**) and $[ClF_2]^-$ (**17.10**) can be rationalized using the VSEPR model. Iodine monochloride and monobromide are less reactive than ClF, but of importance is the fact that, *in polar solvents*, ICl is a source of I^+ and iodinates aromatic compounds.

$$W + 6ClF \longrightarrow WF_6 + 3Cl_2 \quad (17.22)$$

$$2ClF + AsF_5 \longrightarrow [Cl_2F]^+[AsF_6]^- \quad (17.23)$$

$$ClF + CsF \longrightarrow Cs^+[ClF_2]^- \quad (17.24)$$

(17.9)

(17.10)

With the exception of I_2Cl_6, the higher interhalogens contain F and are extremely reactive, exploding or reacting violently with water or organic compounds; ClF_3 even ignites asbestos. Despite these hazards, they are valuable fluorinating agents, e.g. the highly reactive ClF_3 converts metals, metal chlorides and metal oxides to metal fluorides. One of its main uses is in nuclear fuel reprocessing for the formation of UF_6 (reaction 17.25).

$$U + 3ClF_3 \xrightarrow{\Delta} UF_6 + 3ClF \quad (17.25)$$

Reactivity decreases in the general order $ClF_n > BrF_n > IF_n$, and within a series having common halogens, the compound with the highest value of n is the most reactive, e.g. $BrF_5 > BrF_3 > BrF$. In line with these trends is the use of IF_5 as a relatively mild fluorinating agent in organic synthesis.

We have already discussed the self-ionization of BrF_3 and its use as a non-aqueous solvent (see Section 9.10). There is some evidence for the self-ionization of IF_5 (eq. 17.26), but little to support similar processes for other interhalogens.

$$2IF_5 \rightleftharpoons [IF_4]^+ + [IF_6]^- \quad (17.26)$$

Reactions 17.23 and 17.24 showed the fluoride donor and acceptor abilities of ClF. All the higher interhalogens undergo similar reactions, although ClF_5 does not form stable complexes at 298 K with alkali metal fluorides. However, it does react with CsF or $[Me_4N]F$ at low temperatures to give salts containing $[ClF_6]^-$. Examples of F^- donation and acceptance by interhalogens are given in eqs. 9.42 and 17.27–17.31.

$$NOF + ClF_3 \longrightarrow [NO]^+[ClF_4]^- \quad (17.27)$$

$$CsF + IF_7 \longrightarrow Cs^+[IF_8]^- \quad (17.28)$$

$$IF_3 \xrightarrow{[Me_4N]F} [Me_4N]^+[IF_4]^- \xrightarrow{[Me_4N]F} [Me_4N]^+_2[IF_5]^{2-} \quad (17.29)$$

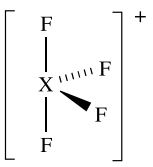
$$ClF_3 + AsF_5 \longrightarrow [ClF_2]^+[AsF_6]^- \quad (17.30)$$

$$IF_5 + 2SbF_5 \longrightarrow [IF_4]^+[Sb_2F_{11}]^- \quad (17.31)$$

The choice of a large cation (e.g. Cs^+, $[NMe_4]^+$) for stabilizing $[XY_n]^-$ anions follows from lattice energy considerations; see also Boxes 11.5 and 24.1. Thermal decomposition of salts of $[XY_n]^-$ leads to the halide salt of highest lattice energy, e.g. reaction 17.32.

$$Cs[ICl_2] \xrightarrow{\Delta} CsCl + ICl \quad (17.32)$$

Whereas $[IF_6]^+$ can be made by treating IF_7 with a fluoride acceptor (e.g. AsF_5), $[ClF_6]^+$ or $[BrF_6]^+$ must be made from ClF_5 or BrF_5 using an extremely powerful oxidizing agent because ClF_7 and BrF_7 are not known. Reaction 17.33 illustrates the use of $[KrF]^+$ to oxidize Br(V) to Br(VII). $[ClF_6]^+$ can be prepared in a similar reaction, or by using PtF_6 as oxidant. However, PtF_6 is not a strong enough oxidizing agent to oxidize BrF_5. In reaction 17.34, the active oxidizing species is $[NiF_3]^+$.[†] This cation is formed *in situ* in the $Cs_2[NiF_6]/AsF_5$/HF system, and is a more powerful oxidative fluorinating agent than PtF_6.



$$[KrF]^+[AsF_6]^- + BrF_5 \longrightarrow [BrF_6]^+[AsF_6]^- + Kr \quad (17.33)$$

$$Cs_2[NiF_6] + 5AsF_5 + XF_5 \quad (17.34)$$

$$\xrightarrow[\text{213 K warmed to 263 K}]{\text{anhydrous HF}} [XF_6][AsF_6] + Ni(AsF_6)_2 + 2CsAsF_6 \quad (X = Cl, Br)$$

Reaction 17.35 further illustrates the use of a noble gas fluoride in interhalogen synthesis. Unlike reaction 17.29, this route to $[Me_4N][IF_4]$ avoids the use of the thermally unstable IF_3.

$$2XeF_2 + [Me_4N]I \xrightarrow{\text{242 K; warm to 298 K}} [Me_4N][IF_4] + 2Xe \quad (17.35)$$

(17.11)

[†] For details of the formation of $[NiF_3]^+$, see: T. Schroer and K.O. Christe (2001) *Inorg. Chem.*, vol. 40, p. 2415.

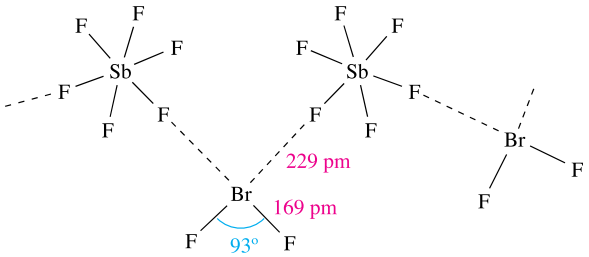


Table 17.4 Structures of selected interhalogens and derived anions and cations. Each is consistent with VSEPR theory.

Shape	Examples
Linear	$[ClF_2]^-$, $[IF_2]^-$, $[ICl_2]^-$, $[IBr_2]^-$
Bent	$[ClF_2]^+$, $[BrF_2]^+$, $[ICl_2]^+$
T-shaped†	ClF_3, BrF_3, IF_3, ICl_3
Square planar	$[ClF_4]^-$, $[BrF_4]^-$, $[IF_4]^-$, $[ICl_4]^-$
See-saw, **17.11**	$[ClF_4]^+$, $[BrF_4]^+$, $[IF_4]^+$
Square-based pyramidal	ClF_5, BrF_5, IF_5
Pentagonal planar	$[IF_5]^{2-}$
Octahedral	$[ClF_6]^+$, $[BrF_6]^+$, $[IF_6]^+$
Pentagonal bipyramidal	IF_7
Square antiprismatic	$[IF_8]^-$

† Low-temperature X-ray diffraction data show that solid ClF_3 contains discrete T-shaped molecules, but in solid BrF_3 and IF_3 there are intermolecular X–F····X bridges resulting in coordination spheres not unlike those in $[BrF_4]^-$ and $[IF_5]^{2-}$.

On the whole, the observed structures of interhalogen anions and cations (Table 17.4) agree with the VSEPR model, but $[BrF_6]^-$ is regular octahedral, indicating the presence of a stereochemically inactive lone pair. Raman spectroscopic data suggest that $[ClF_6]^-$ is isostructural with $[BrF_6]^-$. On the other hand, the vibrational spectrum of $[IF_6]^-$ shows it is not regular octahedral; however, on the ^{19}F NMR timescale, $[IF_6]^-$ is stereochemically non-rigid. The difference between the structures of $[BrF_6]^-$ and $[IF_6]^-$ may be rationalized in terms of the difference in size of the central atom (see Section 16.7, $[SeF_6]^{2-}$ versus $[SeCl_6]^{2-}$). However, a word of caution: the solid state structure of $[Me_4N][IF_6]$ reveals the presence of loosely bound $[I_2F_{12}]^{2-}$ dimers (Fig. 17.9a).

Of particular interest in Table 17.4 is $[IF_5]^{2-}$. Only two examples of pentagonal planar XY_n species are known, the other being $[XeF_5]^-$ (see Section 18.4). In salts such as $[BrF_2][SbF_6]$, $[ClF_2][SbF_6]$ and $[BrF_4][Sb_2F_{11}]$, there is significant cation–anion interaction. Diagram **17.12** focuses on the Br environment on the solid state structure of $[BrF_2][SbF_6]$, and Fig. 17.9b shows part of a chain of alternating cations and anions in crystalline $[BrF_4][Sb_2F_{11}]$.

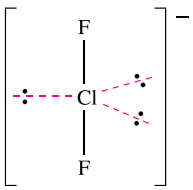
Self-study exercises

1. ^{127}I (100%, $I = \frac{5}{2}$) is a quadrupolar nucleus (see Section 4.8), but under certain circumstances (e.g. highly symmetrical environment), narrow line widths can be observed for signals in a ^{127}I NMR spectrum. Rationalize why the ^{127}I NMR spectrum of a liquid HF solution of $[IF_6][Sb_3F_{16}]$ exhibits a well-resolved binomial septet.
[*Ans.* See J.F. Lehmann *et al.* (2004) *Inorg. Chem.*, vol. 43, p. 6905]



2. Draw the structure of an $[Sb_2F_{11}]^-$ anion which possesses D_{4h} symmetry. Indicate on the diagram where the C_4 axis and σ_h plane lie. Compare this structure with the structures of the $[Sb_2F_{11}]^-$ ions shown in Figs. 15.15b and 17.9. Comment on how the anion is able to change its conformation, and what factors might affect the structure.

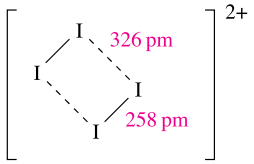
Fig. 17.9. (a) The structure of the $[I_2F_{12}]^{2-}$ dimer present in $[Me_4N][IF_6]$ (determined by X-ray diffraction); the I–F bridge distances are 211 and 282 pm [A.R. Mahjoub *et al.* (1991) *Angew. Chem. Int. Ed.*, vol. 30, p. 323]. Colour code: I, gold; F, green. (b) The solid state structure of $[BrF_4][Sb_2F_{11}]$ (determined by X-ray diffraction) consists of infinite chains of $[BrF_4]^+$ and $[Sb_2F_{11}]^-$ ions supported by Br····F interactions (Br····F = 235 and 241 pm, Sb–F_{term} = 184 pm, Sb–F_{br} = 190 pm, Br–F_{ax} = 173 pm, Br–F_{eq} = 166 pm) [A. Vij *et al.* (2002) *Inorg. Chem.*, vol. 41, p. 6397]. Colour code: Br, brown; Sb, silver; F, green.

Bonding in $[XY_2]^-$ ions

In Section 5.8, we used molecular orbital theory to describe the bonding in XeF_2, and developed a picture which gave a bond order of $\frac{1}{2}$ for each Xe–F bond. In terms of valence electrons, XeF_2 is isoelectronic with $[ICl_2]^-$, $[IBr_2]^-$, $[ClF_2]^-$ and related anions, and all have linear structures. The bonding in these anions can be viewed as being similar to that in XeF_2, and suggests weak X–Y bonds. This is in contrast to the localized hypervalent picture that emerges from a structure such as **17.13**. Evidence for weak bonds comes from the X–Y bond lengths (e.g. 255 pm in $[ICl_2]^-$ compared with 232 pm in gas phase ICl) and from X–Y bond stretching wavenumbers (e.g. 267 and 222 cm^{-1} for the symmetric and asymmetric stretches of $[ICl_2]^-$ compared with 384 cm^{-1} in ICl).

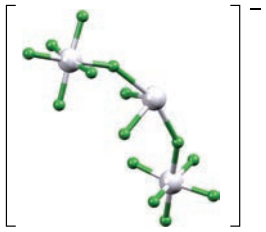
(17.13)

Polyhalogen cations



In addition to the interhalogen cations described earlier, homonuclear cations $[Br_2]^+$, $[I_2]^+$, $[Cl_3]^+$, $[Br_3]^+$, $[I_3]^+$, $[Br_5]^+$, $[I_5]^+$ and $[I_4]^{2+}$ are well established. The cations $[Br_2]^+$ and $[I_2]^+$ can be obtained by oxidation of the corresponding halogen (eqs. 17.36, 17.37 and 9.15).

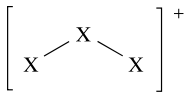
$$Br_2 + SbF_5 \xrightarrow{BrF_5} [Br_2]^+[Sb_3F_{16}]^- \qquad (17.36)$$



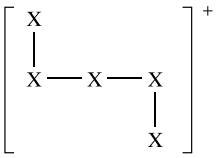
$$2I_2 + S_2O_6F_2 \xrightarrow{HSO_3F} 2[I_2]^+[SO_3F]^- \qquad (17.37)$$

On going from X_2 to the corresponding $[X_2]^+$, the bond shortens consistent with the loss of an electron from an antibonding orbital (see Figs. 2.7 and 2.10). In $[Br_2]^+[Sb_3F_{16}]^-$, the Br–Br distance is 215 pm, and in $[I_2]^+[Sb_2F_{11}]^-$ the I–I bond length is 258 pm (compare values of X_2 in Fig. 17.5). Correspondingly, the stretching wavenumber increases, e.g. 368 cm^{-1} in $[Br_2]^+$ compared with 320 cm^{-1} in Br_2. The cations are paramagnetic, and $[I_2]^+$ dimerizes at 193 K to give $[I_4]^{2+}$ (**17.14**). In reaction 17.38, AsF_5 acts as the oxidizing agent, and as a source of the counterion. When the oxidant is SbF_5, it is possible to isolate $[I_4]^{2+}[Sb_3F_{14}]^-[SbF_6]^-$. The $[Sb_3F_{14}]^-$ ion (**17.15**) contains one Sb(III) and two Sb(V) centres, and can be considered as comprising a $[SbF_2]^+$ cation linked to two $[SbF_6]^-$ ions.

$$2I_2 + 3AsF_5 \xrightarrow{\text{in liquid } SO_2} [I_4][AsF_6]_2 + AsF_3 \qquad (17.38)$$



(17.14)



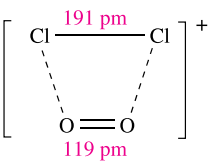
(17.15)

The cations $[Cl_3]^+$, $[Br_3]^+$ and $[I_3]^+$ are bent (**17.16**) as expected from the VSEPR model, and the X–X bond lengths are similar to those in gaseous X_2, consistent with single bonds. Reactions 17.39 and 17.40 may be used to prepare salts of $[Br_3]^+$ and $[I_3]^+$, and use of a higher concentration of I_2 in the I_2/AsF_5 reaction leads to the formation of $[I_5]^+$ (see reaction 9.15). The $[I_5]^+$ and $[Br_5]^+$ ions are structurally similar (**17.17**) with $d(X–X)_{terminal} < d(X–X)_{non\text{-}terminal}$, e.g. in $[I_5]^+$, the distances are 264 and 289 pm.

X = Cl, Br, I

(17.16)

X = Br, I



(17.17)

$$3Br_2 + 2[O_2]^+[AsF_6]^- \longrightarrow 2[Br_3]^+[AsF_6]^- + 2O_2 \qquad (17.39)$$

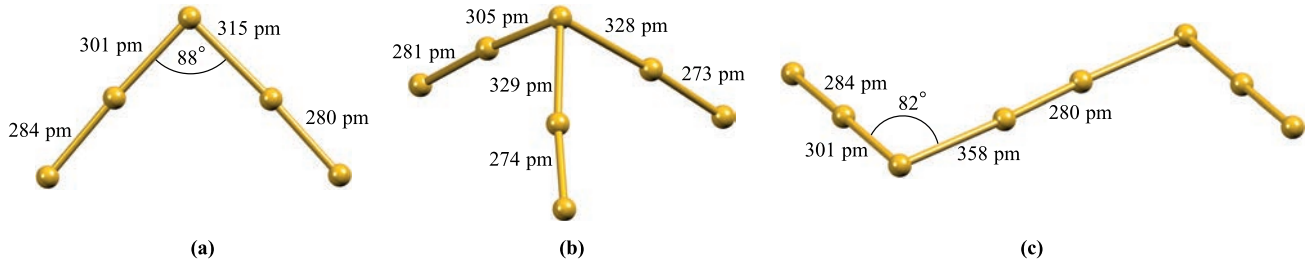
$$3I_2 + 3AsF_5 \xrightarrow{\text{in liquid } SO_2} 2[I_3]^+[AsF_6]^- + AsF_3 \qquad (17.40)$$

Even using extremely powerful oxidizing agents such as $[O_2]^+$, it has not proved possible (so far) to obtain the free $[Cl_2]^+$ ion by oxidizing Cl_2. When Cl_2 reacts with $[O_2]^+[SbF_6]^-$ in HF at low temperature, the product is $[Cl_2O_2]^+$ (**17.18**) which is best described as a charge transfer complex of $[Cl_2]^+$ and O_2. With IrF_6 as oxidant, reaction 17.41 takes place. The blue $[Cl_4][IrF_6]$ contains $[Cl_4]^+$ and decomposes at 195 K; X-ray diffraction data at 153 K show that the $[Cl_4]^+$ ion is structurally analogous to **17.14** (Cl–Cl = 194 pm, Cl···Cl = 294 pm).

$$2Cl_2 + IrF_6 \xrightarrow[<193\ K]{\text{anhydrous HF}} [Cl_4]^+[IrF_6]^- \qquad (17.41)$$

Cl----O = 242 pm

(17.18)



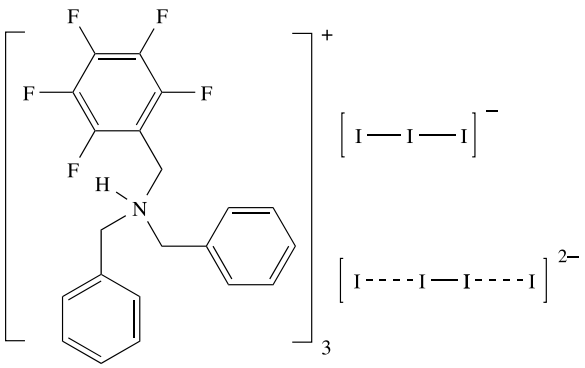


Fig. 17.10. The structures (X-ray diffraction) of (a) $[I_5]^-$ in $[Fe(S_2CNEt_2)_3][I_5]$ [C.L. Raston *et al.* (1980) *J. Chem. Soc., Dalton Trans.*, p. 1928], (b) $[I_7]^-$ in $[Ph_4P][I_7]$ [R. Poli *et al.* (1992) *Inorg. Chem.*, vol. 31, p. 3165] and (c) $[I_8]^{2-}$ in $[C_{10}H_8S_8]_2[I_3][I_8]_{0.5}$ [M.A. Beno *et al.* (1987) *Inorg. Chem.*, vol. 26, p. 1912].

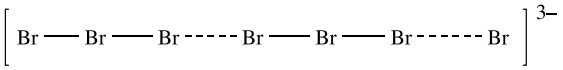


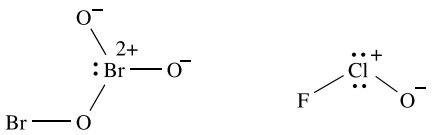
Polyhalide anions

Of the group 17 elements, iodine forms the largest range of homonuclear polyhalide ions, which include $[I_3]^-$, $[I_4]^{2-}$, $[I_5]^-$, $[I_7]^-$, $[I_8]^{2-}$, $[I_9]^-$, $[I_{10}]^{4-}$, $[I_{12}]^{2-}$, $[I_{16}]^{2-}$, $[I_{16}]^{4-}$, $[I_{22}]^{4-}$, $[I_{26}]^{3-}$ and $[I_{29}]^{3-}$. The $[F_3]^-$ ion has not been isolated under ambient conditions, but has been produced at 4 K by laser-ablation of metals with F_2 under conditions of electron capture. The $[F_3]^-$ and $[F_5]^-$ ions have been isolated in neon matrices.[†] Both $[Cl_3]^-$ and $[Br_3]^-$ are well established, but the $[I_3]^-$ ion is the most important member of this family. It is formed when I_2 is dissolved in aqueous solutions containing iodide ion. It has a linear structure, and in the solid state, the two I–I bond lengths may be equal (e.g. 290 pm in $[Ph_4As][I_3]$) or dissimilar (e.g. 283 and 303 pm in $Cs[I_3]$). The latter indicates something approaching an $[I{-}I{\cdots}I]^-$ entity (compare I–I = 266 pm in I_2). In the higher polyiodide ions, different I–I bond distances point to the structures being described in terms of association between I_2, I^- and $[I_3]^-$ units as examples in Fig. 17.10 show. This reflects their origins, since the higher polyiodides are formed upon crystallization of solutions containing I_2 and I^-. Details of the solid state structures of the anions are cation-dependent, e.g. although usually V-shaped (Fig. 17.10a), linear $[I_5]^-$ has also been observed in the solid state. The reaction between HI and pentafluorobenzyldibenzylamine produces compound **17.19**. The $[I_3]^-$ ion is essentially symmetrical (I–I = 290 and 292 pm). In the $[I_4]^{2-}$ ion, the central I–I distance is 276 pm, while the outer distances are 336 pm, indicating that, in this solid state structure, the $[I_4]^{2-}$ ion comprises an I_2 molecule interacting weakly with two I^- ions.

(17.19)

Compared with polyiodides, fewer polybromide ions have been characterized. Many salts involving $[Br_3]^-$ are known, and the association in the solid state of $[Br_3]^-$ and Br^- has been observed to give rise to the linear species **17.20**. The $[Br_8]^{2-}$ ion is structurally analogous to $[I_8]^{2-}$ (Fig. 17.10c) with Br–Br bond distances that indicate association between Br_2 and $[Br_3]^-$ units in the crystal.

(17.20)



Polyiodobromide ions are exemplified by $[I_2Br_3]^-$ and $[I_3Br_4]^-$. In the 2,2'-bipyridinium salt, $[I_2Br_3]^-$ is V-shaped like $[I_5]^-$ (Fig. 17.10a), while in the $[Ph_4P]^+$ salt, $[I_3Br_4]^-$ resembles $[I_7]^-$ (Fig. 17.10b). Both $[I_2Br_3]^-$ and $[I_3Br_4]^-$ can be described as containing IBr units linked by a Br^- ion.

17.8 Oxides and oxofluorides of chlorine, bromine and iodine

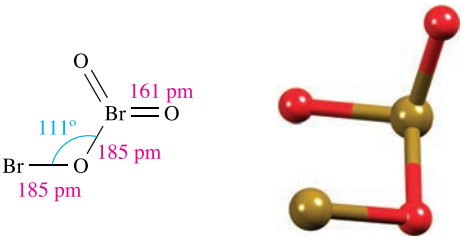
Earlier in the book (e.g. Sections 15.3 and 16.3), we described how heavier elements of the *p*-block can expand

[†] See: S. Riedel, T. Köchner, X. Wang and L. Andrews (2010) *Inorg. Chem.*, vol. 49, p. 7156; T. Vent-Schmidt *et al.* (2015) *Angew. Chem. Int. Ed.*, vol. 54, p. 8279.

their coordination numbers beyond 4 but still retain an octet of electrons in the valence shell. In this section, we discuss oxides and oxofluorides of Cl, Br and I, and in the majority of these compounds, halogen atoms are in an oxidation state of +3, +5 or +7. In terms of bonding, charge-separated species and sets of resonance structures can be drawn to represent the bonding in many of these molecules. For example, the bonding in Br_2O_3 and FClO may be described as follows (lone pairs are shown explicitly only on the high oxidation state halogen atom):

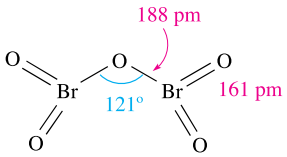
While these structures show each atom obeying the octet rule, drawing them becomes cumbersome for many species. Furthermore, for halogen atoms in oxidation state +7, charge separated structures place an unusually high positive formal charge on the central atom. We have therefore chosen to illustrate the structures of high oxidation state oxides and oxofluorides of Cl, Br and I showing hypervalent halogen atoms. Throughout the section, you should keep in mind that the representation of a 'line' between two atoms in a structural diagram does not necessarily imply a 2-centre 2-electron interaction.

Oxides



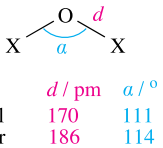
Oxygen fluorides were described in Section 16.7. Iodine is the only halogen to form an oxide which is *thermodynamically stable* with respect to decomposition into its elements (eq. 17.42). The chlorine and bromine oxides are hazardous materials which tend to explode.

$$I_2 + \tfrac{5}{2}O_2 \longrightarrow I_2O_5 \qquad \Delta_f H^\circ(298\,K) = -158.1\,kJ\,mol^{-1} \tag{17.42}$$



Chlorine oxides, although not difficult to prepare, are all liable to decompose explosively. Far less is known about the oxides of Br (which are very unstable) than those of chlorine and iodine, although Br_2O_3 (**17.21**) and Br_2O_5 (**17.22**) have been unambiguously prepared (scheme 17.43) and structurally characterized. The Br(V) centres are trigonal pyramidal and in Br_2O_5, the BrO_2 groups are eclipsed. The oxide Br_2O may be made by reaction 17.44 and has the non-linear structure **17.23**.

$$\underset{\text{brown}}{Br_2} \xrightarrow{O_3,\ 195\,K} \underset{\text{orange}}{Br_2O_3} \xrightarrow{O_3,\ 195\,K} \underset{\text{colourless}}{Br_2O_5} \tag{17.43}$$

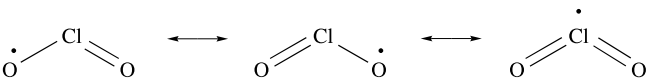


$$H_2O + 2BrOTeF_5 \xrightarrow{\text{in } CCl_3F,\ 195\,K} Br_2O + 2HOTeF_5 \tag{17.44}$$

(17.21)

(17.22)

X	d / pm	a / °
Cl	170	111
Br	186	114



(17.23)

Dichlorine monoxide, Cl_2O (**17.23**), is obtained as a yellow-brown gas by action of Cl_2 on mercury(II) oxide or moist sodium carbonate (eqs. 17.45 and 17.46). Cl_2O liquefies at ≈277 K, and explodes on warming. It hydrolyses to hypochlorous acid (eq. 17.47), and is formally the anhydride of this acid (see Section 15.8).

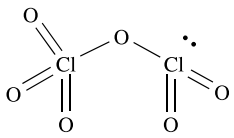
$$2Cl_2 + 3HgO \longrightarrow Cl_2O + Hg_3O_2Cl_2 \tag{17.45}$$

$$2Cl_2 + 2Na_2CO_3 + H_2O \longrightarrow 2NaHCO_3 + 2NaCl + Cl_2O \tag{17.46}$$

$$Cl_2O + H_2O \longrightarrow 2HOCl \tag{17.47}$$

Cl—O = 147 pm; ∠O–Cl–O = 117°

(17.24)



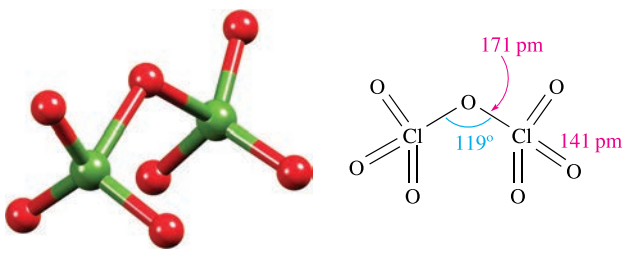
Chlorine dioxide, ClO_2 (**17.24**) is a yellow gas (bp 283 K), and is produced in the highly dangerous reaction between potassium chlorate, $KClO_3$, and concentrated H_2SO_4. Reaction 17.48 is a safer method of synthesis, and reactions 17.2 and 17.3 showed two of the commercial methods used to make ClO_2. ClO_2 is used to bleach flour and wood pulp and for water treatment. Its application as a bleach in the paper industry has increased (see Fig. 17.2).

$$2KClO_3 + 2H_2C_2O_4 \longrightarrow K_2C_2O_4 + 2ClO_2 + 2CO_2 + 2H_2O \tag{17.48}$$

Despite being a radical, ClO_2 shows no tendency to dimerize. It dissolves unchanged in water, but is slowly hydrolysed to HCl and $HClO_3$, a reaction that involves the $ClO^\bullet$ radical. In alkaline solution, hydrolysis is rapid (eq. 17.49). Ozone reacts with ClO_2 at 273 K to form Cl_2O_6, a dark red liquid which is also made by reaction 17.50.

$$2ClO_2 + 2[OH]^- \longrightarrow [ClO_3]^- + [ClO_2]^- + H_2O \quad (17.49)$$

$$ClO_2F + HClO_4 \longrightarrow Cl_2O_6 + HF \quad (17.50)$$



(17.25)

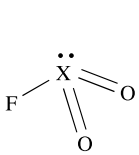
Reaction 17.50, and the hydrolysis of Cl_2O_6 to chlorate and perchlorate, suggest that it has structure **17.25** and is the mixed anhydride of $HClO_3$ and $HClO_4$. The IR spectrum of matrix-isolated Cl_2O_6 is consistent with a molecular structure with two inequivalent Cl centres. The solid, however, contains $[ClO_2]^+$ and $[ClO_4]^-$ ions. Cl_2O_6 is unstable with respect to decomposition into ClO_2, $ClOClO_3$ and O_2, and, with H_2O, reaction 17.51 occurs. The oxide $ClOClO_3$ is the mixed acid anhydride of HOCl and $HClO_4$, and is made by reaction 17.52.

$$Cl_2O_6 + H_2O \longrightarrow HClO_4 + HClO_3 \quad (17.51)$$

$$Cs[ClO_4] + ClSO_3F \longrightarrow Cs[SO_3F] + ClOClO_3 \quad (17.52)$$

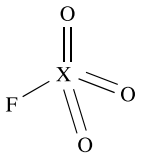
The anhydride of perchloric acid is Cl_2O_7 (**17.26**), an oily, explosive liquid (bp ≈353 K), which is made by dehydrating $HClO_4$ using phosphorus(V) oxide at low temperatures.

(17.26)



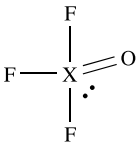
In contrast to Br_2O_5 which is thermally unstable, I_2O_5 is stable to 573 K. It is a white, hygroscopic solid, prepared by dehydration of iodic acid (HIO_3). The reaction is reversed when I_2O_5 dissolves in water (eq. 17.53). I_2O_5 is used in analysis for CO (see eq. 14.62).

$$I_2O_5 + H_2O \longrightarrow 2HIO_3 \quad (17.53)$$

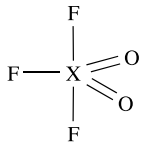


In the solid state, I_2O_5 is structurally related to Br_2O_5 (**17.22**), with the difference that it has a staggered conformation, probably as a result of extensive intermolecular interactions (I····O ≤ 223 pm).

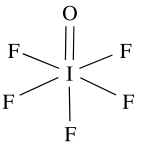
Oxofluorides



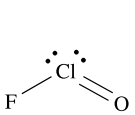
Several families of halogen oxides with X–F bonds exist: FXO_2 (X = Cl, Br, I), FXO_3 (X = Cl, Br, I), F_3XO (X = Cl, Br, I), F_3XO_2 (X = Cl, I) and F_5IO. The thermally unstable FClO is also known. Their structures are consistent with the VSEPR model (**17.27–17.32**).



(17.27)



(17.28)



(17.29)

(17.30)

(17.31)

(17.32)

Chloryl fluoride, $FClO_2$, is a colourless gas (bp 267 K) and can be prepared by reacting F_2 with ClO_2. It hydrolyses to $HClO_3$ and HF, and acts as a fluoride donor towards SbF_5 (eq. 17.54) and a fluoride acceptor with CsF (eq. 17.55).

$$FClO_2 + SbF_5 \longrightarrow [ClO_2]^+[SbF_6]^- \quad (17.54)$$

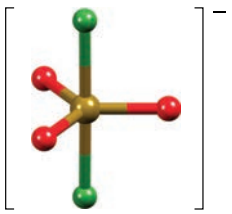
$$CsF + FClO_2 \longrightarrow Cs^+[F_2ClO_2]^- \quad (17.55)$$

Perchloryl fluoride, $FClO_3$ (bp 226 K, $\Delta_f H^\circ(298\,K) = -23.8\,kJ\,mol^{-1}$) is surprisingly stable and decomposes only above 673 K. It can be prepared by reaction 17.56, or by treating $KClO_3$ with F_2.

$$KClO_4 + 2HF + SbF_5 \longrightarrow FClO_3 + KSbF_6 + H_2O \quad (17.56)$$

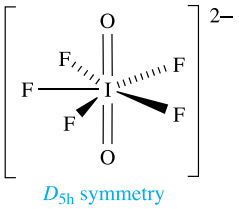
Alkali attacks $FClO_3$ only slowly, even at 500 K. Perchloryl fluoride is a mild fluorinating agent and has been used in the preparation of fluorinated steroids. It is also a powerful oxidizing agent at elevated temperatures, e.g. it oxidizes SF_4 to SF_6. Reaction 17.57 illustrates its reaction with an organic nucleophile. In contrast to $FClO_2$, $FClO_3$ does not behave as a fluoride donor or acceptor.

$$C_6H_5Li + FClO_3 \longrightarrow LiF + C_6H_5ClO_3 \quad (17.57)$$



The reaction between F_2 and Cl_2O at low temperatures yields F_3ClO (mp 230 K, bp 301 K, $\Delta_f H^\circ(g, 298\,K) = -148\,kJ\,mol^{-1}$) which decomposes at 570 K to ClF_3 and O_2. Reactions of F_3ClO with CsF and SbF_5 show its ability to accept or donate F^-, producing $[F_4ClO]^-$ and $[F_2ClO]^+$ respectively.

The compound $FBrO_3$ is one of only a few examples of bromine in oxidation state +7. It is made by treating $K[BrO_4]$ with AsF_5 or SbF_5 in liquid HF. $FBrO_3$ is more

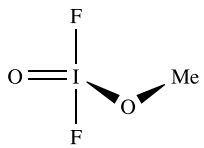


reactive than $FClO_3$ and is hydrolysed more rapidly than $FClO_3$ by aqueous alkali at room temperature (eq. 17.58). Unlike $FClO_3$, $FBrO_3$ acts as a fluoride acceptor (eq. 17.59) to give *trans*-$[F_2BrO_3]^-$ (**17.33**).

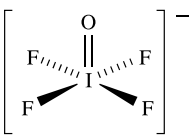
$$FBrO_3 + 2[OH]^- \longrightarrow [BrO_4]^- + H_2O + F^- \qquad (17.58)$$

$$MF + FBrO_3 \longrightarrow M[F_2BrO_3] \qquad \text{e.g. } M^+ = Cs^+, [NO]^+ \qquad (17.59)$$

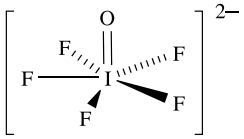
(17.33)



D_{5h} symmetry



(17.34)



The only representative of the neutral F_5XO family of oxofluorides is F_5IO, produced when IF_7 reacts with water. It does not readily undergo further reaction with H_2O. One reaction of note is that of F_5IO with $[Me_4N]F$ in which the pentagonal bipyramidal ion $[F_6IO]^-$ is formed; X-ray diffraction data show that the oxygen atom is in an axial site and that the equatorial F atoms are essentially coplanar, in contrast to the puckering observed in IF_7 (see Section 2.8). The pentagonal pyramidal $[F_5IO]^{2-}$ is formed as the Cs^+ salt when CsF, I_2O_5 and IF_5 are heated at 435 K. The stoichiometry of the reaction must be controlled to prevent $[F_4IO]^-$ being formed as the main product. Transfer of F^- from $[Me_4N]F$ to F_3IO_2 (**17.30**) leads to a mixture of *cis*- and *trans*-$[F_4IO_2]^-$. The *trans*-isomer reacts further to give $[F_5IO_2]^{2-}$, and this gives a means of isolating the pure *cis*-isomer of $[F_4IO_2]^-$ from the *cis*/*trans* mixture. Vibrational spectroscopic data are consistent with $[F_5IO_2]^{2-}$ possessing D_{5h} symmetry (**17.34**).

Self-study exercises

1. Rationalize each of the following structures in terms of the VSEPR model.

2. Confirm that the $[IOF_5]^{2-}$ ion (the structure is given above) has C_{5v} symmetry.
3. To what point groups do the following fluorides belong: BrF_5, $[BrF_4]^-$, $[BrF_6]^+$? Assume that each structure is regular. [*Ans.* C_{4v}; D_{4h}; O_h]
4. In the IR spectra of isotopically labelled $F^{35}ClO_2$ and $F^{37}ClO_2$, bands at 630 and 622 cm^{-1}, respectively, are assigned to the Cl–F stretching mode. What is the origin of the shift in wavenumber? Confirm that the observed shift is consistent with that expected.

17.9 Oxoacids and their salts

Hypofluorous acid, HOF

Fluorine is unique among the halogens in forming no species in which it has a formal oxidation state other than −1. The only known oxoacid is hypofluorous acid, HOF, which is unstable and does not ionize in water but reacts according to eq. 17.60; no salts are known. It is obtained by passing F_2 over ice at 230 K (eq. 17.61) and condensing the gas produced. At 298 K, HOF decomposes rapidly (eq. 17.62). The solid state structure of HOF has been determined by X-ray diffraction at 113 K, and shows that HOF molecules associate into chains through O–H···O hydrogen bonds.

$$HOF + H_2O \longrightarrow H_2O_2 + HF \qquad (17.60)$$

$$F_2 + H_2O \xrightarrow{230\,K} HOF + HF \qquad (17.61)$$

$$2HOF \longrightarrow 2HF + O_2 \qquad (17.62)$$

Oxoacids of chlorine, bromine and iodine

Table 17.5 lists the families of oxoacids known for Cl, Br and I. The hypohalous acids, HOX, are obtained in aqueous solution by reaction 17.63 (compare reactions 17.45 and 17.47).

$$2X_2 + 3HgO + H_2O \longrightarrow Hg_3O_2X_2 + 2HOX \qquad (17.63)$$

In contrast to HOF, HOCl, HOBr and HOI are unknown as isolated compounds, but in aqueous solution they act as weak acids (pK_a values: HOCl, 7.53; HOBr, 8.69; HOI, 10.64). Hypochlorite salts such as NaOCl, KOCl and $Ca(OCl)_2$ (eq. 17.64) can be isolated. NaOCl can be crystallized from a solution obtained by electrolysing aqueous NaCl in such a way that the Cl_2 liberated at the anode mixes with the NaOH produced at the cathode. Hypochlorites are powerful oxidizing agents and in the presence of alkali convert $[IO_3]^-$ to $[IO_4]^-$, Cr^{3+} to $[CrO_4]^{2-}$, and

Table 17.5 Oxoacids of chlorine, bromine and iodine.

Oxoacids of chlorine		Oxoacids of bromine		Oxoacids of iodine	
Hypochlorous acid	HOCl	Hypobromous acid	HOBr	Hypoiodous acid	HOI
Chlorous acid	HOClO ($HClO_2$)				
Chloric acid	$HOClO_2$ ($HClO_3$)	Bromic acid	$HOBrO_2$ ($HBrO_3$)	Iodic acid	$HOIO_2$ (HIO_3)
Perchloric acid	$HOClO_3$ ($HClO_4$)	Perbromic acid	$HOBrO_3$ ($HBrO_4$)	Periodic acid Orthoperiodic acid	$HOIO_3$ (HIO_4) $(HO)_5IO$ (H_5IO_6)

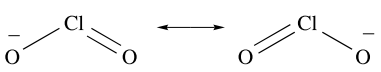
even Fe^{3+} to $[FeO_4]^{2-}$. Bleaching powder is a non-deliquescent mixture of $CaCl_2$, $Ca(OH)_2$ and $Ca(OCl)_2$ and is manufactured by the action of Cl_2 on $Ca(OH)_2$. NaOCl is a bleaching agent and disinfectant.

$$2CaO + 2Cl_2 \longrightarrow Ca(OCl)_2 + CaCl_2 \qquad (17.64)$$

All hypohalites are unstable with respect to disproportionation (eq. 17.65). At 298 K, the reaction is slow for $[OCl]^-$, fast for $[OBr]^-$ and very fast for $[OI]^-$. Sodium hypochlorite disproportionates in hot aqueous solution (eq. 17.66), and the passage of Cl_2 through *hot* aqueous alkali yields chlorate and chloride salts rather than hypochlorites. Hypochlorite solutions decompose by reaction 17.67 in the presence of cobalt(II) compounds as catalysts.

$$3[OX]^- \longrightarrow [XO_3]^- + 2X^- \qquad (17.65)$$

$$3NaOCl \longrightarrow NaClO_3 + 2NaCl \qquad (17.66)$$



$$2[OX]^- \longrightarrow 2X^- + O_2 \qquad (17.67)$$

Like HOCl, chlorous acid, $HClO_2$, is not isolable but is known in aqueous solution and is prepared by reaction 17.68. It is a relatively weak acid ($pK_a = 2.0$). Sodium chlorite (used as a bleach) is made by reaction 17.69. The chlorite ion has the bent structure **17.35**.

$$Ba(ClO_2)_2 + H_2SO_4(aq) \longrightarrow 2HClO_2(aq) + BaSO_4(s) \qquad (17.68)$$

suspension

$$Na_2O_2 + 2ClO_2 \longrightarrow 2NaClO_2 + O_2 \qquad (17.69)$$

Cl—O = 157 pm; ∠O–Cl–O = 111°

(17.35)

Alkaline solutions of chlorites persist unchanged over long periods, but in the presence of acid, $HClO_2$ disproportionates according to eq. 17.70.

$$5HClO_2 \longrightarrow 4ClO_2 + H^+ + Cl^- + 2H_2O \qquad (17.70)$$

Chloric and bromic acids, $HClO_3$ and $HBrO_3$, are both strong acids but cannot be isolated as pure compounds. The aqueous acids can be made by reaction 17.71 (compare with reaction 17.68).

$$Ba(XO_3)_2 + H_2SO_4 \longrightarrow BaSO_4 + 2HXO_3 \quad (X = Cl, Br) \qquad (17.71)$$

Iodic acid, HIO_3, is a stable, white solid at room temperature, and is produced by reacting I_2O_5 with water (eq. 17.53) or by the oxidation of I_2 with nitric acid. Crystalline iodic acid contains trigonal pyramidal HIO_3 molecules connected into chains by extensive hydrogen bonding (Fig. 17.11). In aqueous solution it is a fairly strong acid ($pK_a = 0.77$).

Chlorates are strong oxidizing agents. Commercially, $NaClO_3$ is used for the manufacture of ClO_2 (eq. 17.2), and is used as a weedkiller, although this application has been banned in the EU since 2009. $KClO_3$ has applications in fireworks and safety matches. Chlorates are produced by

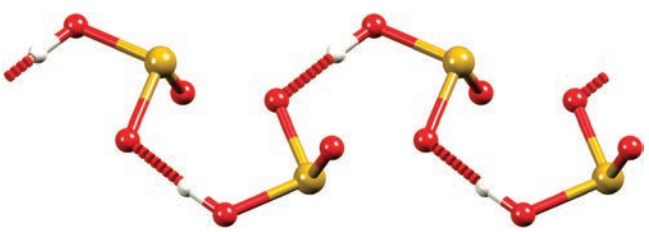


Fig. 17.11. In the solid state, molecules of HIO_3 form hydrogen-bonded chains. The structure was determined by neutron diffraction [K. Staahl (1992) *Acta Chem. Scand.*, vol. 46, p. 1146]. Colour code: I, gold; O, red; H, white.

electrolysis of brine at 340 K, allowing the products to mix efficiently (scheme 17.72); chlorate salts are crystallized from the mixture. Anodic oxidation of $[OCl]^-$ produces further $[ClO_3]^-$.

Electrolysis:

$$2Cl^- \longrightarrow Cl_2 + 2e^-$$

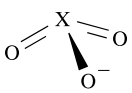
$$2H_2O + 2e^- \longrightarrow H_2 + 2[OH]^-$$

Mixing and disproportionation:

$$Cl_2 + 2[OH]^- \longrightarrow Cl^- + [OCl]^- + H_2O$$

$$3[OCl]^- \longrightarrow [ClO_3]^- + 2Cl^-$$

(17.72)



Bromates are made by, for example, reaction 17.73 under alkaline conditions. Reaction 17.74 is a convenient synthesis of KIO_3.

$$KBr + 3KOCl \longrightarrow KBrO_3 + 3KCl \quad (17.73)$$

$$2KClO_3 + I_2 \longrightarrow 2KIO_3 + Cl_2 \quad (17.74)$$

Potassium bromate and iodate are commonly used in volumetric analysis. Very pure KIO_3 is easily obtained, and reaction 17.75 is used as a source of I_2 for the standardization of thiosulfate solutions (reaction 16.118).

$$[IO_3]^- + 5I^- + 6H^+ \longrightarrow 3I_2 + 3H_2O \quad (17.75)$$

X = Cl, Br, I

(17.36)

Halate ions are trigonal pyramidal (**17.36**) although, in the solid state, some metal iodates contain infinite structures in which two O atoms of each iodate ion bridge two metal centres.† The thermal decomposition of alkali metal chlorates follows reaction 17.76, but in the presence of a suitable catalyst, $KClO_3$ decomposes to give O_2 (eq. 16.4). Some iodates (e.g. KIO_3) decompose when heated to iodide and O_2, but others (e.g. $Ca(IO_3)_2$) give oxide, I_2 and O_2. Bromates behave similarly and the interpretation of these observations is a difficult problem in energetics and kinetics.

$$4[ClO_3]^- \longrightarrow 3[ClO_4]^- + Cl^- \quad (17.76)$$

Caution: risk of explosion!

† For further discussion, see: A.F. Wells (1984) *Structural Inorganic Chemistry*, 5th edn, Clarendon Press, Oxford, pp. 327–337.

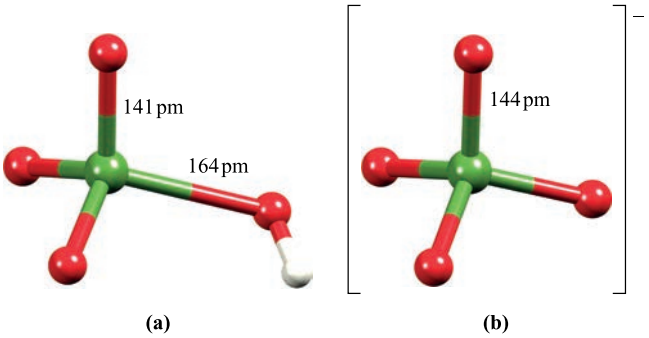


Fig. 17.12. Structures of (a) perchloric acid (vapour state), in which one Cl–O bond is unique, and (b) perchlorate ion, in which all Cl–O bonds are equivalent. Colour code: Cl, green; O, red; H, white.

Perchloric acid is the only oxoacid of Cl that can be isolated, and its vapour state structure is shown in Fig. 17.12a. Discrete molecules are also present in crystalline, anhydrous $HClO_4$, the structure having been determined at 113 K. At 298 K, $HClO_4$ is a colourless liquid (bp 363 K with some decomposition). It is made by heating $KClO_4$ with concentrated H_2SO_4 under reduced pressure. Pure perchloric acid is liable to explode when heated or in the presence of organic material, but in dilute solution, $[ClO_4]^-$ is very difficult to reduce despite the reduction potentials (which provide thermodynamic but not kinetic data) shown in eqs. 17.77 and 17.78. Zinc, for example, merely liberates H_2, and iodide ion has no action. Reduction to Cl^- can be achieved by Ti(III) in acidic solution or by Fe(II) in the presence of alkali.

$$[ClO_4]^- + 2H^+ + 2e^- \rightleftharpoons [ClO_3]^- + H_2O \qquad E^\circ = +1.19\,V \quad (\text{at pH } 0) \quad (17.77)$$

$$[ClO_4]^- + 8H^+ + 8e^- \rightleftharpoons Cl^- + 4H_2O \qquad E^\circ = +1.39\,V \quad (\text{at pH } 0) \quad (17.78)$$

Perchloric acid is an extremely strong acid in aqueous solution (see Table 7.3). Although $[ClO_4]^-$ (Fig. 17.12b) does form complexes with metal cations, the tendency to do so is less than for other common anions. Consequently, $NaClO_4$ solution is a standard medium for the investigation of ionic equilibria in aqueous systems, e.g. it is used as a supporting electrolyte in electrochemical experiments (see Box 8.2). Alkali metal perchlorates can be obtained by disproportionation of chlorates (eq. 17.76) under carefully controlled conditions; traces of impurities can catalyse decomposition to chloride and O_2. ***Perchlorate salts are potentially explosive and must be handled with particular care***. For example, solid NH_4ClO_4 decomposes at 298 K according to eq. 17.79, and mixtures of ammonium perchlorate and aluminium are standard missile propellants.

$$4NH_4ClO_4(s) \longrightarrow 2Cl_2(g) + 2N_2O(g) + 3O_2(g) + 8H_2O(l) \quad (17.79)$$

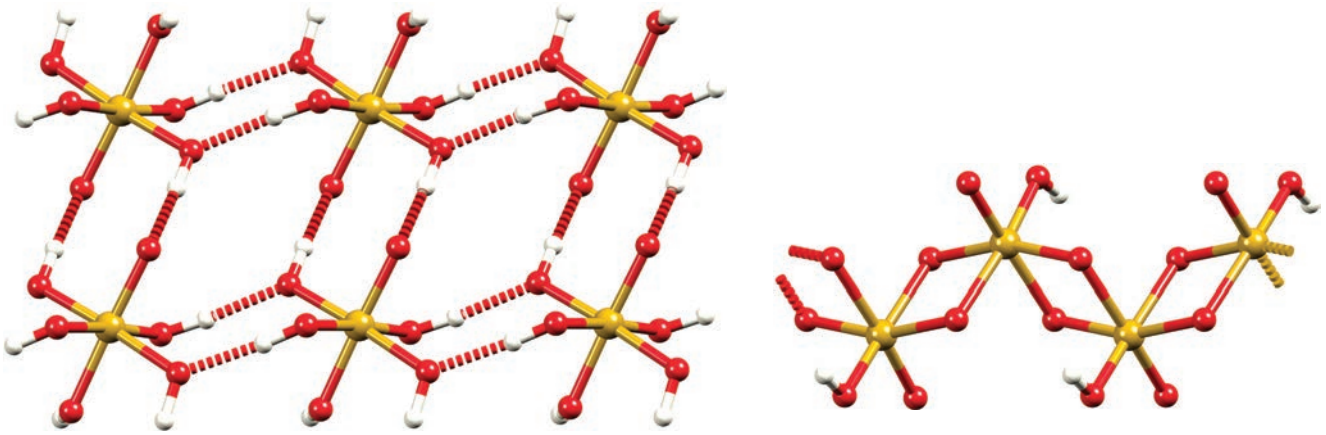

Fig. 17.13. (a) Part of the 3-dimensional hydrogen-bonded network in crystalline H_5IO_6 (determined by neutron diffraction) [Y.D. Feikema (1966) *Acta Crystallogr.*, vol. 20, p. 765]. (b) Part of one chain of *cis*-edge sharing octahedra in crystalline HIO_4 (determined by combined X-ray and neutron diffraction) [T. Kraft *et al.* (1997) *Angew. Chem. Int. Ed.*, vol. 36, p. 1753]. Colour code: I, gold; O, red; H, white.

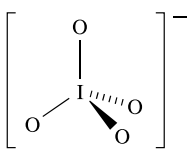
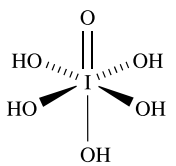
When heated, $KClO_4$ gives KCl and O_2, apparently without intermediate formation of $KClO_3$. Silver perchlorate, like silver salts of some other very strong acids (e.g. $AgBF_4$, $AgSbF_6$ and AgO_2CCF_3), is soluble in many organic solvents including C_6H_6 and Et_2O owing to complex formation between Ag^+ and the organic molecules.



The best method of preparation of perbromate ion is by reaction 17.80. Cation exchange (see Section 11.6) can be used to give $HBrO_4$ in solution, but the anhydrous acid has not been isolated.

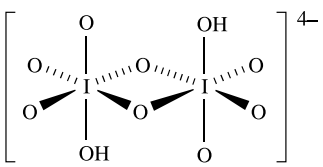
$$[BrO_3]^- + F_2 + 2[OH]^- \longrightarrow [BrO_4]^- + 2F^- + H_2O \qquad (17.80)$$

Potassium perbromate has been structurally characterized and contains tetrahedral $[BrO_4]^-$ ions (Br–O = 161 pm). Thermochemical data show that $[BrO_4]^-$ (half-reaction 17.81) is a slightly stronger oxidizing agent than $[ClO_4]^-$ or $[IO_4]^-$ under the same conditions. However, oxidations by $[BrO_4]^-$ (as for $[ClO_4]^-$) are slow in dilute neutral solution, but more rapid at higher acidities.



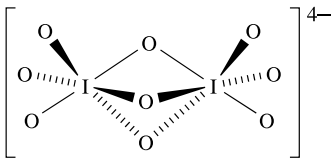
$$[BrO_4]^- + 2H^+ + 2e^- \rightleftharpoons [BrO_3]^- + H_2O \qquad E^\circ = +1.76\,V \quad (\text{at pH } 0) \qquad (17.81)$$

Several different periodic acids and periodates are known; Table 17.5 lists periodic acid, HIO_4 and orthoperiodic acid, H_5IO_6 (compare with H_6TeO_6, Section 16.9). Oxidation of KIO_3 by hot alkaline hypochlorite yields $K_2H_3IO_6$ which is converted to KIO_4 by nitric acid. Treatment of KIO_4 with concentrated alkali yields $K_4H_2I_2O_{10}$, and dehydration of this at 353 K leads to $K_4I_2O_9$. Apart from $[IO_4]^-$ (**17.37**) and $[IO_5]^{3-}$ and $[HIO_5]^{2-}$ (which are square-based pyramidal), periodic acids and periodate ions feature octahedral I centres, e.g. H_5IO_6 (**17.38**), $[H_2I_2O_{10}]^{4-}$ (**17.39**) and $[I_2O_9]^{4-}$ (**17.40**). The presence of five OH groups per molecule in H_5IO_6 leads to extensive intermolecular hydrogen bonding in the solid state, resulting in a 3-dimensional network (Fig. 17.13a). The solid state structure of anhydrous HIO_4 contrasts with that of $HClO_4$. While the latter consists of discrete molecules, solid HIO_4 contains chains of edge-sharing octahedra (Fig. 17.13b); the chains interact with one another through O–H···O hydrogen bonds.



I–O = 178 pm

(17.37)



I–O(terminal) = 178 pm
I–OH = 189 pm

(17.38)

I–O(terminal) = 181 pm
I–O(bridge) = 200 pm
I–OH = 198 pm

(17.39)

I–O(terminal) = 177 pm
I–O(bridge) = 201 pm

(17.40)

The relationships between these ions in aqueous solution may be expressed by equilibria 17.82, and aqueous solutions of periodates are therefore not simple systems.

$$\left.\begin{aligned} &[H_3IO_6]^{2-} + H^+ \rightleftharpoons [IO_4]^- + 2H_2O \\ &2[H_3IO_6]^{2-} \rightleftharpoons 2[HIO_5]^{2-} + 2H_2O \\ &2[HIO_5]^{2-} \rightleftharpoons [H_2I_2O_{10}]^{4-} \rightleftharpoons [I_2O_9]^{4-} + H_2O \end{aligned}\right\} \quad (17.82)$$

Orthoperiodic acid is obtained by electrolytic oxidation of iodic acid, or by adding concentrated nitric acid to $Ba_5(IO_6)_2$, prepared by reaction 17.83.

$$5Ba(IO_3)_2 \xrightarrow{\Delta} Ba_5(IO_6)_2 + 4I_2 + 9O_2 \quad (17.83)$$

Heating H_5IO_6 dehydrates it, first to $H_4I_2O_9$, and then to HIO_4. In aqueous solution, both H_5IO_6 ($pK_a = 3.3$) and HIO_4 ($pK_a = 1.64$) behave as rather weak acids. Periodate oxidizes iodide (eq. 17.84) *rapidly* even in neutral solution (compare the actions of chlorate and bromate). It liberates ozonized O_2 from hot acidic solution, and oxidizes Mn(II) to $[MnO_4]^-$ in acidic solution (eq. 17.85).

$$[IO_4]^- + 2I^- + H_2O \longrightarrow [IO_3]^- + I_2 + 2[OH]^- \quad (17.84)$$

$$5[IO_4]^- + 2Mn^{2+} + 3H_2O \longrightarrow 5[IO_3]^- + 2[MnO_4]^- + 6H^+ \quad (17.85)$$

17.10 Aqueous solution chemistry

In this section, we are mainly concerned with redox processes in aqueous solution; see Section 17.1 for a list of relevant topics already covered in the book. Values of E^o for half-reactions 17.86 can be measured directly for X = Cl, Br and I (Table 17.1) and their magnitudes are determined by the X–X bond energies (Fig. 17.3), the electron affinities of the halogen atoms (Table 17.1) and the standard Gibbs energies of hydration of the halide ions (Table 17.1). This can be seen from scheme 17.87; for X = Br and I, an additional vaporization stage is needed for the element.

$$\tfrac{1}{2}X_2 + e^- \rightleftharpoons X^- \quad (17.86)$$

$$\tfrac{1}{2}X_2 \longrightarrow X(g) \longrightarrow X^-(g) \longrightarrow X^-(aq) \quad (17.87)$$

Dichlorine is a more powerful oxidizing agent in aqueous media than Br_2 or I_2, partly because of a more negative enthalpy of formation of the anion but, more importantly, because the Cl^- ion (which is smaller than Br^- or I^-) interacts more strongly with solvent molecules. (In solid salt formation, the lattice energy factor similarly explains why chloride salts are more exothermic than corresponding bromides or iodides.)

Since F_2 liberates ozonized O_2 from water, the value of E^o for half-reaction 17.86 has no physical reality, but a value of +2.87 V can be estimated by comparing the energy changes for each step in scheme 17.87 for X = F and Cl, and hence deriving the difference in E^o for half-equation 17.86 for X = F and Cl. Most of the difference between these E^o values arises from the much more negative value of $\Delta_{hyd}G^o$ of the smaller F^- ion (Table 17.1).

Diiodine is much more soluble in aqueous iodide solutions than in water. At low concentrations of I_2, eq. 17.88 describes the system; K can be found by partitioning I_2 between the aqueous layer and a solvent immiscible with water (e.g. CCl_4).

$$I_2 + I^- \rightleftharpoons [I_3]^- \qquad K \approx 10^2 \ (298\ K) \quad (17.88)$$

Potential diagrams (partly calculated from thermochemical data) for Cl, Br and I are given in Fig. 17.14. Because several of the oxoacids are weak, the effects of $[H^+]$ on values of some of the reduction potentials are quite complicated. For example, the disproportionation of hypochlorite to chlorate and chloride could be written as equilibrium 17.89 without involving protons.

$$3[OCl]^- \rightleftharpoons [ClO_3]^- + 2Cl^- \quad (17.89)$$

However, the fact that HOCl is a weak acid, while $HClO_3$ and HCl are strong ones (see Table 7.3) means that, in the presence of hydrogen ions, $[OCl]^-$ is protonated and this affects the position of equilibrium 17.89: HOCl is more stable with respect to disproportionation than $[OCl]^-$. On the other hand, the disproportionation of chlorate into perchlorate and chloride is realistically represented by equilibrium 17.90. From the data in Fig. 17.14, this reaction is easily shown to be thermodynamically favourable (see end-of-chapter problem 17.22b). Nevertheless, the reaction does not occur in aqueous solution owing to kinetic factors.

$$4[ClO_3]^- \rightleftharpoons 3[ClO_4]^- + Cl^- \quad (17.90)$$

Another example of the limitations of the data in Fig. 17.14 is the inference that O_2 should oxidize I^- and Br^- at pH 0. Further, the fact that Cl_2 rather than O_2 is evolved when hydrochloric acid is electrolysed is a consequence of the high overpotential for O_2 evolution at most surfaces (see worked example 17.3). Despite some limitations, Fig. 17.14 does provide some useful information: for example, the more powerful oxidizing properties of

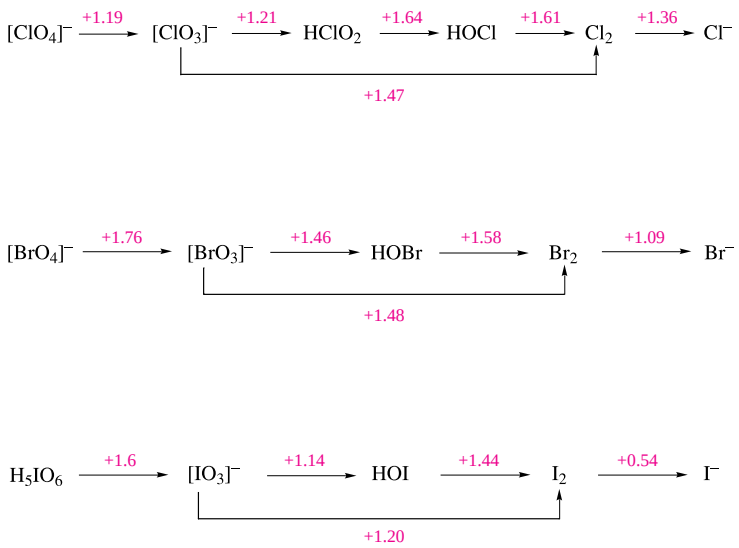


Fig. 17.14. Potential diagrams for chlorine, bromine and iodine at pH = 0. A Frost–Ebsworth diagram for chlorine (pH = 0) is given in Fig. 17.15 in end-of-chapter problem 17.21.

periodate and perbromate than of perchlorate when these species are being reduced to halate ions, and the more weakly oxidizing powers of iodate and iodine than of the other halates or halogens respectively.

The fact that Fig. 17.14 refers only to *specific conditions* is illustrated by considering the stability of I(I). Hypoiodous acid is unstable with respect to disproportionation into $[IO_3]^-$ and I_2, and is therefore not formed when $[IO_3]^-$ acts as an oxidant in aqueous solution. However, in hydrochloric acid, HOI undergoes reaction 17.91.

$$HOI + 2HCl \longrightarrow [ICl_2]^- + H^+ + H_2O \qquad (17.91)$$

Under these conditions, the potential diagram becomes:

$$[IO_3]^- \xrightarrow{+1.23} [ICl_2]^- \xrightarrow{+1.06} I_2$$

and I(I) is now stable with respect to disproportionation.

Worked example 17.3 The effects of overpotentials

Explain why, when aqueous HCl is electrolysed, the anode discharges Cl_2 (or a mixture of Cl_2 and O_2) rather than O_2 even though standard electrode potentials (at pH 0, see Appendix 11) indicate that H_2O is more readily oxidized than Cl_2.

For the anode reaction (i.e. the reverse of that shown in Appendix 11), the relevant half-reactions are:

$$2Cl^-(aq) \longrightarrow Cl_2(g) + 2e^- \qquad E^o = -1.36\,V$$

$$2H_2O(l) \longrightarrow O_2(g) + 4H^+(aq) + 4e^- \qquad E^o = -1.23\,V$$

The second half-reaction originates from the electrolysis of water:

$$2H_2O(l) \longrightarrow 2H_2(g) + O_2(g)$$

The spontaneous process is actually the *reverse* reaction (i.e. formation of H_2O from H_2 and O_2) and for this at pH 7, $E_{cell} = 1.23\,V$ (see the self-study exercises below). In order to drive the electrolysis of H_2O, the electrical power source must be able to supply a minimum of 1.23 V. In practice, however, this potential is insufficient to cause the electrolysis of H_2O and an additional potential (the *overpotential*) is needed. The size of the overpotential depends on several factors, one being the nature of the electrode surface. For Pt electrodes, the overpotential for the electrolysis of H_2O is ≈0.60 V. Thus, in practice, Cl_2 (or a mixture of Cl_2 and O_2) is discharged from the anode during the electrolysis of aqueous HCl.

Self-study exercises

1. For the following process, $E^o = 0\,V$. Calculate E at pH 7.

   $2H^+(aq) + 2e^- \rightleftharpoons H_2(g)$ [*Ans.* −0.41 V]

2. For the process below, $E^o = +1.23\,V$. Determine E at pH 7.

   $O_2(g) + 4H^+(aq) + 4e^- \rightleftharpoons 2H_2O(l)$ [*Ans.* +0.82 V]

3. Using your answers to the first two exercises, calculate E_{cell} at pH 7 for the overall reaction:

   $2H_2(g) + O_2(g) \longrightarrow 2H_2O(l)$ [*Ans.* 1.23 V]

KEY TERMS

The following terms were introduced in this chapter. Do you know what they mean?

- ❑ ion-selective electrode
- ❑ ozonized oxygen
- ❑ charge transfer complex
- ❑ charge transfer band
- ❑ polyhalide ion

PROBLEMS

17.1 (a) What is the collective name for the group 17 elements? (b) Write down, in order, the names and symbols of these elements; check your answer by reference to the first two pages of this chapter. (c) Give a *general* notation showing the ground state electronic configuration of each element.

17.2 (a) Write equations to show the reactions involved in the extraction of Br_2 and I_2 from brines.
(b) What reactions occur in the Downs process, and why must the products of the process be kept apart?
(c) In the electrolysis cell used for the industrial preparation of F_2, a diaphragm is used to separate the products. Give an equation for the reaction that would occur in the absence of the diaphragm and describe the nature of the reaction.

17.3 For a given atom Y, the Y–F bond is usually stronger than the corresponding Y–Cl bond. An exception is when Y is oxygen (Table 16.2). Suggest a reason for this observation.

17.4 Give explanations for the following observations.
(a) pK_a values for CF_3CO_2H and CH_3CO_2H are 0.23 and 4.75, respectively.
(b) The dipole moment of a gas phase NH_3 molecule is 1.47 D, but that of NF_3 is 0.24 D.

(c) In electrophilic substitution reactions in monosubstituted aryl compounds C_6H_4X, X = Me is activating and *ortho*- and *para*-directing, whereas $X = CF_3$ is deactivating and *meta*-directing.

17.5 Briefly discuss the trends in boiling points and values of $\Delta_{vap}H^o$ listed in Table 17.2 for the hydrogen halides.

17.6 Use values of r_{cov} (Table 17.1) to estimate the X–Y bond lengths of ClF, BrF, BrCl, ICl and IBr. Compare the answers with values in Fig. 17.8 and Table 17.3, and comment on the validity of the method of calculation.

17.7 Suggest products for the following reactions (which are not balanced):

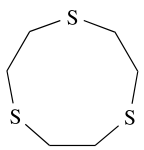
(a) $AgCl + ClF_3 \longrightarrow$
(b) $ClF + BF_3 \longrightarrow$
(c) $CsF + IF_5 \longrightarrow$
(d) $SbF_5 + ClF_5 \longrightarrow$
(e) $Me_4NF + IF_7 \longrightarrow$
(f) $K[BrF_4] \xrightarrow{\Delta}$

17.8 Discuss the role of halide acceptors in the formation of interhalogen cations and anions.

17.9 Predict the structures of (a) $[ICl_4]^-$, (b) $[BrF_2]^+$, (c) $[ClF_4]^+$, (d) IF_7, (e) I_2Cl_6, (f) $[IF_6]^+$, (g) BrF_5.

17.10 (a) Assuming *static* structures and no observed coupling to the central atom, what would you expect to see in the ^{19}F NMR spectra of BrF_5 and $[IF_6]^+$? (b) Do you expect these spectra to be temperature-dependent?

17.11 Discuss the interpretation of each of the following observations:



(a) Al_2Cl_6 and I_2Cl_6 are not isostructural.
(b) Thermal decomposition of $[Bu_4N][ClHI]$ yields $[Me_4N]I$ and HCl.
(c) 0.01 M solutions of I_2 in *n*-hexane, benzene, ethanol and pyridine are violet, purple, brown and yellow respectively. When 0.001 mol of pyridine is added to 100 cm^3 of each of the solutions of I_2 in *n*-hexane, benzene and ethanol, all become yellow.

17.12 The UV–VIS spectrum of a solution of I_2 and hexamethylbenzene in hexane exhibits absorptions at 368 and 515 nm. Assign these absorptions to electronic transitions, and explain how each transition arises.

17.13 The electronic spectra of mixtures of CH_2Cl_2 solutions (each 0.993 mmol dm^{-3}) of I_2 and the donor D shown in the diagram after the table were recorded for different volume ratios of the two solutions. Values of the absorbance for the absorption at $\lambda_{max} = 308$ nm are as follows:

Volume ratio I_2 : D	Absorbance
0 : 10	0.000
1 : 9	0.056
2 : 8	0.097
3 : 7	0.129
4 : 6	0.150
5 : 5	0.164
6 : 4	0.142
7 : 3	0.130
8 : 2	0.103
9 : 1	0.070
10 : 0	0.000

[Data: A.J. Blake *et al.* (1997) *J. Chem. Soc., Dalton Trans.*, p. 1337.]

Donor, D

(a) Suggest how compound D might interact with I_2.
(b) Use the data in the table to establish the stoichiometry of the complex formed between D and I_2. Why can the absorbance data be used for this purpose?
(c) In the Raman spectrum of the complex, a band at 162 cm^{-1} is assigned to the I_2 stretching mode. Explain why this value is shifted from that of 215 cm^{-1} for I_2 itself.

17.14 Suggest likely structures for (a) $[F_2ClO_2]^-$, (b) $FBrO_3$, (c) $[ClO_2]^+$, (d) $[F_4ClO]^-$.

17.15 (a) Give equations to show the effect of temperature on the reaction between Cl_2 and aqueous NaOH.
(b) In neutral solution 1 mol $[IO_4]^-$ reacts with excess I^- to produce 1 mol I_2. On acidification of the resulting solution, a further 3 mol I_2 is liberated. Derive equations for the reactions which occur under these conditions.
(c) In strongly alkaline solution containing an excess of barium ions, a solution containing 0.01587 g of I^- was treated with 0.1 M $[MnO_4]^-$ until a pink colour persisted in the solution; 10.0 cm^3 was

required. Under these conditions, $[MnO_4]^-$ was converted into the sparingly soluble $BaMnO_4$. What is the product of the oxidation of iodide?

17.16 (a) Give descriptions of the bonding in ClO_2 and $[ClO_2]^-$ (**17.24** and **17.35**), and rationalize the differences in Cl–O bond lengths. (b) Rationalize why $KClO_4$ and $BaSO_4$ are isomorphous.

17.17 Suggest products for the following (which are not balanced):

(a) $[ClO_3]^- + Fe^{2+} + H^+ \longrightarrow$

(b) $[IO_3]^- + [SO_3]^{2-} \longrightarrow$

(c) $[IO_3]^- + Br^- + H^+ \longrightarrow$

17.18 Describe in outline how you would attempt:

(a) to determine the equilibrium constant and standard enthalpy change for the aqueous solution reaction:

$$Cl_2 + H_2O \rightleftharpoons HCl + HOCl$$

(b) to show that the oxide I_4O_9 (reported to be formed by reaction between I_2 and O_3) reacts with water according to the reaction:

$$I_4O_9 + 9H_2O \longrightarrow 18HIO_3 + I_2$$

(c) to show that when alkali metal atoms and Cl_2 interact in a solidified noble gas matrix at very low temperatures, the ion $[Cl_2]^-$ is formed.

17.19 Discuss the interpretation of each of the following observations:

(a) Although the hydrogen bonding in HF is stronger than that in H_2O, water has much the higher boiling point.

(b) Silver chloride and silver iodide are soluble in saturated aqueous KI, but insoluble in saturated aqueous KCl.

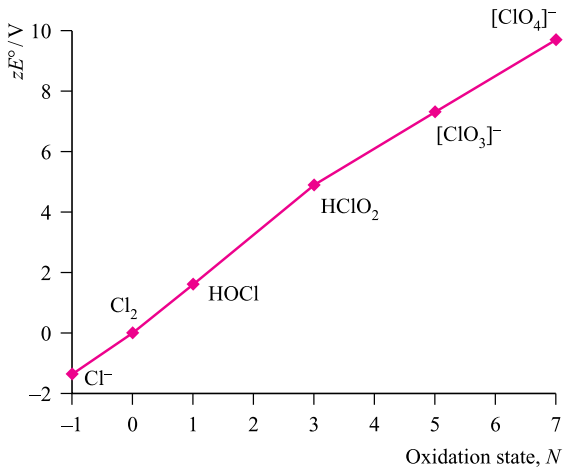


Fig. 17.15. A Frost–Ebsworth diagram for chlorine at pH = 0.

17.20 Explain why:

(a) $[NH_4]F$ has the wurtzite structure, unlike other ammonium halides which possess the CsCl or NaCl lattice depending on temperature;

(b) $[PH_4]I$ is the most stable of the $[PH_4]^+X^-$ halides with respect to decomposition to PH_3 and HX.

17.21 Figure 17.15 shows a Frost–Ebsworth diagram for chlorine.

(a) How is this diagram related to the potential diagram for chlorine in Fig. 17.14?

(b) Which is the most thermodynamically favoured species in Fig. 17.15? Explain how you reach your conclusion.

(c) State, with reasons, which species in the figure is the best oxidizing agent.

(d) Why is it important to state the pH value in the caption to Fig. 17.15?

OVERVIEW PROBLEMS

17.22 (a) The reaction of CsF, I_2O_5 and IF_5 at 435 K leads to Cs_2IOF_5. When the amount of CsF is halved, the product is $CsIOF_4$. Write balanced equations for the reactions. Are they redox reactions?

(b) Using data in Fig. 17.14, calculate ΔG°(298 K) for the reaction:

$$4[ClO_3]^-(aq) \rightleftharpoons 3[ClO_4]^-(aq) + Cl^-(aq)$$

Comment on the fact that the reaction does not occur at 298 K.

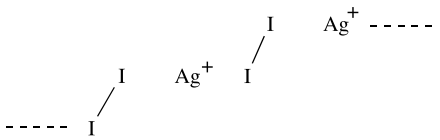
(c) Chlorine dioxide is the major bleaching agent in the pulp industry. While some statistics for bleaching agents list ClO_2, others give $NaClO_3$ instead. Suggest reasons for this difference.

17.23 (a) BrO has been detected in the emission gases from volcanoes (N. Bobrowski *et al.* (2003) *Nature*, vol. 423, p. 273). Construct an MO diagram for the formation of BrO from Br and O atoms. Comment on any properties and bonding features of BrO that you can deduce from the diagram.

(b) $[Cl_2O_2]^+$ is approximately planar and is described as a charge transfer complex of $[Cl_2]^+$ and O_2. By considering the HOMOs and LUMOs of $[Cl_2]^+$ and O_2, suggest what orbital interactions are involved in the charge transfer.

17.24 (a) Comment on the fact that HOI disproportionates in aqueous solution at pH 0, but in aqueous HCl at pH 0, iodine(I) is stable with respect to disproportionation.

(b) The solid state structure of $[ClF_4][SbF_6]$ reveals the presence of ions, but asymmetrical Cl–F–Sb bridges result in infinite zigzag chains running through the lattice. The Cl atoms are in pseudo-octahedral environments. Draw the structures of the separate ions present in $[ClF_4][SbF_6]$, and use the structural description to illustrate part of one of the infinite chains.



17.25 Which description in the second list below can be correctly matched to each element or compound in the first list? There is only one match for each pair.

List 1	List 2
$HClO_4$	Weak acid in aqueous solution
CaF_2	Charge transfer complex
I_2O_5	Solid contains octahedrally sited chloride ion
ClO_2	Strong acid in aqueous solution
$[BrF_6]^+$	Contains a halogen atom in a square planar coordination environment
$[IF_6]^-$	Its formation requires the use of an extremely powerful oxidative fluorinating agent
HOCl	Anhydride of HIO_3
$C_6H_6{\cdot}Br_2$	Adopts a prototype structure
ClF_3	Possesses a distorted octahedral structure
RbCl	Used in the nuclear fuel industry to fluorinate uranium
I_2Cl_6	Radical

17.26 (a) How many degrees of vibrational freedom does each of ClF_3 and BF_3 possess? The IR spectrum of ClF_3 in an argon matrix exhibits six absorptions, whereas that of BF_3 has only three. Explain why the spectra differ in this way.

(b) Which of the following compounds are potentially explosive and must be treated with caution: ClO_2, $KClO_4$, KCl, Cl_2O_6, Cl_2O, Br_2O_3, HF, CaF_2, ClF_3 and BrF_3? State particular conditions under which explosions may occur. Are other serious hazards associated with any of the compounds in the list?

17.27 (a) Figure 17.7 showed the structure of $[(AgI_2)_n]^{n+}$ and an MO scheme for the bonding. The bonding may also be represented using the valence bond approach. The diagram below illustrates the positive charge localized on Ag^+ centres. Use this as a starting point to draw a set of resonance structures which illustrate I_2 acting as a charge donor. How does this compare with a VB scheme for the bonding in $[I_5]^+$?

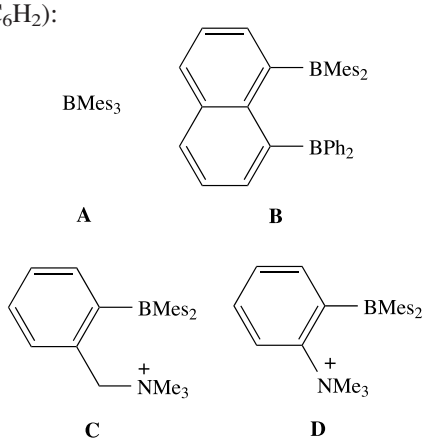
(b) When I_2 reacts with SbF_5 in liquid SO_2, the compound $[I_4][Sb_3F_{14}][SbF_6]$ is formed. Explain what happens in this reaction, and draw the structures of the ions present in the product. Assign oxidation states to each atom in the product.

INORGANIC CHEMISTRY MATTERS

17.28 Both HBr and BrO (see problem 17.23) are present in volcanic plumes. A model for reactions in the plume involves the following sequence:

$$BrO + HO_2 \longrightarrow HOBr + O_2 \quad \text{(i)}$$

$$HOBr + HBr \longrightarrow Br_2 + H_2O \quad \text{(ii)}$$



$$Br_2 \xrightarrow{h\nu} 2Br \quad \text{(iii)}$$

$$Br + O_3 \longrightarrow BrO + O_2 \quad \text{(iv)}$$

(a) Briefly discuss the types of reactions shown above.

(b) Discuss the roles of ClO and Cl in ozone depletion over Antarctica. Comment on any similarities between these reactions and those occurring in the volcanic plume.

17.29 Fluoride ions are added to drinking water, toothpaste and drugs used to treat osteoporosis. However, an excess of F^- is toxic to the body. The design of water-soluble, selective fluoride ion receptors is therefore topical. One group of receptors that has been investigated consists of the boron-containing species shown below (Mes = mesityl = 2,4,6-$Me_3C_6H_2$):

(a) Explain in detail how compound **A** binds F^-.
(b) Suggest why the stability constant of the complex formed between **B** and F^- is greater than that formed between **A** and F^-.
(c) Compounds **C** and **D** form zwitter-ionic complexes with F^-. Explain what this means.
(d) The ^1H NMR spectrum of the complex formed between **C** and F^- shows two signals for the CH_2 protons: δ 3.82 (d, $J_{HH} = 12.9$ Hz) and 6.50 (dd, $J_{HH} = 12.9$ Hz, $J_{HF} = 9.2$ Hz). Draw the structure for a complex that is consistent with this observation, and also explains the high stability of the complex.
(e) Which of the receptors would you expect to form water-soluble complexes with F^-?

17.30 Comment on the following statements, giving equations to illustrate relevant reactions:

(a) Iodine supplements for the human body comprise I_2/KI.
(b) HF is used commercially to etch silica glass.
(c) Mixtures of solid ammonium perchlorate and powdered aluminium are used as rocket propellants.

18.1 Introduction

The group 18 elements (helium, neon, argon, krypton, xenon, radon and oganesson) are called the ***noble gases***.

This section gives a brief, partly historical, introduction to the group 18 elements, the ground state electronic configurations of which tend to suggest chemical inertness. Until 1962, the chemistry of the noble gases was restricted to a few very unstable species such as $[HHe]^+$, $[He_2]^+$, $[ArH]^+$, $[Ar_2]^+$ and $[HeLi]^+$ formed by the combination of an ion and an atom under highly energetic conditions, and detected spectroscopically. Molecular orbital theory provides a simple explanation of why diatomic species such as He_2 and Ne_2 are not known. In He_2, bonding and antibonding MOs are fully occupied (Section 2.3). However, in a monocation such as $[Ne_2]^+$, the highest energy MO is *singly* occupied, meaning that there is a *net bonding* interaction. Thus, the bond energies in $[He_2]^+$, $[Ne_2]^+$ and $[Ar_2]^+$ are 126, 67 and 104 kJ mol^{-1}, respectively, but no stable compounds containing these cations have been isolated. Although $[Xe_2]^+$ has been known for some years and characterized by Raman spectroscopy ($\bar{\nu}$(XeXe) = 123 cm^{-1}), it was only in 1997 that $[Xe_2][Sb_4F_{21}]$ (prepared from $[XeF][Sb_2F_{11}]$ and HF/SbF_5, see Section 9.9) was crystallographically characterized. Discrete $[Xe_2]^+$ ions (**18.1**) are present in the solid state of $[Xe_2][Sb_4F_{21}]$, although there are weak Xe····F interactions. The Xe–Xe bond is extremely long, the longest structurally confirmed homonuclear bond between main group elements. Under a 30–50 bar pressure of Xe and in the presence of excess SbF_5, the $[Sb_4F_{11}]^-$ salt of green $[Xe_2]^+$ transforms into a salt of blue $[Xe_4]^+$. Reducing the pressure of Xe gas reverses the reaction. The $[Xe_4]^+$ ion has been characterized by Raman spectroscopy and the observed absorption at 110 cm^{-1} agrees with that calculated for the stretch of the central Xe–Xe bond in a linear cation with structure **18.2**.

(18.1)

(18.2)

When H_2O is frozen in the presence of Ar, Kr or Xe at high pressures, clathrates (see Box 14.5 and Section 12.8) of limiting composition $Ar{\cdot}6H_2O$, $Kr{\cdot}6H_2O$ and $Xe{\cdot}6H_2O$ are obtained. The noble gas atoms are guests within hydrogen-bonded host lattices. Other noble gas-containing clathrates include $3.5Xe{\cdot}8CCl_4{\cdot}136D_2O$

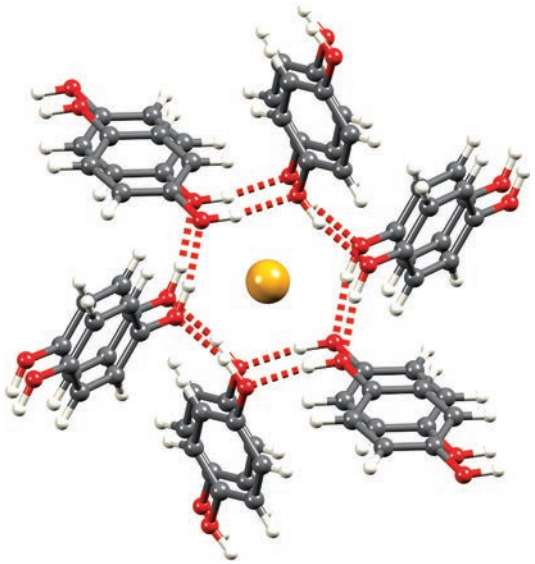

Fig. 18.1. Part of the solid state structure of tris(β-hydroquinone) xenon clathrate showing the arrangement of hydrogen-bonded organic molecules around a xenon atom [T. Birchall *et al.* (1989) *Acta Crystallogr., Sect. C*, vol. 45, p. 944]. Colour code: Xe, yellow; C, grey; O, red; H, white.

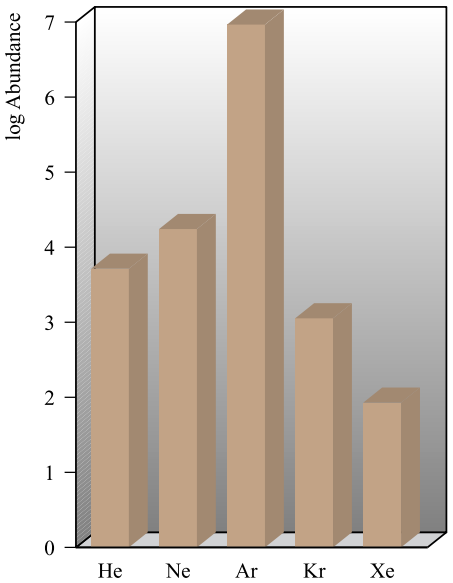

Fig. 18.2. Relative abundances of the noble gases (excluding radon, the abundance of which is 1×10^{-12} ppb) in the Earth's atmosphere. The data are plotted on a logarithmic scale. The units of abundance are parts per billion by volume (1 billion = 10^9).

and $0.866Xe{\cdot}3[1,4\text{-}(HO)_2C_6H_4]$ (Fig. 18.1). This type of system is well established, but note that no *chemical* change occurs to the noble gas atoms upon formation of the clathrate.

The first indication that Xe was not chemically inert came in 1962 from work of Neil Bartlett[†] when the reaction between Xe and PtF_6 gave a compound formulated as '$XePtF_6$' (see Section 6.17). A range of species containing Xe chemically bonded to other elements (most commonly F or O) is now known. Compounds of Kr are limited to KrF_2 and its derivatives. In principle, there should be many more compounds of Rn. However, the longest lived isotope, ^{222}Rn, has a half-life of 3.8 d and is an intense α-emitter (which leads to decomposition of its compounds), and, in practice, information about the chemistry of Rn is very limited.

Oganesson (Og, $Z = 118$) is the last of the 'superheavy' elements known to date (as of 2017). It is artificially made (see Section 27.5) and its discovery and name were confirmed by the IUPAC in 2015[‡] and 2016, respectively. Oganesson is radioactive and decays by loss of an α-particle. The most stable isotope, ^{294}Og, is extremely short-lived and the lack of chemical data for Og precludes further discussion in this chapter.

18.2 Occurrence, extraction and uses

Occurrence

After hydrogen, He is the second most abundant element in the universe. It occurs to an extent of ≤7% by volume in natural gas from sources in the US and Canada, and this origin is doubtless from the radioactive decay of heavier elements (α-particle = ^4_2He). Helium is also found in various minerals containing α-emitting unstable isotopes. Helium was first detected spectroscopically in the Sun's atmosphere. Nuclear fusion reactions taking place in the Sun start at temperatures above 10^7 K, and the following reactions are believed to be the main source of the Sun's energy (β^+ = positron, ν_e = neutrino):

$$^1_1H + {}^1_1H \longrightarrow {}^2_1H + \beta^+ + \nu_e$$

$$^1_1H + {}^2_1H \longrightarrow {}^3_2He + \gamma$$

$$^3_2He + {}^3_2He \longrightarrow {}^4_2He + 2{}^1_1H$$

Figure 18.2 shows the relative abundances of the noble gases in the Earth's atmosphere. Argon is present to an extent of 0.92% by volume in the Earth's atmosphere (Fig. 15.1b). Radon is formed by decay of ^{226}Ra in the ^{238}U decay chain (see Fig. 27.3), and poses a serious health hazard in uranium mines, being linked to cases of lung cancer.[*]

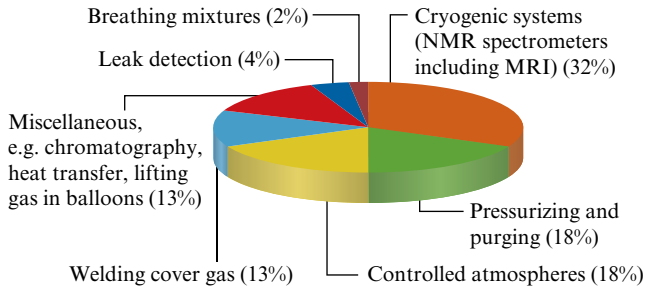

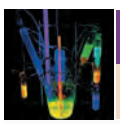

Fig. 18.3. Uses of helium in the US in 2015. The total consumption of 'grade A' helium in the US in 2009 was 43×10^6 m^3. [Data: US Geological Survey.]

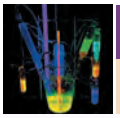
Extraction

In terms of commercial production, He and Ar are the two most important noble gases. Helium is extracted from natural gas by liquefaction of other gases present (He has the lowest boiling point of all the elements), leaving gaseous He which is removed by pumping. Neon is extracted as a by-product when air is liquefied, being left behind as the only gas. Argon has almost the same boiling point as O_2 (Ar, 87 K; O_2, 90 K) and the two gases remain together during the fractionation of liquid air. The O_2/Ar mixture can be partially separated by further fractionation. The crude Ar is mixed with H_2 and sparked to remove O_2 as H_2O, excess H_2 being removed by passage over hot CuO. Krypton and xenon are usually separated from O_2 by selective absorption on charcoal.

Uses

Figure 18.3 summarizes the main uses of helium. Both helium and argon are used to provide inert atmospheres, for example for arc-welding (see Box 18.1) and during the growth of single Si or Ge crystals for the semiconductor industry (see Box 6.3). Argon is also used in laboratory inert atmosphere ('dry' or 'glove') boxes for handling air-sensitive compounds. Being very light and non-inflammable, He is used to inflate the tyres of large aircraft, and in balloons including weather balloons and NASA's unmanned sub-orbital research balloons. Liquid He is an important coolant and is used in highfield NMR spectrometers including those used in medical imaging (see Box 4.3). The superconductivity of metals cooled to the temperature of liquid He suggests that the latter may become important in power transmission. An O_2/He mixture is used in place of O_2/N_2 for deep-sea divers. Helium is much less soluble in blood than N_2, and does not cause 'the bends' when the pressure is released on surfacing. Helium is also used as a heat-transfer agent in gas-cooled nuclear reactors, for which it has the advantages of being non-corrosive and of not becoming radioactive under irradiation. Neon, krypton and xenon are used in electric discharge signs (e.g. for advertising) and Ar



APPLICATIONS

Box 18.1 Protective inert gases for metal arc-welding

The high-temperature conditions under which metal arc-welding takes place would, in the absence of protective gases, lead to reaction between molten metal and atmospheric gases including O_2 and N_2. Noble gases such as He and Ar are an obvious choice for the protective blanket, but these may be mixed with an active ingredient such as CO_2 (or H_2) to provide an oxidizing (or reducing) component to the protective layer. Of He and Ar, the latter is of greater industrial importance and is used in welding CrNi alloy steels and a range of metals. Argon is denser than He (1.78 versus 0.18 kg m^{-3} at 273 K) and so gives better protection. High-purity Ar (>99.99%) is commercially available and such levels of purity are essential when dealing with metals such as Ti, Ta and Nb which are extremely prone to attack by O_2 or N_2 during arc-welding.

A welder using a metal inert gas welding torch to join sheets of metal.

APPLICATIONS

Box 18.2 Xenon in 21st century space propulsion systems

In October 1998, at the start of its New Millennium Program, NASA launched a new space probe called *Deep Space 1* (DS1), designed to test new technologies with potential applications in future solar exploration. One of the revolutionary technologies on this flight was a xenon-based ion propulsion system, ten times more efficient than any other used prior to the DS1 mission. The system operates by using a solar power source, and ionizes Xe gas contained in a chamber, at one end of which is a pair of metal grids charged at 1280 V. A xenon-ion beam is produced as ions are ejected through the grids at $\approx 145\,000\,\text{km}\,\text{h}^{-1}$, and the resultant thrust is used to propel *DS1* through space. Since the fuel is Xe gas (and only 81 kg is required for an approximately two-year mission), an advantage of the system, in addition to the efficient thrust, is that *DS1* is smaller and lighter than previous unmanned spacecraft.

Deep Space 1 was taken out of service in December 2001. During its three years in space, it trialled a number of new technologies and proved the future potential of the xenon propulsion system. After *DS1*, the next spacecraft to be propelled by xenon-ion thrusters was *SMART-1* (SMART = Small Missions for Advanced Research in Technology). This was launched by the European Space Agency in 2003 for a lunar mission, and maintained an orbit around the moon from 2004 to 2006. The Japanese Institute of Space and Astronautical Science (ISAS) has also developed a xenon ion propulsion system for application in its MUSES-C asteroid sample return mission. NASA is developing a new generation of ion propulsion systems as part of its Evolutionary Xenon Thruster (NEXT) programme. These thrusters are for use in outer planet missions (e.g. Neptune orbiter, Titan explorer, Saturn ring observer) and inner solar system missions. NASA's *Dawn* spacecraft was launched in 2007 on a mission to asteroid Vesta (orbited 2011–2012) and Dwarf planet Ceres (orbited 2015–2016), the two largest bodies in the asteroid belt between Mars and Jupiter.

Computer illustration of *SMART-1* lunar spacecraft. Two large solar panels collect the energy from the Sun needed to ionize the onboard xenon fuel.

is contained in metal filament bulbs to reduce evaporation from the filament.

18.3 Physical properties

Some physical properties of the group 18 elements are listed in Table 18.1. Of particular significance is the fact that the noble gases have the highest ionization energies of the elements in their respective periods (Fig. 1.16), but there is a decrease in values on descending the group (Fig. 6.28). The extremely low values of $\Delta_{\text{fus}}H^{\circ}$ and $\Delta_{\text{vap}}H^{\circ}$ correspond to the weak van der Waals interactions between the atoms, and the increase in values of $\Delta_{\text{vap}}H^{\circ}$ down the group is due to increased interatomic interactions as atomic size and polarizability increase.

The properties of He deserve special note. It can diffuse through rubber and most glasses. Below 2.18 K, ordinary liquid ^{4}He (but not ^{3}He) is transformed into liquid He(II) which has the remarkable properties of a thermal conductivity 600 times that of copper, and a viscosity approaching zero. Liquid He(II) forms films only a few hundred atoms thick which flow up and over the side of the containing vessel.

NMR active nuclei

In the NMR spectroscopic characterization of Xe-containing compounds, use is made of ^{129}Xe, with a natural abundance of 26.4% and $I = \frac{1}{2}$. Although direct observation of ^{129}Xe is possible, the observation of satellite peaks in, for example, ^{19}F NMR spectra of xenon fluorides is a valuable diagnostic tool as is illustrated for $[XeF_5]^-$ in Case study 5, Section 4.8. For a potential clinical application of ^{129}Xe, see Box 4.3.

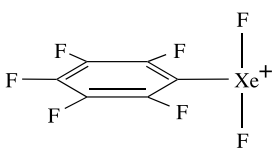
† Helium cannot be solidified under any conditions of temperature and pressure.

Worked example 18.1 NMR spectroscopy of xenon-containing compounds

Reaction of XeF_4 and $C_6F_5BF_2$ at 218 K yields $[C_6F_5XeF_2][BF_4]$. (a) Use the VSEPR model to suggest a structure for $[C_6F_5XeF_2]^+$. (b) The ^{129}Xe NMR spectrum of $[C_6F_5XeF_2][BF_4]$ consists of a triplet ($J = 3892$ Hz), and the ^{19}F NMR spectrum shows a three-line signal (relative intensities ≈1:5.6:1), three multiplets and a singlet. The relative integrals of the five signals are 2:2:1:2:4. Rationalize these data.

(a) Xe has eight valence electrons.



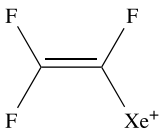
The positive charge can be formally localized on Xe, leaving seven valence electrons.

Each F atom provides one electron to the valence shell of Xe.

The C_6F_5 group is bonded through carbon to Xe and provides one electron to the valence shell of Xe.

Total number of electrons in the valence shell of Xe = 10.

The parent shape for $[C_6F_5XeF_2]^+$ is a trigonal bipyramid with the two lone pairs in the equatorial plane to minimize lone pair–lone pair repulsions. For steric reasons, the C_6F_5 group is expected to lie in the equatorial plane with the plane of the aryl ring orthogonal to the plane containing the XeF_2 unit. The expected structure is T-shaped:



(b) The triplet in the ^{129}Xe NMR spectrum of $[C_6F_5XeF_2][BF_4]$ shows a large coupling constant (3892 Hz) and arises from coupling between ^{129}Xe and the two equivalent, directly bonded ^{19}F nuclei.

There are four F environments in $[C_6F_5XeF_2]^+$ (*ortho*, *meta* and *para*-F atoms in the aryl group and the two equivalent F atoms bonded to Xe, with a ratio 2:2:1:2, respectively. The signals for the aryl F atoms appear as multiplets because of ^{19}F–^{19}F coupling between non-equivalent F atoms. There are four equivalent F atoms in the $[BF_4]^-$ ion leading to a singlet; coupling to ^{11}B is not observed. Only the directly bonded ^{19}F nuclei couple to ^{129}Xe ($I = \frac{1}{2}$, 26.4%). The signal in the ^{19}F NMR spectrum assigned to these F atoms appears as a singlet with satellites for the 26.4% of the ^{19}F bonded to spin-active ^{129}Xe. The relative intensities 1:5.6:1 correspond to 26.4% of the signal split into a doublet (see Fig. 4.24).

Self-study exercises

Nuclear spin data: see Tables 4.3 and 18.1.

1. The reaction of $CF_2{=}CFBF_2$ with XeF_2 gives the $[BF_4]^-$ salt of the following cation:

The solution ^{129}Xe NMR spectrum of the compound exhibits an eight-line multiplet with lines of equal intensity. Account for this observation.

[*Ans*. See H.-J. Frohn *et al*. (1999) *Chem. Commun*., p. 919]

2. What would you expect to see in the ^{19}F NMR spectrum of XeF_4, the structure of which is consistent with the VSEPR model?

[*Ans*. Similar to Fig. 4.24 (experimental data: δ 317 ppm, $J = 3895$ Hz)]

18.4 Compounds of xenon

Fluorides

The most stable Xe compounds are the colourless fluorides XeF_2, XeF_4 and XeF_6 (Table 18.2). Upon irradiation with UV light, Xe reacts with F_2 at ambient temperature to give XeF_2. The rate of formation is increased by using HF as a catalyst and pure XeF_2 can be prepared by this method. Xenon difluoride may also be made by action of an electrical discharge on a mixture of Xe and F_2, or by passing these gases through a short nickel tube at 673 K. The latter method gives a mixture of XeF_2 and XeF_4, and the yield of XeF_4 is optimized by using a 1:5 $Xe:F_2$ ratio. With an NiF_2 catalyst, the reaction proceeds at a lower temperature, and even at 393 K, XeF_6 can be formed under these same conditions. It is not possible to prepare XeF_4 free of XeF_2 and/or XeF_6. Similarly, XeF_6 always forms with contamination by the lower fluorides. Separation of XeF_4 from a mixture involves preferential complexation of XeF_2 and XeF_6 (eq. 18.1) and the XeF_4 is then removed *in vacuo*, while separation of XeF_6 involves reaction 18.2 followed by thermal decomposition of the complex.

$$\left.\begin{matrix}XeF_2\\XeF_4\\XeF_6\end{matrix}\right\} \xrightarrow{\text{excess } AsF_5 \text{ in liq. } BrF_5} \left\{\begin{matrix}[Xe_2F_3]^+[AsF_6]^-\\XeF_4\\[XeF_5]^+[AsF_6]^-\end{matrix}\right. \quad (18.1)$$

$$XeF_6 + 2NaF \longrightarrow Na_2[XeF_8] \quad (18.2)$$

All the fluorides sublime *in vacuo*, and all are readily decomposed by water, XeF_2 very slowly, and XeF_4 and XeF_6, rapidly (eqs. 18.3–18.5 and 18.14).

$$2XeF_2 + 2H_2O \longrightarrow 2Xe + 4HF + O_2 \quad (18.3)$$

$$6XeF_4 + 12H_2O \longrightarrow 2XeO_3 + 4Xe + 24HF + 3O_2 \quad (18.4)$$

$$XeF_6 + 3H_2O \longrightarrow XeO_3 + 6HF \quad (18.5)$$

All three fluorides are powerful oxidizing and fluorinating agents, the relative reactivities being $XeF_6 > XeF_4 > XeF_2$. The difluoride is available commercially and is widely used for fluorinations, e.g. eqs. 17.35, 18.6 and 18.7. At 298 K, XeF_6 reacts with silica (preventing the handling of XeF_6 in silica glass apparatus, eq. 18.8) and with H_2, while XeF_2 and XeF_4 do so only when heated.

$$S + 3XeF_2 \xrightarrow{\text{anhydrous HF}} SF_6 + 3Xe \quad (18.6)$$

$$2Ir + 5XeF_2 \xrightarrow{\text{anhydrous HF}} 2IrF_5 + 5Xe \quad (18.7)$$

$$2XeF_6 + SiO_2 \longrightarrow 2XeOF_4 + SiF_4 \quad (18.8)$$

Table 18.2 Selected properties of XeF_2, XeF_4 and XeF_6.

Property	XeF_2	XeF_4	XeF_6

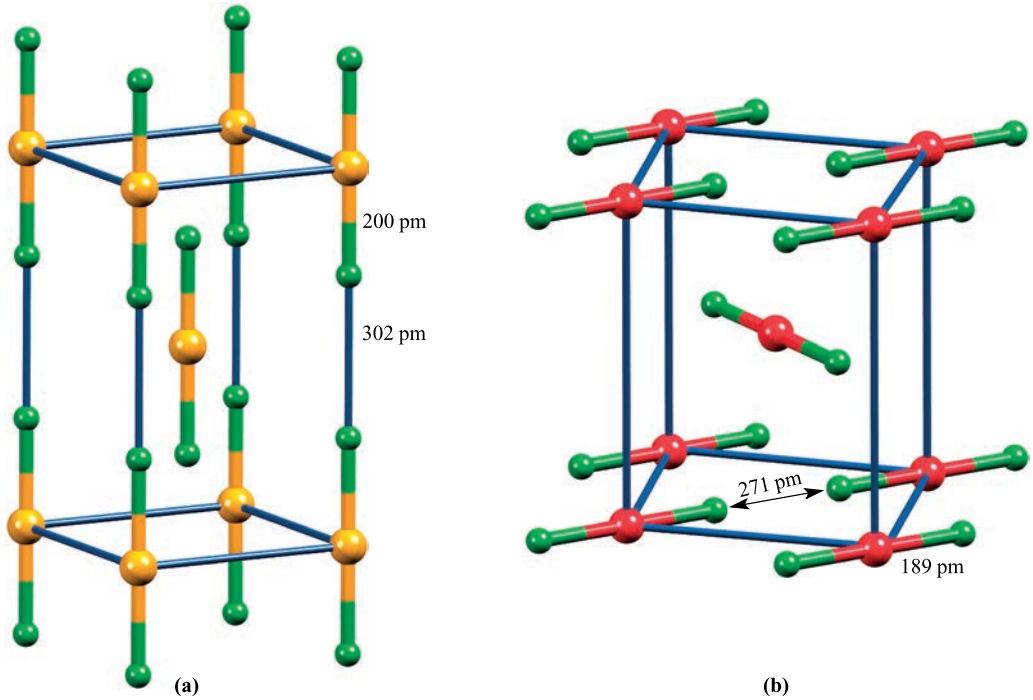
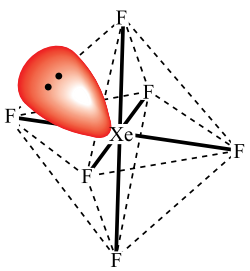
† The results of high-level computational studies indicate that the currently available experimental thermochemical data may be too negative. As a consequence, the Xe–F bond enthalpy terms may also be in error [D.A. Dixon, W.A. de Jong, K.A. Peterson, K.O. Christe and G.J. Schrobilgen (2005) *J. Am. Chem. Soc*., vol. 127, p. 8627].
‡ Neutron diffraction.
* Gas-phase electron diffraction.





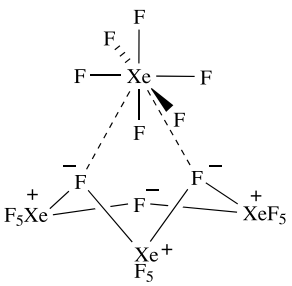


Fig. 18.4. Unit cells (dark blue lines) of (a) XeF_2 and (b) β-KrF_2 showing the arrangements and close proximity of molecular units. Colour code: Xe, yellow; Kr, red; F, green.

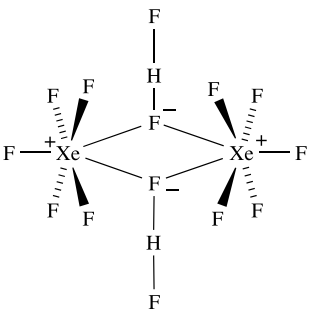
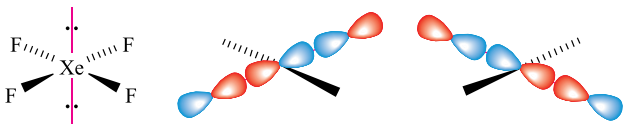


The structures of the xenon halides are consistent with the VSEPR model.† The XeF_2 molecule is linear, but in the solid state, there are significant intermolecular interactions (Fig. 18.4a). The XeF_4 molecule is square planar (D_{4h}). Discrete molecules are present in solid XeF_4, but there are extensive intermolecular F····Xe interactions with an average distance of 324 pm, significantly less than the sum of the van der Waals radii (349 pm). In the vapour state, the vibrational spectrum of XeF_6 indicates C_{3v} symmetry, i.e. an octahedron distorted by a stereochemically active lone pair in the centre of one face (**18.3**), but the molecule is readily converted into other configurations. High-level theoretical studies indicate that the energies of C_{3v} and O_h structures for XeF_6 are very similar, and that the lone pair is highly fluxional. Solid XeF_6 exists in a number of crystalline forms which were reinvestigated in 2006.‡ The two highest temperature modifications are formed by crystallization at 303 K over several days or by rapid sublimation, respectively. Although crystallographically distinct, the two forms are similar at the molecular level and are formulated as $\{[XeF_5]^+F^-\}_3{\cdot}XeF_6$ (**18.4**). The room temperature crystalline form of XeF_6 comprises both tetramers and hexamers, each made up of square pyramidal $[XeF_5]^+$ units bridged by F^- ions: $\{[XeF_5]^+F^-\}_4$ and $\{[XeF_5]^+F^-\}_6$. The low-temperature structural modifications contain tetramers, $\{[XeF_5]^+F^-\}_4$. Crystallization of XeF_6 from anhydrous HF produces $[XeF_5]_2[HF_2]_2{\cdot}HF$ which contains dimeric units of $[XeF_5]^+$ ions bridged by $[HF_2]^-$ ions (**18.5**). Thus, in crystalline XeF_6, the most common building block is the $[XeF_5]^+$ unit.

(18.3)

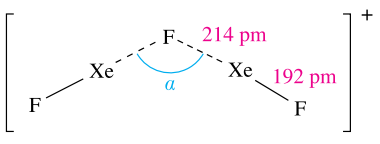
(18.4)



(18.5)

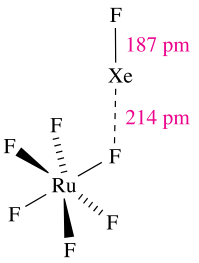
† For an overview of VSEPR and noble gas compounds, see: I. Hargittai and D.K. Menyhárd (2010) *J. Mol. Struct.*, vol. 978, p. 136 – 'Further VSEPRing about molecular geometries'.

‡ S. Hoyer, T. Emmler and K. Seppelt (2006) *J. Fluorine Chem.*, vol. 127, p. 1415 – 'The structure of xenon hexafluoride in the solid state'.



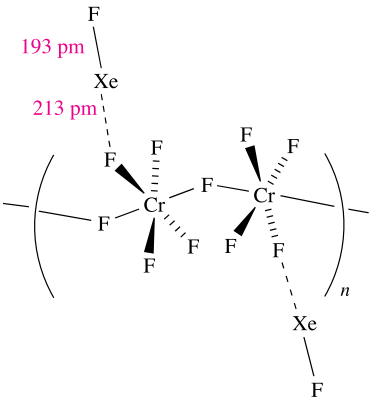
The bonding in XeF_2 and XeF_4 can be described in terms of using only *s* and *p* valence orbitals. We showed in Fig. 5.30 that the net bonding in linear XeF_2 can be considered in terms of the overlap of a 5*p* orbital on the Xe atom with an out-of-phase combination of F 2*p* orbitals (a σ_u-orbital). This gives a formal bond order of $\frac{1}{2}$ per Xe–F bond. A similar bonding scheme can be developed for square planar XeF_4. The net σ-bonding orbitals are shown in diagram **18.6**. These are fully occupied, resulting in a formal bond order of $\frac{1}{2}$ per Xe–F bond.

(18.6)



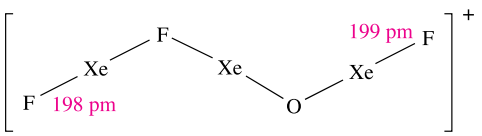
If the $[XeF]^+$ ion (see below) is taken to contain a single bond, then the fact that its bond distance of 184–190 pm (depending on the salt) is noticeably shorter than those in XeF_2 and XeF_4 (Table 18.2) is consistent with a model of 3c-2e interactions in the xenon fluorides. Further support for low bond orders in XeF_2 and XeF_4 comes from the fact that the strengths of the Xe–F bonds in XeF_2, XeF_4 and XeF_6 are essentially the same (Table 18.2, but see table footnote), in contrast to the significant decrease noted (Section 17.7) along the series $ClF > ClF_3 > ClF_5$.

Xenon difluoride reacts with F^- acceptors. With pentafluorides such as SbF_5, AsF_5, BrF_5, NbF_5 and IrF_5, it forms three types of complex: $[XeF]^+[MF_6]^-$, $[Xe_2F_3]^+[MF_6]^-$ and $[XeF]^+[M_2F_{11}]^-$, although in the solid state, there is evidence for cation–anion interaction through the formation of Xe–F–M bridges. The $[Xe_2F_3]^+$ cation has structure **18.7**. A number of complexes formed between XeF_2 and metal tetrafluorides have been reported, e.g. the reactions of XeF_2 with RuF_5 or CrF_4 give $[XeF]^+[RuF_6]^-$ (**18.8**) and polymeric $[XeF]^+[CrF_5]^-$ (**18.9**), respectively. In these and related compounds, cation–anion interactions in the solid state are significant.



α = 140–160° depending on counter-ion

(18.7)



(18.8)

(18.9)

The reaction of $[XeF][AsF_6]$ with a stoichiometric amount of H_2O in HF solution produces $[H_3O][AsF_6]\cdot 2XeF_2$ and $[Xe_3OF_3][AsF_6]$, but is highly sensitive to reaction conditions. The $[Xe_3OF_3]^+$ cation is the first example of a xenon(II) oxofluoride. It possesses structure **18.10** although there is an O/F atom disorder in the solid state (see Box 15.5), making it difficult to determine Xe–O/F bond lengths for the central bonds in **18.10**. The terminal Xe–F bond distances are close to those in XeF_2 (200 pm).

(18.10)

Xenon hexafluoride acts as an F^- donor to numerous pentafluorides, giving complexes of types $[XeF_5]^+[MF_6]^-$, $[XeF_5]^+[M_2F_{11}]^-$ (for M = Sb or V) and $[Xe_2F_{11}]^+[MF_6]^-$. The $[XeF_5]^+$ ion (average Xe–F = 184 pm) is isoelectronic and isostructural with IF_5 (**17.6**), but in solid state salts, there is evidence for fluoride bridge formation between cations and anions. The $[Xe_2F_{11}]^+$ cation can be considered as $[F_5Xe\cdots F\cdots XeF_5]^+$ in the same way that $[Xe_2F_3]^+$ can be written as $[FXe\cdots F\cdots XeF]^+$. The compounds $[XeF_5][AgF_4]$ and $[Xe_2F_{11}]_2[NiF_6]$ contain Ag(III) and Ni(IV) respectively, and are prepared from XeF_6, the metal(II) fluoride and KrF_2. In these cases, XeF_6 is not strong enough to oxidize Ag(II) to Ag(III) or Ni(II) to Ni(IV), and KrF_2 is employed as the oxidizing agent. The range of Xe–F bond distances in $[Xe_2F_{11}]_2[NiF_6]$ (Fig. 18.5) illustrates the $[F_5Xe\cdots F\cdots XeF_5]^+$ nature of the cation and the longer F···Xe contacts between anion and cations. Xenon tetrafluoride is much less reactive than XeF_2 with F^- acceptors. Among the few complexes formed is $[XeF_3]^+[Sb_2F_{11}]^-$. The $[XeF_3]^+$ cation (**18.11**) is isostructural with ClF_3 (**17.5**).

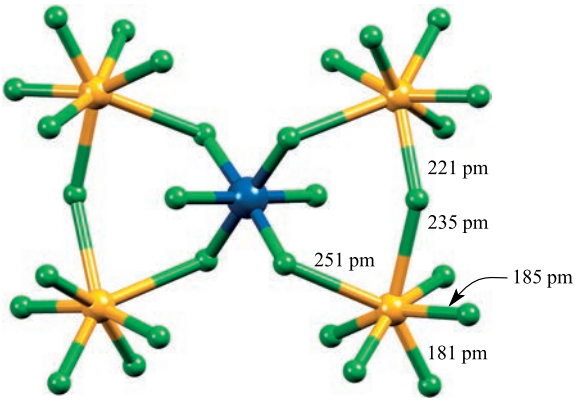


Fig. 18.5. The structure of $[Xe_2F_{11}]_2[NiF_6]$ determined by X-ray diffraction [A. Jesih *et al.* (1989) *Inorg. Chem.*, vol. 28, p. 2911]. The environment about each Xe centre is similar to that in the solid state $[XeF_6]_4$ (**18.3**). Colour code: Xe, yellow; Ni, blue; F, green.

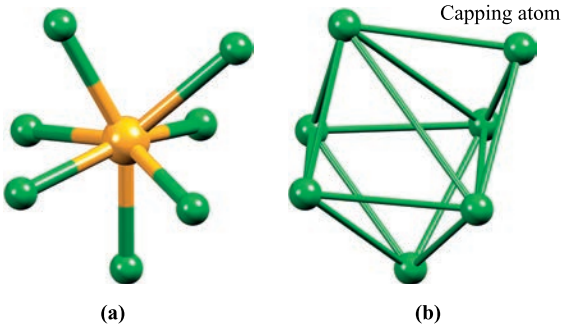

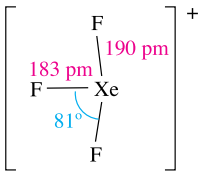

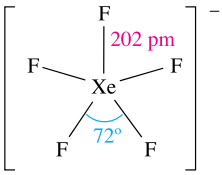

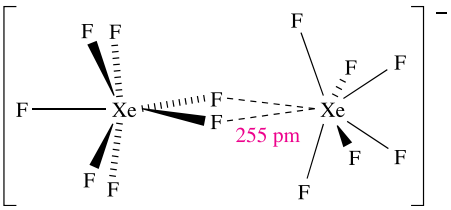

Fig. 18.6. (a) The structure of $[XeF_7]^-$, determined by X-ray diffraction for the caesium salt [A. Ellern *et al.* (1996) *Angew. Chem. Int. Ed.*, vol. 35, p. 1123]; (b) the capped octahedral arrangement of the F atoms in $[XeF_7]^-$. Colour code: Xe, yellow; F, green.

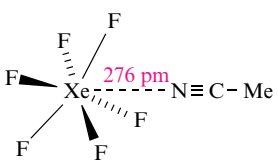
(18.11)

(18.12)

(18.13)

Both XeF_4 and XeF_6 act as F^- acceptors. The ability of XeF_4 to accept F^- to give $[XeF_5]^-$ has been observed in reactions with CsF and $[Me_4N]F$. The $[XeF_5]^-$ ion (**18.12**) is one of only two pentagonal planar species known, the other being the isoelectronic $[IF_5]^{2-}$ (Section 17.7). Equation 18.9 shows the formations of $[XeF_7]^-$ and $[XeF_8]^{2-}$ (which has a square-antiprismatic structure with a stereochemically inactive lone pair). The salts $Cs_2[XeF_8]$ and $Rb_2[XeF_8]$ are the most stable compounds of Xe yet made, and decompose only when heated above 673 K.



$$MF + XeF_6 \longrightarrow \underset{M = Rb,\ Cs,\ NO}{M[XeF_7]} \xrightarrow{\Delta,\ -XeF_6} M_2[XeF_8] \qquad (18.9)$$

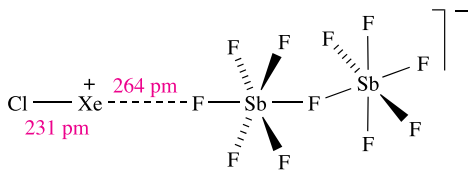
Structural information on $[XeF_7]^-$ has been difficult to obtain because of its ready conversion into $[XeF_8]^{2-}$. Recrystallization of freshly prepared $Cs[XeF_7]$ from liquid BrF_5 yields crystals suitable for X-ray diffraction studies. The $[XeF_7]^-$ ion has a capped octahedral structure (Fig. 18.6a) with Xe–F = 193 and 197 pm in the octahedron and Xe–F = 210 pm to the capping F atom. The coordination sphere defined by the seven F atoms is shown in Fig. 18.6b; the octahedral part is significantly distorted. The reaction between NO_2F and excess XeF_6 gives $[NO_2]^+[Xe_2F_{13}]^-$, the solid state structure of which reveals that the anion can be described as an adduct of $[XeF_7]^-$ and XeF_6 (structure **18.13**).

The compounds $F_6Xe(NCMe)$ (**18.14**) and $F_6Xe(NCMe)_2$ contain the first examples of Xe(VI)–N bonds, and are formed by reactions 18.10 and 18.11. Although kinetically stable, the products are very shock sensitive. The Xe–N interactions are confirmed in the solid state (X-ray data collected at 100 K) with Xe–N distances being appreciably less than the sum of the van der Waals radii (368 pm).

$$XeF_6 + MeCN \xrightarrow[233\,K]{1,2\text{-}Cl_2C_2F_4\ (Freon\text{-}114),} F_6Xe(NCMe) \qquad (18.10)$$

$$XeF_6 + 3MeCN \xrightarrow[233\,K]{1,2\text{-}Cl_2C_2F_4\ (Freon\text{-}114),} F_6Xe(NCMe)_2 \cdot MeCN \qquad (18.11)$$

(18.14)



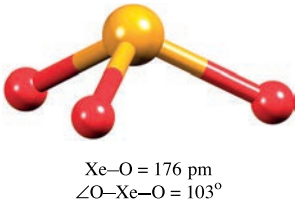
Self-study exercise

$F_6Xe(NCMe)$ has approximately C_{3v} symmetry, and in the gas phase, XeF_6 also has C_{3v} symmetry. Why does XeF_6 not belong to the O_h point group? Explain how an octahedral (O_h) XeF_6 unit distorts to achieve C_{3v} symmetry. [*Hint*: what symmetry does a model *fac*-MX_3Y_3 molecule possess?]

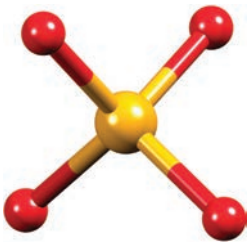
[*Ans*. See: K. Matsumoto *et al*. (2015) *Angew. Chem. Int. Ed.*, vol. 55, p. 14169; J. Haner *et al*. (2016) *Chem. Eur. J.*, vol. 22, p. 4833]

Chlorides

Xenon dichloride has been detected by matrix isolation. It is obtained on condensing the products of a microwave discharge in a mixture of Cl_2 and a large excess of Xe at 20 K. Fully characterized compounds containing Xe−Cl bonds are rare, and most also contain Xe−C bonds (see the end of Section 18.4). The $[XeCl]^+$ ion is formed as the $[Sb_2F_{11}]^-$ salt on treatment of $[XeF]^+[SbF_6]^-$ in anhydrous HF/SbF_5 with $SbCl_5$. In the solid state (data collected at 123 K), cation–anion interactions are observed in $[XeCl][Sb_2F_{11}]$ (**18.15**). The Xe−Cl bond length is the shortest known to date. At 298 K, $[XeCl][Sb_2F_{11}]$ decomposes according to eq. 18.12.



(18.15)



$$2[XeCl][Sb_2F_{11}] \longrightarrow Xe + Cl_2 + [XeF][Sb_2F_{11}] + 2SbF_5 \quad (18.12)$$

Oxides

Equations 18.4 and 18.5 showed the formation of XeO_3 by hydrolysis of XeF_4 and XeF_6. Solid XeO_3 forms colourless crystals and is dangerously explosive ($\Delta_fH^o(298\,K) = +402\,kJ\,mol^{-1}$). The solid contains trigonal pyramidal molecules (**18.16**). Xenon trioxide is only weakly acidic and its aqueous solution is virtually non-conducting. Reactions of XeO_3 and MOH (M = K, Rb, Cs) produce xenates (eq. 18.13) which slowly disproportionate in solution (eq. 18.14).

(18.16)

(18.17)

$$XeO_3 + MOH \longrightarrow M[HXeO_4] \quad (18.13)$$

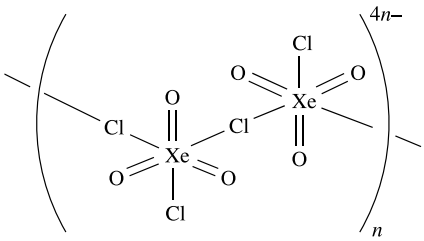
$$2[HXeO_4]^- + 2[OH]^- \longrightarrow \underset{\text{perxenate}}{[XeO_6]^{4-}} + Xe + O_2 + 2H_2O \quad (18.14)$$

Aqueous $[XeO_6]^{4-}$ is formed when O_3 is passed through a dilute solution of XeO_3 in alkali. Insoluble salts such as $Na_4XeO_6{\cdot}8H_2O$ and Ba_2XeO_6 may be precipitated, but perxenic acid 'H_4XeO_6' (a weak acid in aqueous solution) has not been isolated. The perxenate ion is a powerful oxidant and is rapidly reduced in aqueous acid (eq. 18.15). Oxidations such as Mn(II) to $[MnO_4]^-$ occur instantly in acidic media at 298 K.

$$[XeO_6]^{4-} + 3H^+ \longrightarrow [HXeO_4]^- + \tfrac{1}{2}O_2 + H_2O \quad (18.15)$$

Xenon tetraoxide is prepared by the slow addition of concentrated H_2SO_4 to Na_4XeO_6 or Ba_2XeO_6. It is a pale yellow, highly explosive solid ($\Delta_fH^o(298\,K) = +642\,kJ\,mol^{-1}$) which is a very powerful oxidizing agent. Tetrahedral XeO_4 molecules (**18.17**) are present in the gas phase.

Oxofluorides and oxochlorides



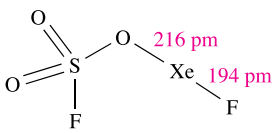
Oxofluorides are known for Xe(II) (structure **18.10**), Xe(IV), Xe(VI) and Xe(VIII): for example, $XeOF_2$, $XeOF_4$, XeO_2F_2, XeO_2F_4 and XeO_3F_2. The number of Xe(IV) oxofluorides is less than those containing Xe in other oxidation states because of the tendency for the former to undergo disproportionation or redox elimination reactions. The structures of xenon oxofluorides are consistent with VSEPR theory: see end-of-chapter problem 18.8. The 1:1 reaction of XeF_4 and H_2O in liquid HF yields $XeOF_2$, isolated as a pale yellow solid which decomposes explosively at 273 K. In contrast to reaction 18.5, *partial* hydrolysis of XeF_6 (eq. 18.16) gives $XeOF_4$ (a colourless liquid, mp 227 K), which can be converted to XeO_2F_2 by reaction 18.17. Reaction 18.18 is used to prepare XeO_3F_2 which can be separated *in vacuo*. Further reaction between XeO_3F_2 and XeF_6 yields XeO_2F_4.

$$XeF_6 + H_2O \longrightarrow XeOF_4 + 2HF \quad (18.16)$$

$$XeO_3 + XeOF_4 \longrightarrow 2XeO_2F_2 \qquad (18.17)$$

$$XeO_4 + XeF_6 \longrightarrow XeOF_4 + XeO_3F_2 \qquad (18.18)$$

The stable salts $M[XeO_3F]$ (M = K or Cs) are obtained from MF and XeO_3, and contain infinite chain anions with F^- ions bridging XeO_3 groups. Similar complexes are obtained from CsCl or RbCl with XeO_3 but these contain linked $[XeO_3Cl_2]^{2-}$ anions as shown in **18.18**.



(18.18)

Other compounds of xenon

Members of a series of compounds of the type FXeA where, for example, A^- is $[OClO_3]^-$, $[OSO_2F]^-$, $[OTeF_5]^-$ or $[O_2CCF_3]^-$ have been prepared by the highly exothermic elimination of HF between XeF_2 and HA. Further loss of HF leads to XeA_2 (e.g. eq. 18.19). Elimination of HF also drives the reaction of XeF_2 with $HN(SO_3F)_2$ to yield $FXeN(SO_3F)_2$, a relatively rare example of Xe–N bond formation.

$$XeF_2 + HOSO_2F \xrightarrow{-HF} FXeOSO_2F \xrightarrow[-HF]{HOSO_2F} Xe(OSO_2F)_2 \qquad (18.19)$$

(18.19)

(18.19)

For Xe(II), a linear coordination environment is typical and in the solid state, salts containing $[XeF]^+$, $[XeOTeF_5]^+$ or related cations exhibit significant cation---anion interactions as shown in structures **18.7–18.9** and **18.15**. Similarly, in $[XeOTeF_5][AsF_6]$, the second coordination site on the Xe centre is occupied by an F atom of $[AsF_6]^-$ (Xe····F = 224 pm). In an attempt to produce a salt containing a 'naked' cation, use has been made of the $[Sb(OTeF_5)_6]^-$ anion (Fig. 18.7a). This is a very weakly coordinating anion because the negative charge is spread out over 30 F atoms; $[Sb(OTeF_5)_6]^-$ is also sterically demanding. $[XeOTeF_5][Sb(OTeF_5)_6]$ is prepared by reaction 18.20, in which one equivalent of

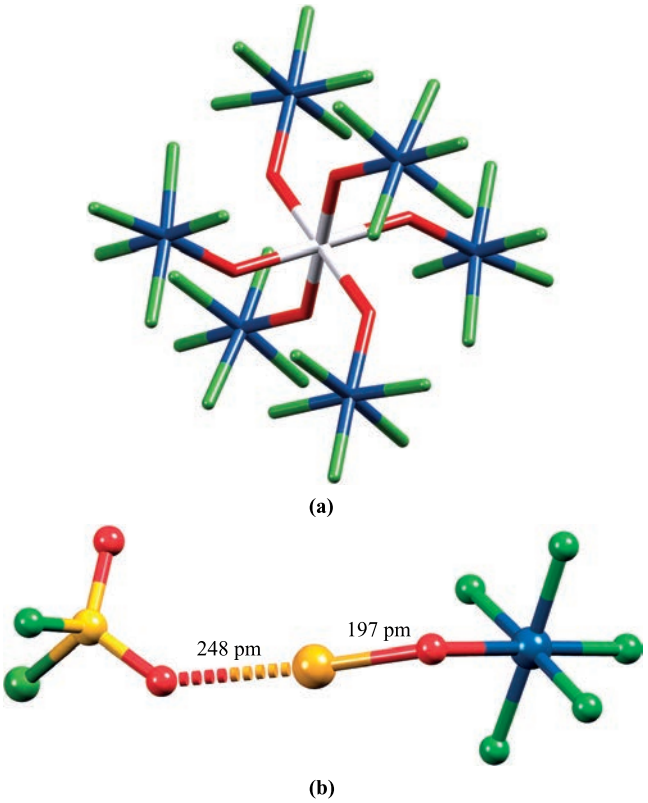


Fig. 18.7. The structure of (a) the $[Sb(OTeF_5)_6]^-$ anion (in stick-representation) and (b) the SO_2ClF adduct of the $[XeOTeF_5]^+$ cation in $[XeOTeF_5][Sb(OTeF_5)_6]\cdot SO_2ClF$ (determined by X-ray diffraction) [H.P. A. Mercier *et al.* (2005) *Inorg. Chem.*, vol. 44, p. 49]. Colour code: Xe and S, yellow; O, red; Cl and F, green; Te, blue; Sb, silver.

$Xe(OTeF_5)_2$ acts as an oxidant. Although the structure of $[XeOTeF_5][Sb(OTeF_5)_6]$ confirms an absence of cation---anion interactions, the Xe(II) centre persists in being 2-coordinate by virtue of association with the SO_2ClF solvent (Fig. 18.7b).

$$2Xe(OTeF_5)_2 + Sb(OTeF_5)_3 \xrightarrow[253\ K]{\text{in liquid } SO_2ClF} [XeOTeF_5][Sb(OTeF_5)_6] + Xe \qquad (18.20)$$

Xenon–carbon bond formation is now well exemplified for Xe(II), and many products contain fluorinated aryl substituents, e.g. $(C_6F_5CO_2)Xe(C_6F_5)$, $[(2,6\text{-}F_2C_5H_3N)XeC_6F_5]^+$ (Fig. 18.8a), $[(2,6\text{-}F_2C_6H_3)Xe][BF_4]$ (Fig. 18.8b), $[(2,6\text{-}F_2C_6H_3)Xe][CF_3SO_3]$ and $[(MeCN)Xe(C_6F_5)]^+$. The degree of interaction between the Xe centre and non-carbon donor (i.e. F, O or N) in these species varies. Some species are best described as containing Xe in a linear environment (e.g. Fig. 18.8a) and others tend towards containing an $[RXe]^+$ cation (e.g. Fig. 18.8b). The compounds C_6F_5XeF and $(C_6F_5)_2Xe$ are obtained using the reactions in scheme

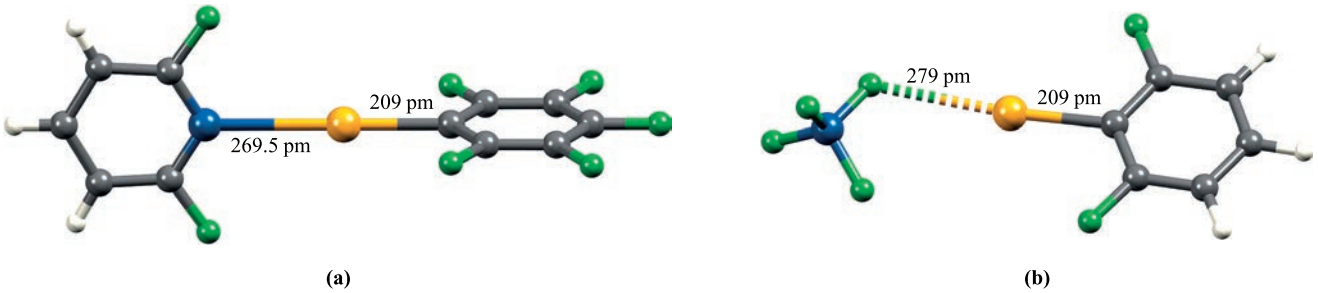

Fig. 18.8. The structures (X-ray diffraction) of (a) $[(2,6\text{-}F_2C_5H_3N)Xe(C_6F_5)]^+$ in the $[AsF_6]^-$ salt [H.J. Frohn *et al.* (1995) *Z. Naturforsch., Teil B*, vol. 50, p. 1799] and (b) $[(2,6\text{-}F_2C_6H_3)Xe][BF_4]$ [T. Gilles *et al.* (1994) *Acta Crystallogr., Sect. C*, vol. 50, p. 411]. Colour code: Xe, yellow; N, blue; B, blue; C, grey; F, green; H, white.

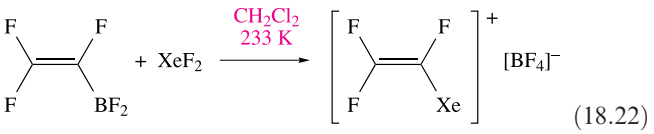
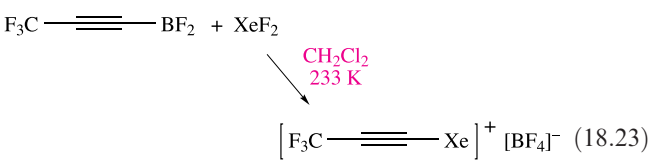
18.21. Stringent safety precautions must be taken when handling such compounds; $(C_6F_5)_2Xe$ decomposes explosively above 253 K.



$$Me_3SiC_6F_5 + XeF_2 \longrightarrow Me_3SiF + C_6F_5XeF$$

$$\downarrow \text{Me}_3\text{SiC}_6\text{F}_5 \qquad (18.21)$$

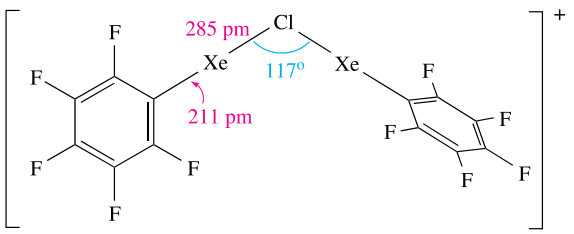


$$Me_3SiF + (C_6F_5)_2Xe$$

The $[C_6F_5XeF_2]^+$ ion (formed as the $[BF_4]^-$ salt from $C_6F_5BF_2$ and XeF_4, see worked example 18.1) is an extremely powerful oxidative-fluorinating agent, e.g. it converts I_2 to IF_5.

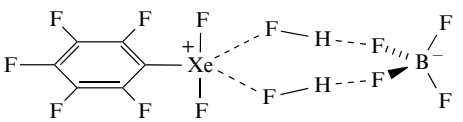
The use of a difluoroborane, RBF_2, precursor has proved to be a successful strategy for alkyl, alkenyl and alkynyl derivatives of xenon(II). Xenon–carbon(alkene) and Xe–C(alkyne) bond formation is illustrated by reactions 18.22 and 18.23.

(18.22)



(18.23)

Compounds containing linear C−Xe−Cl units are now known, the first examples being C_6F_5XeCl (eq. 18.24) and $[(C_6F_5Xe)_2Cl]^+$ (eq. 18.25 and structure **18.20**).

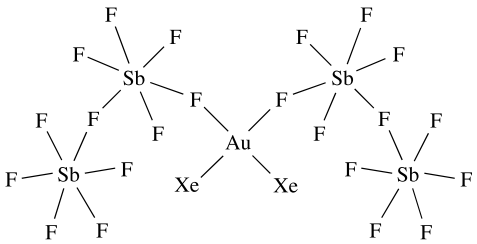


$$[C_6F_5Xe]^+[AsF_6]^- + \underset{\text{4-chloropyridine hydrochloride}}{4\text{-}ClC_5H_4N{\cdot}HCl} \xrightarrow[195\,K]{CH_2Cl_2} C_6F_5XeCl + [4\text{-}ClC_5H_4NH]^+[AsF_6]^- \qquad (18.24)$$

$$2[C_6F_5Xe]^+[AsF_6]^- + 6Me_3SiCl \xrightarrow[195\,K]{CH_2Cl_2} [(C_6F_5Xe)_2Cl]^+[AsF_6]^- + 6Me_3SiF + AsCl_3 + Cl_2 \qquad (18.25)$$

(18.20)

Xenon(IV)−C bond formation is exemplfied in $[C_6F_5XeF_2][BF_4]$. In the solid state structure of the solvate $[C_6F_5XeF_2][BF_4]{\cdot}2HF$, HF molecules bridge between cation and anion (**18.21**).



(18.21)

The first detection of compounds containing metal–xenon bonds ($Fe(CO)_4Xe$ and $M(CO)_5Xe$ with M = Cr, Mo, W) was in the 1970s and involved matrix isolation studies. Since 2000, a number of fully isolated and characterized compounds containing Au–Xe or Hg–Xe bonds have been reported, but even the most stable of these compounds decomposes at ≈298 K with loss of Xe. Their isolation depends upon the solvent and counter-ion being a weaker base than Xe(0). The first example was the square planar $[AuXe_4]^{2+}$ cation (av. Au−Xe = 275 pm). It is produced when AuF_3 is reduced to Au(II) in anhydrous HF/SbF_5 in the presence of Xe (eq. 18.26).

$$AuF_3 + 6Xe + 3H^+ \xrightarrow[\text{warm to 298 K}]{HF/SbF_5,\ 77\ K,} [AuXe_4]^{2+} + [Xe_2]^{2+} + 3HF \qquad (18.26)$$

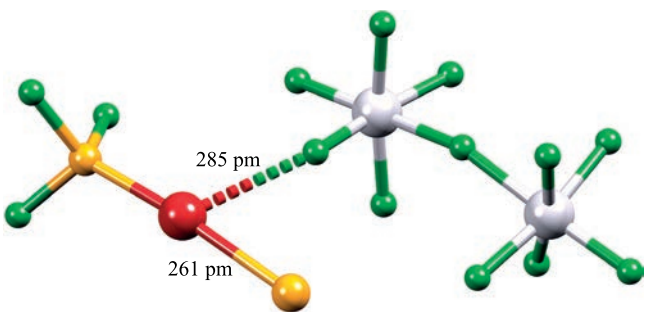
Removal of Xe from $[AuXe_4][Sb_2F_{11}]_2$ under vacuum at 195 K leads to $[cis\text{-}AuXe_2][Sb_2F_{11}]_2$. The *cis*-description arises as a result of Au–F–Sb bridge formation in the solid state (diagram **18.22**). The *trans*-isomer of $[AuXe_2]^{2+}$ is formed by reacting finely divided Au with XeF_2 in HF/SbF_5 under a pressure of Xe, but if the pressure is lowered, the product is the Au(II) complex $[XeAuFAuXe][SbF_6]_3$. The +2 oxidation state is rare for gold (see Section 22.12).

Au–Xe = 266, 267 pm Au–F = 218, 224 pm

(18.22)

The acid strength of the HF/SbF_5 system can be lowered by reducing the amount of SbF_5 relative to HF. Under these conditions, crystals of the Au(III) complex **18.23** (containing *trans*-$[AuXe_2F]^{2+}$) are isolated from the reaction of XeF_2, Au and Xe. Bond formation between Xe(0) and Au(I) is exemplified in $[F_3AsAuXe]^+$ (reaction 18.27). In crystalline $[F_3AsAuXe][Sb_2F_{11}]$, the ions are essentially discrete species, with the shortest cation---anion contact being that shown in Fig. 18.9.

$$[F_3AsAu]^+[SbF_6]^- + Xe \xrightarrow[HF/SbF_5]{\text{in anhydrous}} [F_3AsAuXe]^+[Sb_2F_{11}]^- \qquad (18.27)$$



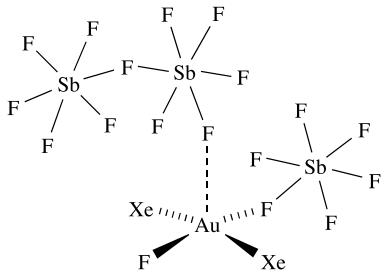


Fig. 18.9. The structure of $[F_3AsAuXe][Sb_2F_{11}]$ (X-ray diffraction, 173 K) shows the Xe(0) centre bonded to linear Au(I), and only weak cation---anion interactions; the shortest contact is shown [I.-C. Hwang *et al.* (2003) *Angew. Chem. Int. Ed.*, vol. 42, p. 4392]. Colour code: Xe, yellow; Au, red; As, yellow; Sb, silver; F, green.

(18.23)

18.5 Compounds of argon, krypton and radon

The chemistry of argon is still in its infancy. Photolysis of HF in a solid argon matrix results in the formation of HArF, which has been identified by comparing the IR spectra of $^1H^{40}ArF$, $^1H^{36}ArF$ and $^2H^{40}ArF$. Theoretical studies suggest that the formation of Ar–C and Ar–Si bonds should be possible, and that crystalline ArF_2 could be stabilized by working under high-pressure conditions.[†]

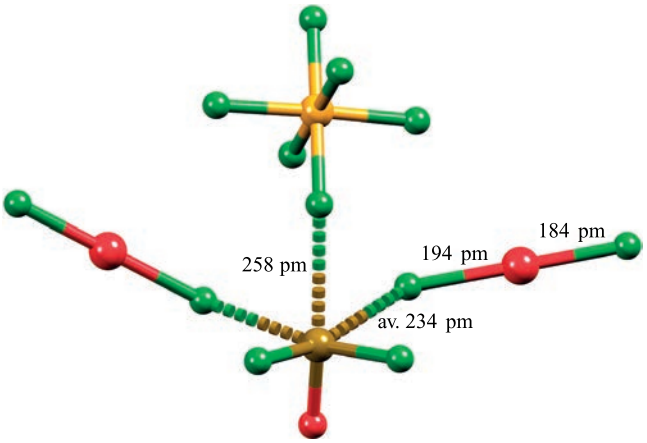
The only binary compound containing Kr is KrF_2. It is a colourless solid which decomposes >250 K, and is best prepared by UV irradiation of a mixture of Kr and F_2 (4 : 1 molar ratio) at 77 K. Krypton difluoride is dimorphic. The low-temperature phase, α-KrF_2, is isomorphous with XeF_2 (Fig. 18.4a). The structure of the β-form of KrF_2 is shown in Fig. 18.4b. The phase transition from β- to α-KrF_2 occurs below 193 K. Krypton difluoride is much less stable than XeF_2. It is rapidly hydrolysed by water (in an analogous manner to reaction 18.3), and dissociates into Kr and F_2 at 298 K ($\Delta_f H^\circ(298\,K) = +60.2\,kJ\,mol^{-1}$). We have already exemplified the use of KrF_2 as a powerful oxidizing agent in the syntheses of $[XeF_5][AgF_4]$ and $[Xe_2F_{11}]_2[NiF_6]$ (Section 18.4).

Krypton difluoride reacts with a number of pentafluorides, MF_5 (typically in anhydrous HF or BrF_5 at low temperature), to form $[KrF]^+[MF_6]^-$ (M = As, Sb, Bi, Ta), $[KrF]^+[M_2F_{11}]^-$ (M = Sb, Ta, Nb) and $[Kr_2F_3]^+[MF_6]^-$ (M = As, Sb, Ta). In the solid state, the $[KrF]^+$ ion in $[KrF]^+[MF_6]^-$ (M = As, Sb, Bi) is strongly associated with the anion (e.g. structure **18.24**). The $[Kr_2F_3]^+$ ion (**18.25**)[‡] is structurally similar to $[Xe_2F_3]^+$ (**18.7**). The oxidizing and fluorinating powers of KrF_2 are illustrated by its reaction with metallic gold to give $[KrF]^+[AuF_6]^-$ (eq. 18.28).

$$7KrF_2 + 2Au \longrightarrow 2[KrF][AuF_6] + 5Kr \qquad (18.28)$$

[†] See: D. Kurzydłowski and P. Zaleski-Ejgierd (2016) *Phys. Chem. Chem. Phys.*, vol. 18, p. 2309 – 'High-pressure stabilization of argon fluorides'.

[‡] For details of variation of bond lengths and angles in $[Kr_2F_3]^+$ with the salt, see J.F. Lehmann *et al.* (2001) *Inorg. Chem.*, vol. 40, p. 3002.



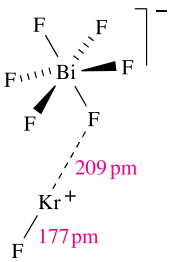


Fig. 18.10. The structure of $[BrOF_2][AsF_6]\cdot 2KrF_2$ (X-ray diffraction, 100 K) showing Br····F interactions between the structural units [D.S. Brock *et al*. (2010) *J. Am. Chem. Soc.*, vol. 132, p. 3533]. Colour code: Kr, red; Br, brown; As, yellow; O, red; F, green.

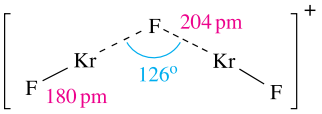

In the examples above, KrF_2 reacts with Lewis acids that are strong enough F^- acceptors to abstract F^-. In reaction 18.28, KrF_2 also acts as a very powerful oxidizing agent. An unusual example of the interaction of KrF_2 with a *p*-block element without oxidation of the latter or transfer of F^-, is observed in the reaction of KrF_2 with $[BrOF_2][AsF_6]$ (eq. 18.29). The product is stable at low temperature for several days and the solid state structure (Fig. 18.10) confirms adduct formation between KrF_2 and the bromine(V) atom.

$$[BrOF_2][AsF_6]^- + 2KrF_2 \xrightarrow[/195K]{\text{anhydrous HF,}} [BrOF_2][AsF_6]\cdot 2KrF_2 \qquad (18.29)$$

Few compounds are known that contain Kr bonded to elements other than F. The reactions between KrF_2, $RC{\equiv}N$ (e.g. R = H, CF_3) and AsF_5 in liquid HF or BrF_5 yield $[(RCN)KrF]^+[AsF_6]^-$ with Kr–N bond formation, and Kr–O bond formation has been observed in the reaction of KrF_2 and $B(OTeF_5)_3$ to give $Kr(OTeF_5)_2$.

(18.24)

(18.25)

Radon is oxidized by halogen fluorides (e.g. ClF, ClF_3) to the non-volatile RnF_2. The latter is reduced by H_2 at 770 K, and is hydrolysed by water in an analogous manner to XeF_2 (eq. 18.3). As we mentioned in Section 18.1, little chemistry of radon has been explored.

PROBLEMS

18.1 (a) What is the collective name for the group 18 elements? (b) Write down, in order, the names and symbols of these elements; check your answer by reference to the first page of this chapter. (c) What common feature does the ground state electronic configuration of each element possess?

18.2 Construct MO diagrams for He_2 and $[He_2]^+$ and rationalize why the former is not known but the latter may be detected.

18.3 Confirm that the observed gas-phase structures of XeF_2, XeF_4 and XeF_6 are consistent with the VSEPR model.

18.4 Rationalize the structure of $[XeF_8]^{2-}$ (a square antiprism) in terms of the VSEPR model.

18.5 How would you attempt to determine values for (a) $\Delta_f H^o(XeF_2, 298\,K)$ and (b) the Xe–F bond energy in XeF_2?

18.6 Why is $XeCl_2$ likely to be much less stable than XeF_2?

18.7 How may the standard enthalpy of the unknown salt Xe^+F^- be estimated?

18.8 Predict the structures of $[XeO_6]^{4-}$, $XeOF_2$, $XeOF_4$, XeO_2F_2, XeO_2F_4 and XeO_3F_2.

18.9 Suggest products for the following reactions (which are not necessarily balanced on the left-hand sides):

(a) $CsF + XeF_4 \longrightarrow$
(b) $SiO_2 + XeOF_4 \longrightarrow$
(c) $XeF_2 + SbF_5 \longrightarrow$
(d) $XeF_6 + [OH]^- \longrightarrow$
(e) $KrF_2 + H_2O \longrightarrow$

18.10 Write a brief account of the chemistry of the xenon fluorides.

18.11 (a) The reaction of XeF_2 with RuF_5 at 390 K results in the formation of a compound, the Raman spectrum of which is similar to that of $CsRuF_6$ but with an additional band at 600 cm^{-1}. Rationalize these data. (b) When the product of the reaction in part (a) reacts with excess F_2 at 620 K, a compound of molecular formula $RuXeF_{11}$ is formed. The compound is monomeric in the solid state. Propose a structure for this product.

18.12 The reaction of $F_2C{=}CClBF_2$ with XeF_2 gives a product **A** for which the NMR spectroscopic data are as follows: ^{19}F NMR δ/ppm –64.3 (s + d, J 8 Hz, 1F), –75.9 (s + d, J 138 Hz, 1F), –148.1 (non-binomial quartet, J 11 Hz); ^{129}Xe NMR δ/ ppm –3550 (dd, J 8 Hz, 138 Hz) (s = singlet, d = doublet, dd = doublet of doublets). Rationalize the data and suggest the identity of **A**.

18.13 Equation 18.27 showed the preparation of $[F_3AsAuXe][Sb_2F_{11}]$ from $[F_3AsAu][SbF_6]$. Solid $[F_3AsAu][SbF_6]$ contains a distorted $[SbF_6]^-$ ion; one Sb–F bond is 193 pm, and five are in the range 185–189 pm. The Au centre interacts with the F atom of the long Sb–F bond (Au–F = 212 pm, compared with 203 pm calculated for the hypothetical $[AuF_2]^-$ ion). Suggest why $[F_3AsAu][SbF_6]$ was chosen as the precursor to $[F_3AsAuXe]^+$, rather than a route involving reduction of AuF_3 in anhydrous HF/SbF_5 in the presence of Xe.

OVERVIEW PROBLEMS

18.14 (a) The ^{19}F NMR spectrum of $[Kr_2F_3][SbF_6]$ in BrF_5 at 207 K contains a doublet (J = 347 Hz) and triplet (J = 347 Hz) assigned to the cation. Explain the origin of these signals.
(b) Give examples that illustrate the role of E–F–Xe and E–F–Kr bridge formation (E = any element) in the solid state. To what extent does bridge formation occur betwen cations and anions, and how does it affect the description of a solid as containing discrete ions?

18.15 Suggest products for the following reactions, which are not necessarily balanced on the left-hand side:

(a) $KrF_2 + Au \longrightarrow$
(b) $XeO_3 + RbOH \longrightarrow$
(c) $[XeCl][Sb_2F_{11}] \xrightarrow{298\,K}$
(d) $KrF_2 + B(OTeF_5)_3 \longrightarrow$
(e) $C_6F_5XeF + Me_3SiOSO_2CF_3 \longrightarrow$
(f) $[C_6F_5XeF_2]^+ + C_6F_5I \longrightarrow$

18.16 By referring to the following literature source, assess the safety precautions required when handling XeO_4: M. Gerken and G.J. Schrobilgen (2002) *Inorg. Chem.*, vol. 41, p. 198.

18.17 The vibrational modes of KrF_2 are at 590, 449 and 233 cm^{-1}. Explain why only the bands at 590 and 233 cm^{-1} are observed in the IR spectrum of gaseous KrF_2.

18.18 Use MO theory to rationalize why the Xe–F bond strength in $[XeF]^+$ is greater than in XeF_2.

INORGANIC CHEMISTRY MATTERS

18.19 High-field NMR spectrometers, including those used for magnetic resonance imaging in hospitals, contain magnets with superconducting coils, e.g. NbTi which becomes superconducting at 9.5 K. (a) Why is liquid helium used to cool the magnet? (b) For He, $\Delta_{vap}H(\text{bp}) = 0.1\,\text{kJ mol}^{-1}$. To what process does this refer and why is the value so low? (c) Suggest why the liquid helium tank in an NMR spectrometer is surrounded by a tank of liquid N_2.

18.20 Discharge lamps are used throughout the world for lighting and advertising. Such a lamp consists of a sealed tube with a metal electrode at each end, and contains a gas (e.g. He, Ar, Ne) or vapour (Na, Hg). The atoms are excited by an electrical discharge. Explain the origin of the pale yellow glow emitted by a helium discharge lamp.

19.1 Topic overview

In Chapters 19–22, we discuss the chemistry of the *d*-block metals, covering first some general principles including magnetic and electronic spectroscopic properties. We move then to a systematic coverage of the metals and their inorganic compounds. The organometallic chemistry of the *d*-block metals is covered in Chapter 24 after an account of *p*-block organometallic chemistry in Chapter 23. We have already discussed some aspects of the *d*-block metals:

- ground state electronic configurations (Table 1.3);
- trends in first ionization energies (Fig. 1.16 and Section 1.10);
- structures of bulk metals (Section 6.3);
- polymorphism (Section 6.4);
- metallic radii (Section 6.5);
- trends in melting points and $\Delta_a H^o(298\,K)$ (Section 6.6);
- alloys and intermetallic compounds (Section 6.7);
- metallic bonding including electrical resistivity (Section 6.8 and Fig. 6.11);
- aquated cations: formation and acidic properties (Section 7.7);
- solubilities of ionic salts and common-ion effect (Sections 7.9 and 7.10);
- stability constants for metal complexes (Section 7.12);
- selected ligand structures and abbreviations (Table 7.8);
- an introduction to coordination complexes (Section 7.11);
- redox chemistry in aqueous solution, including potential diagrams and Frost–Ebsworth diagrams (Chapter 8);
- stereoisomerism (Section 2.9);
- chiral molecules (Section 3.8);
- binary metal hydrides (Section 10.7).

19.2 Ground state electronic configurations

d-Block metals versus transition elements

The schematic periodic table at the beginning of this chapter shows four rows of *d*-block metals. However, metals in the fourth row are all artificial elements (see Section 27.5) and we shall, therefore, only consider the first three rows (Sc–Zn, Y–Cd and La–Hg) in this and the following two chapters. Lanthanum (La) is usually classed with the lanthanoid metals (Chapter 27). The *d*-block metals are also referred to as the 'transition elements' (metals), although the group 12 metals (Zn, Cd and Hg) are not always included.[†] Throughout our discussions, we shall use the terms *d*-block and *f*-block metals, so being consistent with the use of the terms *s*-block and *p*-block elements in earlier

[†] *IUPAC Nomenclature of Inorganic Chemistry* (Recommendations 2005), senior eds N.G. Connelly and T. Damhus, RSC Publishing, Cambridge, p. 51.

chapters. Three further points should be noted if we consider only the first three rows of metals:

- each group of *d*-block metals consists of three members and is called a *triad*;
- metals of the second and third rows are sometimes called the *heavier d-block metals*;
- Ru, Os, Rh, Ir, Pd and Pt are collectively known as the *platinum-group metals*.

Electronic configurations

To a first approximation, the observed ground state electronic configurations of the first, second and third row *d*-block metal atoms correspond to the progressive filling of the 3*d*, 4*d* and 5*d* atomic orbitals respectively (Table 1.3). However, there are minor deviations from this pattern, e.g. in the first row, the ground state of chromium is $[Ar]4s^1 3d^5$ rather than $[Ar]4s^2 3d^4$. The reasons for these deviations are beyond the scope of this book: we should need to know both the energy difference between the 3*d* and 4*s* atomic orbitals when the nuclear charge is 24 (the atomic number of Cr) and the interelectronic interaction energies for each of the $[Ar]4s^1 3d^5$ and $[Ar]4s^2 3d^4$ configurations. Fortunately, M^{2+} and M^{3+} *ions* of the *first* row *d*-block metals all have electronic configurations of the general form $[Ar]3d^n$, and so the comparative chemistry of these metals is largely concerned with the consequences of the successive filling of the 3*d* orbitals. For metals of the second and third rows, the picture is more complicated, and a systematic treatment of their chemistry cannot be given. The emphasis in this and the next chapter is therefore on the first row metals, but we shall include some material that illustrates ways in which the heavier metals differ from their lighter congeners.

An important point that must not be forgotten is that *d*-block metal atoms are, of course, *many-electron* species, and when we discuss, for example, radial distribution functions of the *nd* atomic orbitals, we refer to hydrogen-like atoms and, therefore, the discussion is extremely approximate.

19.3 Physical properties

In this section, we consider physical properties of the *d*-block metals (see cross-references in Section 19.1 for further details). An extended discussion of properties of the heavier metals is given in Section 22.1. Nearly all the *d*-block metals are hard, ductile and malleable, with high electrical and thermal conductivities. With the exceptions of Mn, Zn, Cd and Hg, at room temperature, the metals possess one of the typical metal structures (see Table 6.2). The metallic radii (r_{metal}) for 12-coordination (Table 6.2 and Fig. 19.1) are much smaller than those of the *s*-block metals of comparable atomic number. Figure 19.1 also illustrates that values of r_{metal}:

- show little variation across a given row of the *d*-block;
- are greater for second and third row metals than for first row metals;
- are similar for the second and third row metals in a given triad.

This last observation is due to the so-called *lanthanoid contraction*: the steady decrease in size along the 14 lanthanoid metals between La and Hf (see Section 27.3).

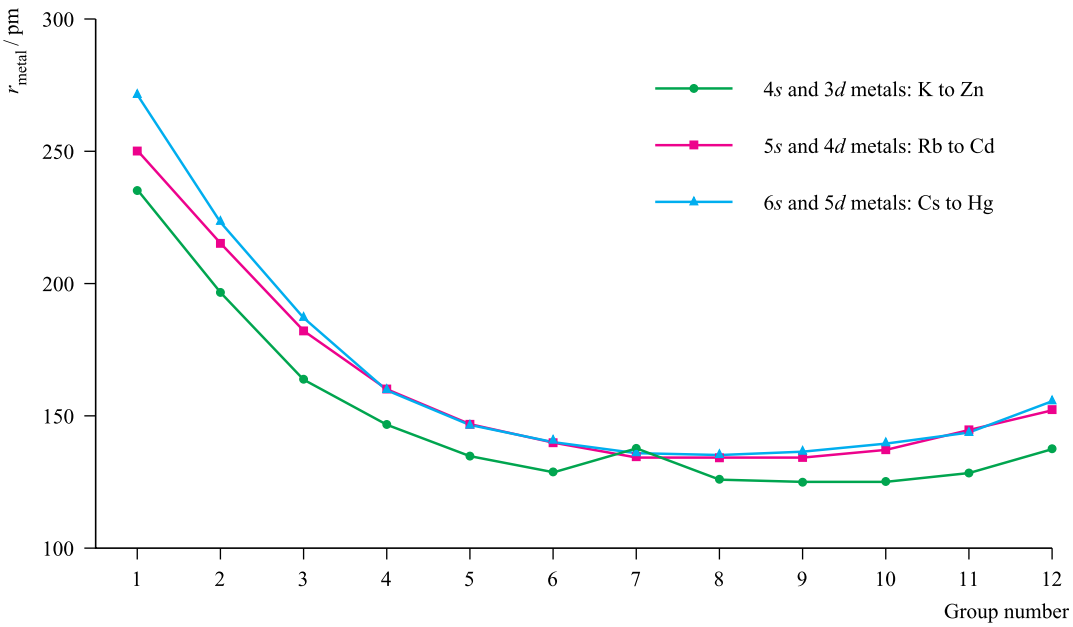

Fig. 19.1. Trends in metallic radii (r_{metal}) across the three rows of *s*- and *d*-block metals K to Zn, Rb to Cd, and Cs to Hg.

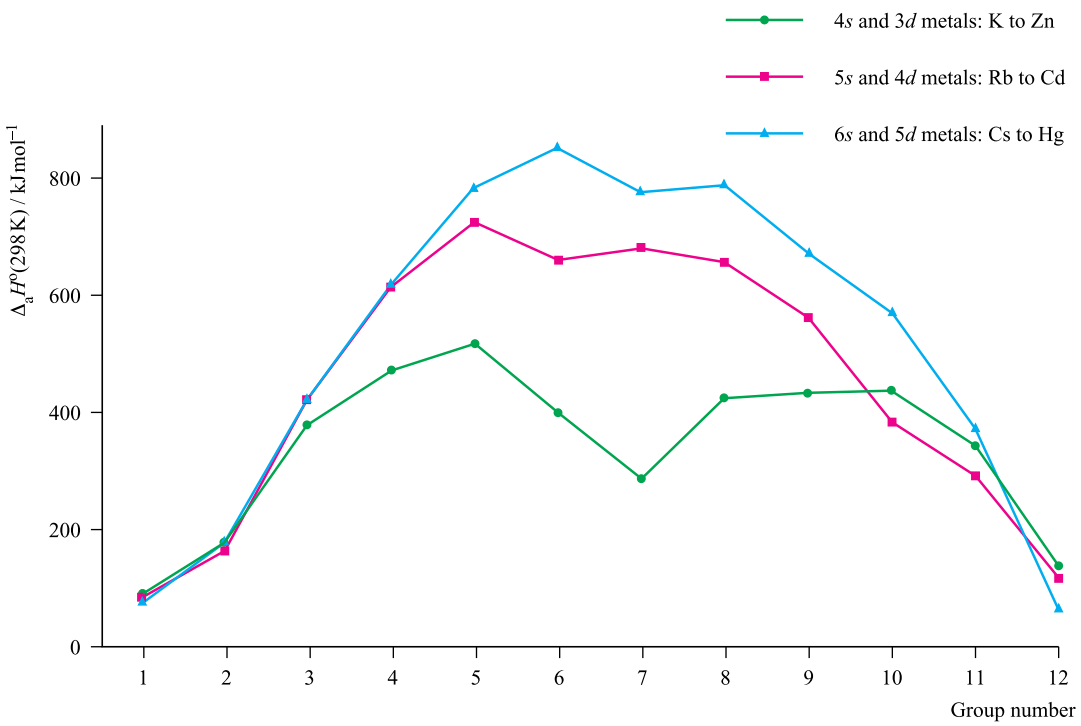

Fig. 19.2. Trends in standard enthalpies of atomization, $\Delta_a H^o(298\,K)$, across the three rows of *s*- and *d*-block metals K to Zn, Rb to Cd, and Cs to Hg.

Metals of the *d*-block are (with the exception of the group 12 metals) much harder and less volatile than those of the *s*-block. The trends in enthalpies of atomization (Table 6.2) are shown in Fig. 19.2. Metals in the second and third rows generally possess higher enthalpies of atomization than the corresponding elements in the first row. This is a substantial factor in accounting for the far greater occurrence of metal–metal bonding in compounds of the heavier *d*-block metals compared with their first row congeners. In general, Fig. 19.2 shows that metals in the centre of the *d*-block possess higher values of $\Delta_a H^o(298\,K)$ than early or late metals. However, one must be careful in comparing metals with different structure types and this is particularly true of manganese (see Section 6.3).

The first ionization energies (IE_1) of the *d*-block metals in a given period (Fig. 1.16 and Appendix 8) are higher than those of the preceding *s*-block metals. Figure 1.16 shows that across each of the periods K to Kr, Rb to Xe, and Cs to Rn, the variation in values of IE_1 is small across the *d*-block and far greater among the *s*- and *p*-block elements. Within each period, the overall trend for the *d*-block metals is for the ionization energies to increase, but many small variations occur. Chemical comparisons between metals from the *s*- and *d*-blocks are complicated by the number of factors involved. Thus, all 3*d* metals have values of IE_1 (Fig. 1.16) and IE_2 larger than those of calcium, and all except zinc have higher values of $\Delta_a H^o$ (Fig. 19.2) than calcium. These factors make the metals less reactive than calcium. However, since all known M^{2+} ions of the 3*d* metals are smaller than Ca^{2+}, lattice and solvation energy effects (see Chapters 6 and 7) are more favourable for the 3*d* metal ions. In practice, it turns out that, in the formation of species containing M^{2+} ions, all the 3*d* metals are thermodynamically less reactive than calcium, and this is consistent with the standard reduction potentials listed in Table 19.1. However, interpretation of observed chemistry based on these E^o data is not always straightforward, since the

Table 19.1 Standard reduction potentials (298 K) for some metals in the first long period; the concentration of each aqueous solution is 1 mol dm^{-3}.

Reduction half-equation	E^o / V
$Ca^{2+}(aq) + 2e^- \rightleftharpoons Ca(s)$	−2.87
$Ti^{2+}(aq) + 2e^- \rightleftharpoons Ti(s)$	−1.63
$V^{2+}(aq) + 2e^- \rightleftharpoons V(s)$	−1.13
$Cr^{2+}(aq) + 2e^- \rightleftharpoons Cr(s)$	−0.91
$Mn^{2+}(aq) + 2e^- \rightleftharpoons Mn(s)$	−1.19
$Fe^{2+}(aq) + 2e^- \rightleftharpoons Fe(s)$	−0.44
$Co^{2+}(aq) + 2e^- \rightleftharpoons Co(s)$	−0.28
$Ni^{2+}(aq) + 2e^- \rightleftharpoons Ni(s)$	−0.25
$Cu^{2+}(aq) + 2e^- \rightleftharpoons Cu(s)$	+0.34
$Zn^{2+}(aq) + 2e^- \rightleftharpoons Zn(s)$	−0.76

formation of a coherent surface film of metal oxide often renders a metal less reactive than expected (see Section 19.4). A few *d*-block metals are very powerful reducing agents, e.g. E^o for the Sc^{3+}/Sc couple (−2.08 V) is more negative than that for Al^{3+}/Al (−1.66 V).

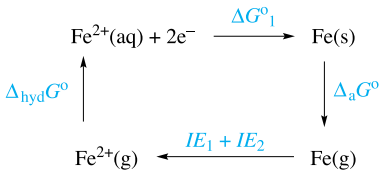
Worked example 19.1 Reduction potentials of the first row *d*-block metals

In what way does the value of E^o for the $Fe^{2+}(aq)/Fe(s)$ couple depend on the first two ionization energies of Fe(g)?

E^o for the $Fe^{2+}(aq)/Fe(s)$ couple refers to the reduction process:

$$Fe^{2+}(aq) + 2e^- \rightleftharpoons Fe(s)$$

relative to the reduction:



$$2H^+(aq) + 2e^- \rightleftharpoons H_2(g)$$

The sum of the first and second ionization energies, IE_1 and IE_2, refers to the process:

$$Fe(g) \longrightarrow Fe^{2+}(g)$$

The entropy changes on ionization are negligible compared with the enthalpy changes. Therefore, IE_1 and IE_2 may be approximated to Gibbs energy changes.

In order to relate the processes, construct a thermochemical cycle:

$\Delta_{hyd}G^o$ is the Gibbs energy change for the hydration of a mole of gaseous Fe^{2+} ions. This cycle illustrates the contribution that the ionization energies of Fe make to $\Delta G^o{}_1$, the Gibbs energy change associated with the reduction of $Fe^{2+}(aq)$. This in turn is related to $E^o{}_{Fe^{2+}/Fe}$ by the equation:

$$\Delta G^o{}_1 = -zFE^o$$

where $F = 96\,485\ C\ mol^{-1}$ and $z = 2$.

Self-study exercises

Use the data in Table 19.1 for these questions.

1. Which of the metals Cu and Zn will liberate H_2 from dilute hydrochloric acid? [*Ans.* See Section 8.2]
2. Calculate a value of $\Delta G^o(298\ K)$ for the reaction:

   $$Zn(s) + 2H^+(aq) \longrightarrow Zn^{2+}(aq) + H_2(g)$$

   Is the result consistent with your answer to question 1? [*Ans.* $-147\ kJ\ mol^{-1}$]
3. A polished Cu rod is placed in an aqueous solution of $Zn(NO_3)_2$. In a second experiment, a polished Zn rod is placed in an aqueous solution of $CuSO_4$. Does anything happen to (a) the Cu rod and (b) the Zn rod? Quantify your answers by calculating appropriate values of $\Delta G^o(298\ K)$. [*Ans.* See Section 8.2]

19.4 The reactivity of the metals

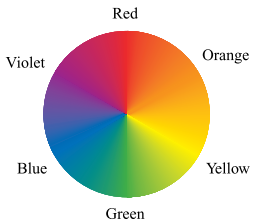
In Chapters 21 and 22 we look at individual elements of the *d*-block in detail. However, a few points are given here as an overview. In general, the metals are moderately reactive and combine to give binary compounds when heated with dioxygen, sulfur or the halogens (e.g. reactions 19.1–19.3), product stoichiometry depending, in part, on the available oxidation states (see below). Combination with H_2, B, C or N_2 may lead to interstitial hydrides (Section 10.7), borides (Section 13.10), carbides (Section 14.7) or nitrides (Section 15.6).

$$Os + 2O_2 \xrightarrow{\Delta} OsO_4 \qquad (19.1)$$

$$Fe + S \xrightarrow{\Delta} FeS \qquad (19.2)$$

$$V + \frac{n}{2}X_2 \xrightarrow{\Delta} VX_n \quad (X = F,\ n = 5;\ X = Cl,\ n = 4;\ X = Br, I,\ n = 3) \qquad (19.3)$$

Most *d*-block metals should, on thermodynamic grounds (e.g. Table 19.1), liberate H_2 from acids but, in practice, many do not since they are passivated by a thin surface coating of oxide or by having a high dihydrogen overpotential, or both. Silver, gold and mercury (i.e. late, second and third row metals) are, even in the thermodynamic sense, the least reactive metals known. For example, gold is not oxidized by atmospheric O_2 or attacked by acids, except by a 3 : 1 mixture of concentrated HCl and HNO_3 (*aqua regia*).



19.5 Characteristic properties: a general perspective

In this section, we introduce properties that are characteristic of *d*-block metal compounds. More detailed discussion follows in Chapter 20.

Colour

Coloured *d*-block metal compounds are a characteristic feature of species with ground state electronic configurations other than d^0 and d^{10}. For example, $[Cr(OH_2)_6]^{2+}$ is sky-blue, $[Mn(OH_2)_6]^{2+}$ very pale pink, $[Co(OH_2)_6]^{2+}$ pink, $[MnO_4]^-$ intense purple and $[CoCl_4]^{2-}$ dark blue. In

Table 19.2 The visible part of the electromagnetic spectrum.

Colour of light *absorbed*	Approximate wavelength ranges / nm	Corresponding wavenumbers (approximate values) / cm^{-1}	Colour of light *transmitted*, i.e. complementary colour of the absorbed light	In a 'colour wheel' representation,† complementary colours are in opposite sectors
Red	700–620	14 300–16 100	Green	
Orange	620–580	16 100–17 200	Blue	
Yellow	580–560	17 200–17 900	Violet	
Green	560–490	17 900–20 400	Red	
Blue	490–430	20 400–23 250	Orange	
Violet	430–380	23 250–26 300	Yellow	

† When an electronic spectrum exhibits more than one absorption in the visible region, the simplicity of the colour wheel does not hold.

contrast, complexes of Sc(III) (d^0) or Zn(II) (d^{10}) are colourless unless the ligands contain a chromophore that absorbs in the visible region.

A ***chromophore*** is the group of atoms in a molecule responsible for the absorption of electromagnetic radiation.

The fact that many of the observed colours are of *low intensity* is consistent with the colour originating from electronic '*d–d*' transitions. If we are dealing with an isolated gas-phase ion, such transitions are forbidden by the Laporte selection rule (eq. 19.4 where l is the orbital quantum number). The pale colours observed in complexes indicate that the probability of a transition occurring is low. Table 19.2 shows relationships between the wavelength of light absorbed and observed colours.

$$\Delta l = \pm 1 \qquad \text{(Laporte selection rule)} \qquad (19.4)$$

The intense colours of species such as $[MnO_4]^-$ have a different origin, namely *charge transfer* absorptions or emissions. The latter are *not* subject to selection rule 19.4 and are always more intense than electronic transitions between different *d* orbitals. We return to electronic spectra in Section 20.7.

Paramagnetism

The occurrence of *paramagnetic* compounds of *d*-block metals is common and arises from the presence of unpaired electrons. This phenomenon can be investigated using electron paramagnetic resonance (EPR) spectroscopy (see Section 4.9). It also leads to signal broadening and anomalous chemical shift values in NMR spectra (see Box 4.2).

Complex formation

d-Block metal ions readily form complexes, with complex formation often being accompanied by a change in colour and sometimes a change in the intensity of colour. Equation 19.5 shows the effect of adding concentrated HCl to aqueous cobalt(II) ions.

$$\underset{\text{pale pink}}{[Co(OH_2)_6]^{2+}} + 4Cl^- \longrightarrow \underset{\text{dark blue}}{[CoCl_4]^{2-}} + 6H_2O \qquad (19.5)$$

The formation of such complexes is analogous to the formation of those of *s*- and *p*-block metals and discussed in previous chapters, e.g. $[K(18\text{-crown-6})]^+$, $[Be(OH_2)_4]^{2+}$, *trans*-$[SrBr_2(py)_5]$, $[AlF_6]^{3-}$, $[SnCl_6]^{2-}$ and $[Bi_2(O_2C_6H_4)_4]^{2-}$.

Self-study exercises

For the answers, refer to Table 7.8.

1. Many ligands in complexes have common abbreviations. Give the full names of the following ligands: en, THF, phen, py, $[acac]^-$, $[ox]^{2-}$.
2. Draw the structures of the following ligands. Indicate the potential donor atoms in and the denticity of each ligand: en, $[EDTA]^{4-}$, DMSO, dien, bpy, phen.

Variable oxidation states

The occurrence of variable oxidation states and, often, the interconversion between them, is a characteristic of most *d*-block metals. Exceptions are in groups 3 and 12 as Table 19.3 illustrates. In group 12, the +1 oxidation state is found for species containing (or formally containing) the $[M_2]^{2+}$ unit. This is extremely common for Hg, but is

Table 19.3 Oxidation states of the *d*-block metals; the most stable states are marked in blue. Tabulation of zero oxidation states refers to their appearance in *compounds* of the metal. In organometallic compounds, oxidation states of less than zero are encountered (see Chapter 23). An oxidation state enclosed in [ ] is rare.

rare for Zn and Cd (see Sections 21.13 and 22.13). A comparison between the available oxidation states for a given metal (Table 19.3) and the electronic configurations listed in Table 1.3 is instructive. As expected, metals that display the greatest number of different oxidation states occur in or near the middle of a *d*-block row. Two cautionary notes (illustrated by *d*- and *f*-block metal compounds) should be made:

- The apparent oxidation state deduced from a molecular or empirical formula may be misleading. For example, (i) LaI_2 is a metallic conductor and is best formulated as $La^{3+}(I^-)_2(e^-)$, and (ii) $MoCl_2$ contains metal cluster units with metal–metal bonds and is formally $[Mo_6Cl_8]^{4+}(Cl^-)_4$. Metal–metal bond formation becomes more important for the heavier metals.
- There are many metal compounds in which it is impossible to assign oxidation states unambiguously, e.g. in the complexes $[Ti(bpy)_3]^{n-}$ ($n = 0, 1, 2$), there is evidence that the negative charge is localized on the bpy ligands (see Table 7.8) not the metal centres, and in nitrosyl complexes, the NO ligand may donate one or three electrons (see Sections 20.4 and 24.2).

19.6 Electroneutrality principle

Pauling's ***electroneutrality principle*** is an *approximate method* of estimating the charge distribution in molecules and complex ions. It states that the distribution of charge in a molecule or ion is such that the charge on any single atom is within the range +1 to −1 (ideally close to zero).

Consider the complex ion $[Co(NH_3)_6]^{3+}$. Figure 19.3a gives a representation of the complex which indicates that the coordinate bonds are formed by lone pair donation from the ligands to the Co(III) centre. It implies transfer of charge from ligand to metal, and Fig. 19.3b shows the resulting charge distribution. This is clearly unrealistic, since the cobalt(III) centre becomes more negatively charged than would be favourable given its electropositive nature. At the other extreme, we could consider the bonding in terms of a wholly ionic model (Fig. 19.3c): the 3+ charge remains localized on the cobalt ion and the six NH_3 ligands remain neutral. However, this model is also flawed. Experimental evidence shows that the $[Co(NH_3)_6]^{3+}$ complex ion remains as an entity in aqueous solution, and the electrostatic interactions implied by the ionic model are unlikely to be

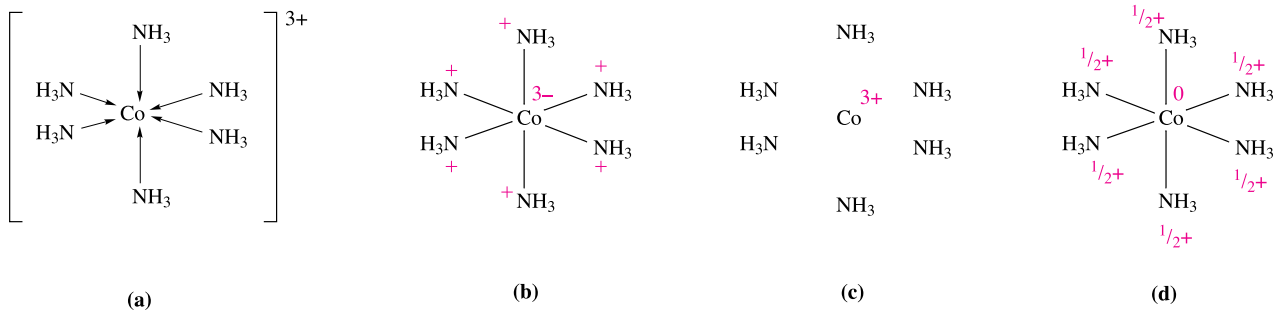

Fig. 19.3. The complex cation $[Co(NH_3)_6]^{3+}$: (a) a conventional diagram showing the donation of lone pairs of electrons from ligands to metal ion; (b) the charge distribution that results from a 100% covalent model of the bonding; (c) the charge distribution that results from a 100% ionic model of the bonding; and (d) the approximate charge distribution that results from applying the electroneutrality principle.

strong enough to allow this to happen. Thus, neither of the extreme bonding models is appropriate.

If we now apply the electroneutrality principle to $[Co(NH_3)_6]^{3+}$, then, ideally, the net charge on the metal centre should be zero. That is, the Co^{3+} ion may accept a total of *only three electrons* from the six ligands, thus giving the charge distribution shown in Fig. 19.3d. The electroneutrality principle results in a bonding description for the $[Co(NH_3)_6]^{3+}$ ion which is 50% ionic (or 50% covalent).

The problems encountered when using simple models to assess charge distributions in coordination compounds are overcome by using a full molecular orbital approach. Modern DFT calculations (see Section 4.13) can now reproduce experimental data for a wide range of *d*-block metal complexes.

Self-study exercises

1. In $[Fe(CN)_6]^{3-}$, a realistic charge distribution results in each ligand carrying a charge of $-\frac{2}{3}$. In this model, what charge does the Fe centre carry and why is this charge consistent with the electroneutrality principle?
2. If the bonding in $[CrO_4]^{2-}$ were described in terms of a 100% ionic model, what would be the charge carried by the Cr centre? Explain how this charge distribution can be modified by the introduction of covalent character into the bonds.

19.7 Coordination numbers and geometries

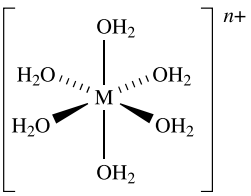
In this section, we give an overview of the coordination numbers and geometries found within *d*-block metal compounds. It is impossible to give a comprehensive account, and several points should be borne in mind:

- most examples in this section involve mononuclear complexes, and in complexes with more than one metal centre, structural features are often conveniently described in terms of individual metal centres (e.g. in polymer **19.4**, each Pd(II) centre is in a square planar environment);
- although coordination environments are often described in terms of *regular* geometries such as those in Table 19.4, in practice they are often distorted, for example as a consequence of steric effects;
- detailed discussion of a particular geometry usually involves bond lengths and angles determined in the solid state and these may be affected by crystal packing forces;
- where the energy difference between different possible structures is small (e.g. for 5- and 8-coordinate complexes), fluxional behaviour in solution may be observed; the small energy difference may also lead to the observation of different structures in the solid state, e.g. in salts of $[Ni(CN)_5]^{3-}$ the shape of the anion depends upon the cation present and in $[Cr(en)_3][Ni(CN)_5]\cdot 1.5H_2O$, *both* trigonal bipyramidal and square-based pyramidal structures are present.

The description of coordination numbers in this section does not include ionic lattices, but instead focuses on mononuclear species in which the metal centre is covalently bonded to the atoms in the coordination sphere. The metal–ligand bonding in complexes can generally be considered in terms of σ-donor ligands interacting with a metal centre which acts as a σ-acceptor. This may, in some complexes, be augmented with interactions involving π-donor ligands (with the metal as a π-acceptor) or π-acceptor ligands (with the metal as a π-donor). For a preliminary discussion of stereochemistry, it is not necessary to detail the metal–ligand bonding but we shall find it useful to draw attention to the electronic configuration of the metal centre. The reasons for this will become clear in Chapter 20, but for now you should remember that both steric and electronic factors are involved in dictating the coordination geometry around a metal ion.

Table 19.4 Coordination geometries; each describes the arrangement of the donor atoms that surround the metal centre. Note that for some coordination numbers, more than one possible arrangement of donor atoms exists.

Coordination number	Arrangement of donor atoms around metal centre	Less common arrangements
2	Linear	
3	Trigonal planar	Trigonal pyramidal
4	Tetrahedral; square planar	
5	Trigonal bipyramidal; square-based pyramidal	
6	Octahedral	Trigonal prismatic
7	Pentagonal bipyramidal	Monocapped trigonal prismatic; monocapped octahedral
8	Dodecahedral; square antiprismatic; hexagonal bipyramidal	Cube; bicapped trigonal prismatic
9	Tricapped trigonal prismatic	



It is difficult to provide generalizations about the trends in coordination *number* within the *d*-block. However, it is useful to bear the following points in mind:

- sterically demanding ligands favour low coordination numbers at metal centres;
- high coordination numbers are most likely to be attained with small ligands and large metal ions;
- the size of a metal ion decreases as the formal charge increases, e.g. $r(Fe^{3+}) < r(Fe^{2+})$;
- low coordination numbers will be favoured by metals in high oxidation states with π-bonding ligands.

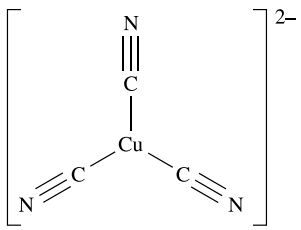
The Kepert model

For many years after the classic work of Werner which laid the foundations for the correct formulation of *d*-block metal complexes,[†] it was assumed that a metal in a given oxidation state would have a fixed coordination number and geometry. In the light of the success (albeit not universal success) of the VSEPR model in predicting the shapes of molecular species of the *p*-block elements (see Section 2.8), we might reasonably expect the structures of the complex ions $[V(OH_2)_6]^{3+}$ (d^2), $[Mn(OH_2)_6]^{3+}$ (d^4), $[Co(OH_2)_6]^{3+}$ (d^6), $[Ni(OH_2)_6]^{2+}$ (d^8) and $[Zn(OH_2)_6]^{2+}$ (d^{10}) to vary as the electronic configuration of the metal ion changes. However, each of these species has an octahedral arrangement of ligands (**19.1**). Thus, it is clear that the VSEPR model is not applicable to *d*-block metal complexes.

[†]Alfred Werner was the first to recognize the existence of coordination complexes and was awarded the 1913 Nobel Prize in Chemistry; see nobelprize.org.

(19.1)

We turn instead to the *Kepert model*, in which the metal lies at the centre of a sphere and the ligands are free to move over the surface of the sphere. The ligands are considered to repel one another in a similar manner to the point charges in the VSEPR model. However, unlike the VSEPR model, that of Kepert *ignores non-bonding electrons*. Thus, the coordination geometry of a *d*-block species is considered by Kepert to be *independent* of the ground state electronic configuration of the metal centre, and so species of type $[ML_n]$, $[ML_n]^{m+}$ and $[ML_n]^{m-}$ have the *same* coordination geometry.



The ***Kepert model*** rationalizes the shapes of *d*-block metal complexes $[ML_n]$, $[ML_n]^{m+}$ or $[ML_n]^{m-}$ by considering the repulsions between the groups L. Lone pairs of electrons are ignored. For coordination numbers between 2 and 6, the following arrangements of donor atoms are predicted:

2 linear
3 trigonal planar
4 tetrahedral
5 trigonal bipyramidal *or* square-based pyramidal
6 octahedral

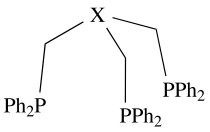


Table 19.4 lists coordination environments associated with coordination numbers between 2 and 9. Some, but not all, of these ligand arrangements are in accord with the Kepert model. For example, the coordination sphere in

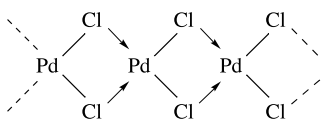
$[Cu(CN)_3]^{2-}$ is predicted by the Kepert model to be trigonal planar (**19.2**). Indeed, this is what is found experimentally. The other option in Table 19.4 is trigonal pyramidal, but this does not minimize interligand repulsions. One of the most important classes of structure for which the Kepert model does not predict the correct answer is that of the square planar complex, and here electronic effects are usually the controlling factor (see Section 20.3). Another factor that may lead to a breakdown of the Kepert model is the inherent constraint of a ligand. For example:

- the four nitrogen donor atoms of a porphyrin ligand (Fig. 12.10a) are confined to a square planar array;
- *tripodal ligands* such as **19.3** have limited flexibility which means that the donor atoms are not necessarily free to adopt the positions predicted by Kepert;
- macrocyclic ligands (see Section 11.8) are less flexible than open chain ligands.

(19.2)



e.g. X = CMe, N, P

(19.3)

A ***tripodal*** ligand (e.g. **19.3**) is one containing three arms, each with a donor atom, which radiate from a central atom or group; this central point may itself be a donor atom.

Coordination numbers in the solid state

In the remaining part of this section, we give a systematic outline of the occurrence of different coordination numbers and geometries in *solid state* *d*-block metal complexes. A general word of caution: molecular formulae can be misleading in terms of coordination number. For example in CdI_2 (Fig. 6.25), each Cd centre is octahedrally sited, and molecular halides or pseudohalides (e.g. $[CN]^-$) may contain M–X–M bridges and exist as oligomers, e.g. α-$PdCl_2$ is polymeric (**19.4**).

(19.4)

A further ambiguity arises when the bonding mode of a ligand can be described in more than one way. This often happens in organometallic chemistry, for example with cyclopentadienyl ligands as discussed in Chapter 23.

Coordination number 2

Examples of coordination number 2 are uncommon, being generally restricted to Cu(I), Ag(I), Au(I) and Hg(II), all d^{10} ions. Examples include $[CuCl_2]^-$, $[Ag(NH_3)_2]^+$, $[Au(CN)_2]^-$, $(R_3P)AuCl$, $[Au(PR_3)_2]^+$ (R = alkyl or aryl, Fig. 19.4a) and $Hg(CN)_2$, in each of which the metal centre is in a linear environment. However, in the solid state, the Cu(I) centre in $K[Cu(CN)_2]$ is 3-coordinate by virtue of cyanido-bridge formation (see structure **21.76**). Bulky amido ligands, e.g. $[N(SiR_3)_2]^-$, are often associated with *low* coordination numbers. For example, in $[Fe\{N(SiMePh_2)_2\}_2]$ ($\angle$N–Fe–N = 169°, Fig. 19.4b), the sterically demanding amido groups force a 2-coordinate environment on a metal centre that usually prefers to be surrounded by a greater number of ligands.

Coordination number 3

3-Coordinate complexes are not common. Usually, trigonal planar structures are observed, and examples involving d^{10} metal centres include:

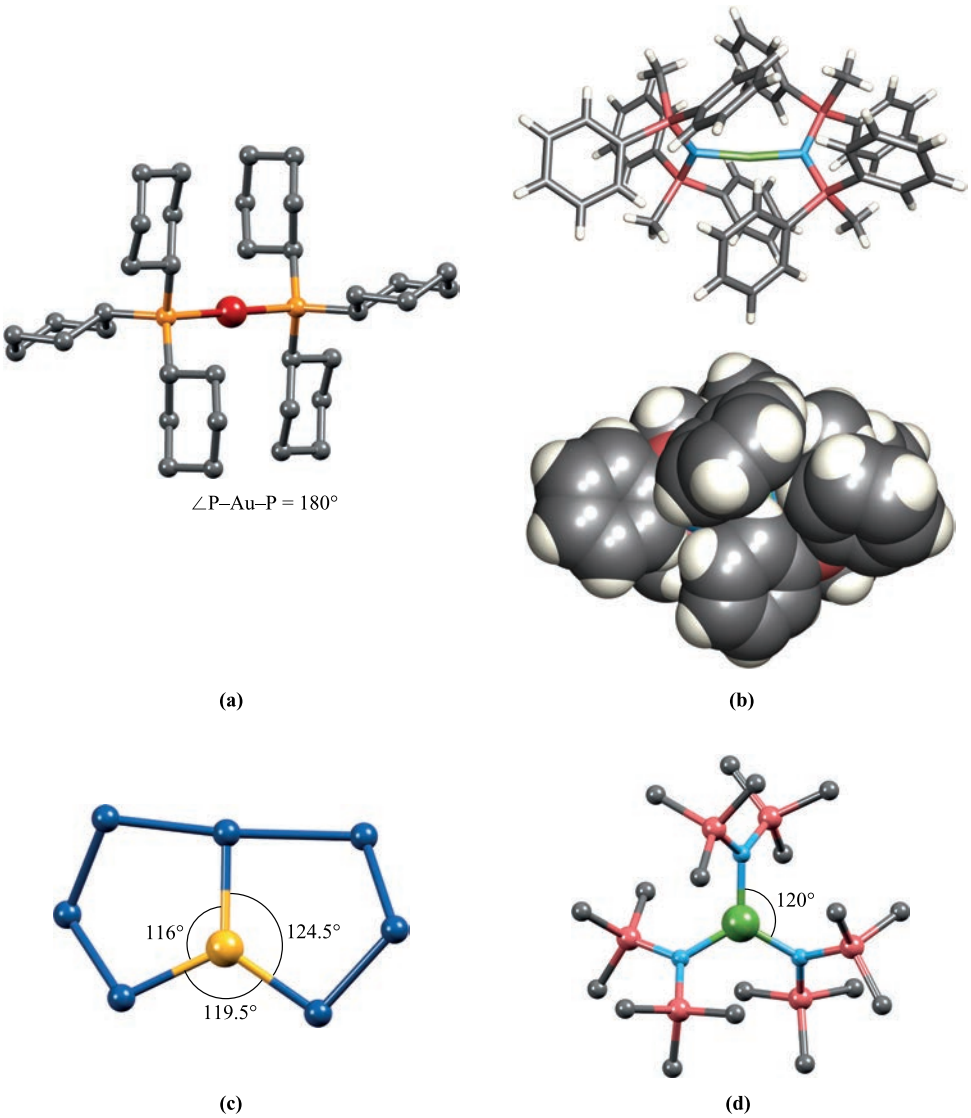
- Cu(I) in $[Cu(CN)_3]^{2-}$ (**19.2**), $[Cu(CN)_2]^-$ (see above), $[Cu(SPMe_3)_3]^+$;
- Ag(I) in $[AgTe_7]^{3-}$ (Fig. 19.4c), $[Ag(PPh_3)_3]^+$;
- Au(I) in $[Au\{PPh(C_6H_{11})_2\}_3]^+$;
- Hg(II) in $[HgI_3]^-$, $[Hg(SPh_3)_3]^-$;
- Pt(0) in $[Pt(PPh_3)_3]$, $[Pt(P^tBu_2H)_3]$.

Sterically demanding amido ligands have been used to stabilize complexes containing 3-coordinate metal ions, e.g. $[Fe\{N(SiMe_3)_2\}_3]$ (Fig. 19.4d). In the solid state, $[Y\{N(SiMe_3)_2\}_3]$ and $[Sc\{N(SiMe_3)_2\}_3]$ possess *trigonal pyramidal* metal centres ($\angle$N–Y–N = 115° and $\angle$N–Sc–N = 115.5°), but it is likely that crystal packing effects cause the deviation from planarity. The fact that in the gas phase $[Sc\{N(SiMe_3)_2\}_3]$ contains a trigonal planar Sc(III) centre supports this proposal.

p-Block chemistry has a number of examples of T-shaped molecules (e.g. ClF_3) in which stereochemically active lone pairs play a crucial role. *d*-Block metal complexes do not mimic this behaviour, although ligand constraints (e.g. the bite angle of a chelate) may distort a 3-coordinate structure away from the expected trigonal planar structure.

Coordination number 4

4-Coordinate complexes are extremely common, with a tetrahedral arrangement of donor atoms being the most frequently observed. The tetrahedron is sometimes 'flattened', distortions being attributed to steric or crystal packing effects or, in some cases, electronic effects. Tetrahedral complexes for d^3 ions are rarely, if ever, encountered. Complex **19.5** exemplifies the stabilization of 4-coordinate Cr^{3+} (d^3) using a tripodal ligand. This coordination geometry is enforced by



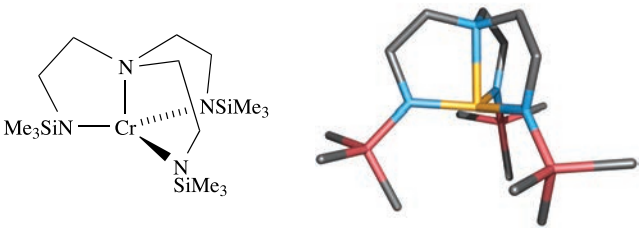


Fig. 19.4. Examples of 2- and 3-coordinate structures (X-ray diffraction data): (a) $[Au\{P(cyclo\text{-}C_6H_{11})_3\}_2]^+$ in the chloride salt [J.A. Muir *et al.* (1985) *Acta Crystallogr., Sect. C*, vol. 41, p. 1174], (b) stick and space-filling representations of the 2-coordinate iron(II) complex $[Fe\{N(SiMePh_2)_2\}_2]$ [R.A. Bartlett *et al.* (1987) *J. Am. Chem. Soc.*, vol. 109, p. 7563], (c) $[AgTe_7]^{3-}$ in the salt $[Et_4N][Ph_4P]_2[AgTe_7]$ [J.M. McConnachie *et al.* (1993) *Inorg. Chem.*, vol. 32, p. 3201], and (d) $[Fe\{N(SiMe_3)_2\}_3]$ [M.B. Hursthouse *et al.* (1972) *J. Chem. Soc., Dalton Trans.*, p. 2100]. Hydrogen atoms are omitted for clarity; colour code: Au, red; Ag, yellow; Fe, green; C, grey; P, orange; Te, dark blue; Si, pink; N, light blue.

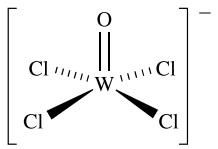
the ligand, and the Cr–N distances in the 'trigonal plane' are shorter (188 pm) than the axial distance (224 pm).

(19.5)

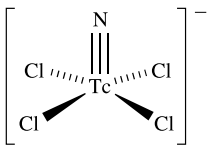
Tetrahedral complexes for d^4 ions have been stabilized only with bulky amido ligands, e.g. $[M(NPh_2)_4]$ and $[M\{N(SiMe_3)_2\}_3Cl]$ for M = Hf or Zr. Simple tetrahedral species include:

- d^0: $[VO_4]^{3-}$, $[CrO_4]^{2-}$, $[MoS_4]^{2-}$, $[WS_4]^{2-}$, $[MnO_4]^-$, $[TcO_4]^-$, RuO_4, OsO_4;
- d^1: $[MnO_4]^{2-}$, $[TcO_4]^{2-}$, $[ReO_4]^{2-}$, $[RuO_4]^-$;
- d^2: $[FeO_4]^{2-}$, $[RuO_4]^{2-}$;
- d^5: $[FeCl_4]^-$, $[MnCl_4]^{2-}$;
- d^6: $[FeCl_4]^{2-}$, $[FeI_4]^{2-}$;
- d^7: $[CoCl_4]^{2-}$;
- d^8: $[NiCl_4]^{2-}$, $[NiBr_4]^{2-}$;
- d^9: $[CuCl_4]^{2-}$ (distorted);
- d^{10}: $[ZnCl_4]^{2-}$, $[HgBr_4]^{2-}$, $[CdCl_4]^{2-}$, $[Zn(OH)_4]^{2-}$, $[Cu(CN)_4]^{3-}$, $[Ni(CO)_4]$.



The solid state structures of salts of apparently simple anions may in fact be polymeric (e.g. the presence of fluoride bridges in $[CoF_4]^{2-}$ and $[NiF_4]^{2-}$ leads to a layered structure with octahedral metal centres) or may be cation-dependent (e.g. discrete tetrahedral $[MnCl_4]^{2-}$ ions are present in the Cs^+ and $[Me_4N]^+$ salts, but a polymeric structure with Mn−Cl−Mn bridges is adopted by the Na^+ salt).

Square planar complexes are rarer than tetrahedral, and are often associated with d^8 configurations where electronic factors strongly favour a square planar arrangement (see Section 20.3), e.g. $[PdCl_4]^{2-}$, $[PtCl_4]^{2-}$, $[AuCl_4]^-$, $[AuBr_4]^-$, $[RhCl(PPh_3)_3]$ and *trans*-$[IrCl(CO)(PPh_3)_2]$. The classification of distorted structures such as those in $[Ir(PMePh_2)_4]^+$ and $[Rh(PMe_2Ph)_4]^+$ (Fig. 19.5a) may be ambiguous, but in this case, the fact that each metal ion is d^8 suggests that steric crowding causes deviation from a square planar arrangement (not from a tetrahedral one). The $[Co(CN)_4]^{2-}$ ion is a rare example of a square planar d^7 complex.



Coordination number 5

The limiting structures for 5-coordination are the trigonal bipyramid and square-based pyramid. In practice, many structures lie between these two extremes, the energy difference between trigonal bipyramidal and square-based pyramidal structures usually being small (see Section 4.8). Among simple 5-coordinate complexes are trigonal bipyramidal $[CdCl_5]^{3-}$, $[HgCl_5]^{3-}$ and $[CuCl_5]^{3-}$ (d^{10}) and a series of square-based pyramidal oxido- or nitrido-complexes in which the oxido or nitrido ligand occupies the axial site:

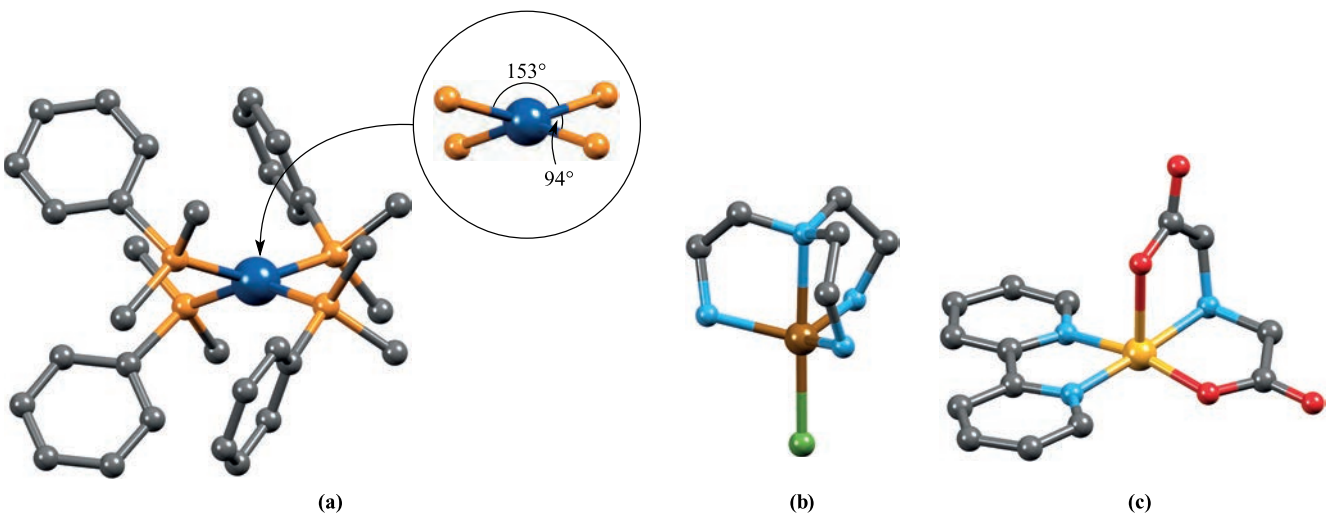
- d^0: $[NbCl_4(O)]^-$;
- d^1: $[V(acac)_2(O)]$, $[WCl_4(O)]^-$ (**19.6**), $[TcCl_4(N)]^-$ (**19.7**), $[TcBr_4(N)]^-$;
- d^2: $[TcCl_4(O)]^-$, $[ReCl_4(O)]^-$.

(19.6)

(19.7)

The formulae of some complexes may misleadingly suggest '5-coordinate' metal centres: e.g. Cs_3CoCl_5 is actually $Cs_3[CoCl_4]Cl$.

5-Coordinate structures are found for many compounds with polydentate amine, phosphane or arsane ligands. Of particular interest among these are complexes containing tripodal ligands (**19.3**) in which the central atom is a donor atom. This makes the ligand ideally suited to occupy one axial and the three equatorial sites of a trigonal bipyramidal complex as in $[CoBr\{N(CH_2CH_2NMe_2)_3\}]^+$, $[Rh(SH)\{P(CH_2CH_2PPh_2)_3\}]$ and $[Zn\{N(CH_2CH_2NH_2)_3\}Cl]^+$ (Fig. 19.5b). On the other hand, the conformational constraints of the ligands may result in a preference for a square-based pyramidal complex in the solid state, e.g. $[Cu(bpy)\{NH(CH_2CO_2)_2\}]\cdot 6H_2O$ (Fig. 19.5c).



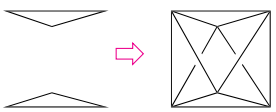


Fig. 19.5. Examples of 4- and 5-coordinate structures (X-ray diffraction data): (a) in $[Rh(PMe_2Ph)_4]^+$, the steric demands of the ligands distort the structure from the square planar structure expected for this d^8 metal centre [J.H. Reibenspies *et al.* (1993) *Acta Crystallogr., Sect. C*, vol. 49, p. 141], (b) $[Zn\{N(CH_2CH_2NH_2)_3\}Cl]^+$ in the $[Ph_4B]^-$ salt [R.J. Sime *et al.* (1971) *Inorg. Chem.*, vol. 10, p. 537], and (c) $[Cu(bpy)\{NH(CH_2CO_2)_2\}]$, crystallized as the hexahydrate [R.E. Marsh *et al.* (1995) *Acta Crystallogr., Sect. B*, vol. 51, p. 300]. Hydrogen atoms are omitted for clarity; colour code: Rh, dark blue; P, orange; Zn, brown; Cl, green; N, light blue; Cu, yellow; O, red; C, grey.

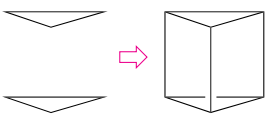
Coordination number 6

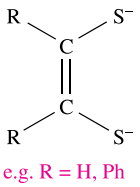
For many years after Werner's proof from stereochemical studies that many 6-coordinate complexes of chromium and cobalt had octahedral structures (see Box 21.6), it was believed that no other form of 6-coordination occurred. A vast amount of data from X-ray diffraction studies seemed to support this. Eventually, however, examples of trigonal prismatic coordination were confirmed.



The regular or nearly regular octahedral coordination sphere is found for all electronic configurations from d^0 to d^{10}, e.g. $[TiF_6]^{2-}$ (d^0), $[Ti(OH_2)_6]^{3+}$ (d^1), $[V(OH_2)_6]^{3+}$ (d^2), $[Cr(OH_2)_6]^{3+}$ (d^3), $[Mn(OH_2)_6]^{3+}$ (d^4), $[Fe(OH_2)_6]^{3+}$ (d^5), $[Fe(OH_2)_6]^{2+}$ (d^6), $[Co(OH_2)_6]^{2+}$ (d^7), $[Ni(OH_2)_6]^{2+}$ (d^8), $[Cu(NO_2)_6]^{4-}$ (d^9) and $[Zn(OH_2)_6]^{2+}$ (d^{10}). There are distinctions between what are termed *low-spin* and *high-spin* complexes (see Section 20.1): where the distinction is meaningful, the examples listed above are high-spin complexes, but many octahedral low-spin complexes are also known, e.g. $[Mn(CN)_6]^{3-}$ (d^4), $[Fe(CN)_6]^{3-}$ (d^5), $[Co(CN)_6]^{3-}$ (d^6). Octahedral complexes of d^4 and d^9 metal ions tend to be *tetragonally distorted*, i.e. they are elongated or squashed. This is an electronic effect called *Jahn–Teller distortion* (see Section 20.3).

While the vast majority of 6-coordinate complexes containing simple ligands are octahedral, there is a small group of d^0 or d^1 metal complexes in which the metal centre is in a trigonal prismatic or distorted trigonal prismatic environment. The octahedron and trigonal prism are closely related, and can be described in terms of two triangles which are staggered (**19.8**) or eclipsed (**19.9**).

octahedron

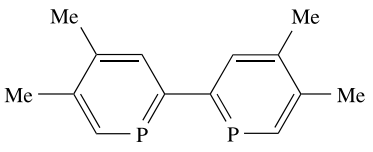


(19.8)

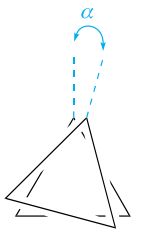
trigonal prism

(19.9)

The complexes $[ReMe_6]$ (d^1), $[TaMe_6]^-$ (d^0) and $[ZrMe_6]^{2-}$ (d^0) contain regular trigonal prismatic (D_{3h}) metal centres, while in $[MoMe_6]$ (d^0), $[WMe_6]$ (d^0, Fig. 19.6a), $[NbMe_6]^-$ (d^0) and $[TaPh_6]^-$ (d^0) the coordination environment is distorted trigonal prismatic (C_{3v}). The common feature of the ligands in these complexes is that they are σ-donors, with no π-donating or π-accepting properties. In $[Li(TMEDA)]_2[Zr(SC_6H_4\text{-}4\text{-}Me)_6]$ (TMEDA = $Me_2NCH_2CH_2NMe_2$), the $[Zr(SC_6H_4\text{-}4\text{-}Me)_6]^{2-}$ ion also has a distorted trigonal prismatic structure. Although thiolate ligands are usually weak π-donor ligands, it has been suggested that the cation–anion interactions in crystalline $[Li(TMEDA)]_2[Zr(SC_6H_4\text{-}4\text{-}Me)_6]$ result in the RS^- ligands behaving only as σ-donors. Another related group of trigonal prismatic d^0, d^1 or d^2 metal complexes contains the dithiolate ligands, **19.10**, and includes $[Mo(S_2C_2H_2)_3]$ and $[Re(S_2C_2Ph_2)_3]$ (Fig. 19.6b). We return to σ-donor and π-donor ligands in Section 20.4, and to the question of octahedral versus trigonal prismatic complexes in Box 20.3.



e.g. R = H, Ph



(19.10)

Fig. 19.6. The trigonal prismatic structures of (a) $[WMe_6]$ [V. Pfennig *et al.* (1996) *Science*, vol. 271, p. 626] and (b) $[Re(S_2C_2Ph_2)_3]$, only the *ipso*-C atoms of each Ph ring are shown [R. Eisenberg *et al.* (1966) *Inorg. Chem.*, vol. 5, p. 411]. Hydrogen atoms are omitted from (b); colour code: W, red; Re, green; C, grey; S, yellow; H, white.

The complexes $[WL_3]$, $[TiL_3]^{2-}$, $[ZrL_3]^{2-}$ and $[HfL_3]^{2-}$ (L is **19.11**) also possess trigonal prismatic structures. For a regular trigonal prism, angle α in **19.12** is 0° and this is observed for $[TiL_3]^{2-}$ and $[HfL_3]^{2-}$. In $[ZrL_3]^{2-}$, $\alpha = 3°$, and in $[WL_3]$, $\alpha = 15°$. Formally, $[WL_3]$ contains W(0) and is a d^6 complex, while $[ML_3]^{2-}$ (M = Ti, Zr, Hf) contains the metal in a −2 oxidation state. However, theoretical results for $[WL_3]$ indicate that negative charge is transferred on to the ligands. In the extreme case, the ligands can be formulated as L^{2-} and the metal as a d^0 centre.†

(19.11)

(19.12)

† For a detailed discussion, see: P. Rosa, N. Mézailles, L. Ricard, F. Mathey and P. Le Floch (2000) *Angew. Chem. Int. Ed.*, vol. 39, p. 1823 and references in this paper.

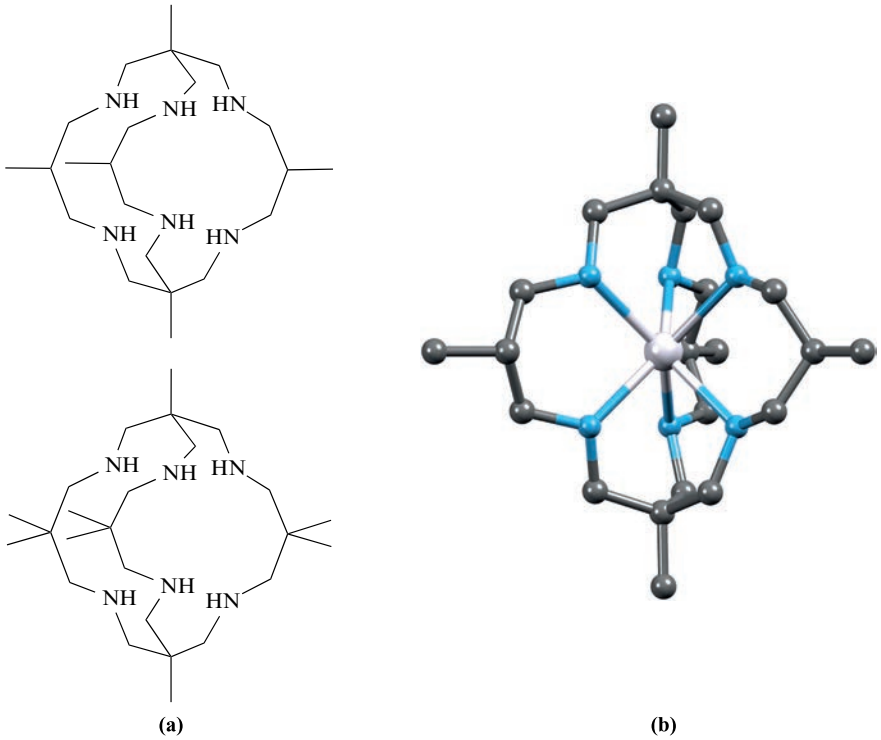


Fig. 19.7. (a) Structures of two bicyclic hexamine cage-ligands. (b) The top ligand in (a), L, coordinates Cd^{2+} in a trigonal prismatic coordination environment as shown in the structure of $[CdL][PF_6]_2 \cdot 2H_2O$ [A.M.T. Bygott *et al.* (2007) *Dalton Trans.*, p. 4778]; H atoms are omitted. Colour code: Cd, silver; C, grey; N, blue.

The bicyclic hexamines shown in Fig. 19.7a are highly pre-organized towards trigonal prismatic coordination. However, they also have some degree of flexibility arising from restricted rotation about the C−C and C−N bonds which can place the *N*-donor atoms in either a trigonal prismatic or octahedral arrangement. With Cd^{2+} or Hg^{2+} ions (d^{10}), trigonal prismatic complexes are formed (Fig. 19.7b), while Zn^{2+} (d^{10}) resides in a distorted octahedral coordination environment. Since Cd−N and Hg−N bonds are longer (≈239–244 pm) than Zn−N bonds (≈220–226 pm), the conformation of the cage-ligands has to change to accommodate the first versus second or third row d^{10} ions.[†]

The solid state structures of $[Mn(acac)_2(bpy)]$ (trigonal prismatic, Fig. 19.8a) and $[Mn(acac)_2(phen)]$ (octahedral, Fig. 19.8b) provide an example in which crystal packing forces appear to dictate the difference in ligand arrangement. The energy difference between the two structures is calculated to be very small, and the preference for a trigonal prism in $[Mn(acac)_2(bpy)]$ is observed only in the solid state.

Coordination number 7

High coordination numbers (≥7) are observed most frequently for ions of the early second and third row *d*-block metals and for the lanthanoids and actinoids, i.e. r_{cation} must be relatively large (see Chapter 27). Figure 19.9a shows the arrangement of the donor atoms for the three idealized 7-coordinate structures. In the capped trigonal prism, the 'cap' is over one of the square faces of the prism. In reality,

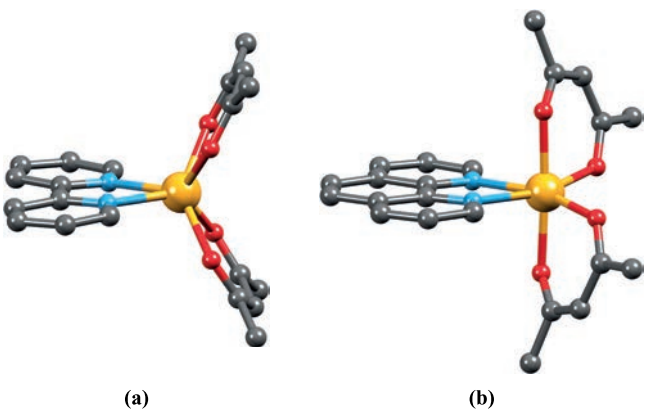

Fig. 19.8. The solid state structures of (a) $[Mn(acac)_2(bpy)]$ (trigonal prismatic) [R. van Gorkum *et al.* (2005) *Eur. J. Inorg. Chem.*, p. 2255] and (b) $[Mn(acac)_2(phen)]$ (octahedral) [F.S. Stephens (1977) *Acta Crystallogr., Sect. B*, vol. 33, p. 3492]. Hydrogen atoms have been omitted; colour code: Mn, yellow; N, blue; O, red; C, grey.

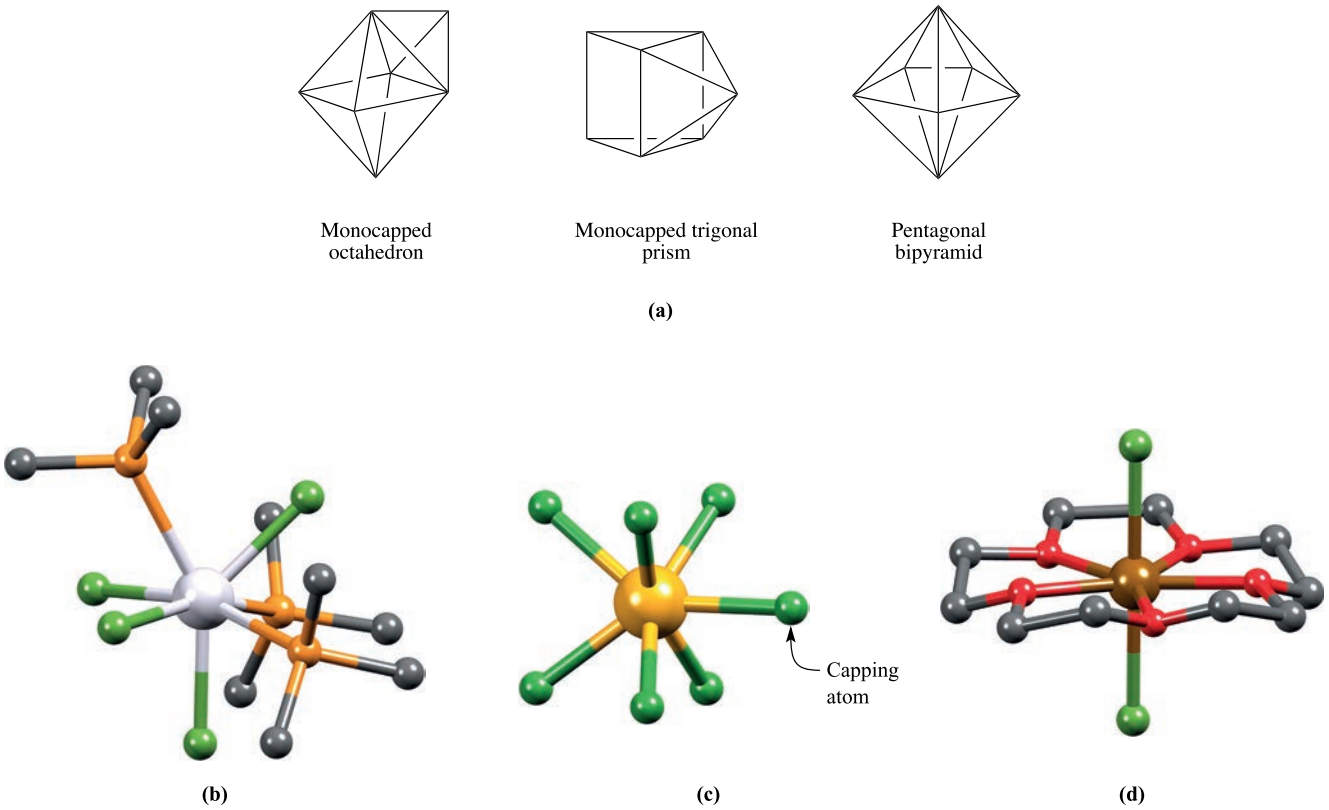
[†] These octahedral vs. trigonal prismatic preferences are discussed in detail in: A.M.T. Bygott, R.J. Geue, S.F. Ralph, A.M. Sargeson and A.C. Willis (2007) *Dalton Trans.*, p. 4778; L.J. Alcock, G. Cavigliasso, A.C. Willis, R. Sranger and S.F. Ralph (2016) *Dalton Trans.*, vol. 45, p. 9036.



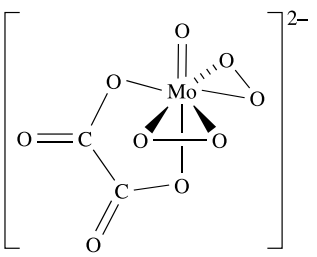


Fig. 19.9. (a) The coordination spheres defined by the donor atoms in idealized 7-coordinate structures. Examples of 7-coordinate complexes (X-ray diffraction data): (b) the capped octahedral structure of $[TaCl_4(PMe_3)_3]$ [F.A. Cotton *et al.* (1984) *Inorg. Chem.*, vol. 23, p. 4046]; (c) the capped trigonal prismatic $[ZrF_7]^{3-}$ in the guanidinium salt [A.V. Gerasimenko *et al.* (1985) *Koord. Khim.*, vol. 11, p. 566]; and (d) the pentagonal bipyramidal cation in $[ScCl_2(15\text{-crown-}5)]_2[CuCl_4]$ with the crown ether occupying the equatorial plane [N.R. Strel'tsova *et al.* (1992) *Zh. Neorg. Khim.*, vol. 37, p. 1822]. Hydrogen atoms have been omitted for clarity; colour code: Ta, silver; Cl, green; P, orange; Zr, yellow; F, green; Sc, brown; C, grey; O, red.

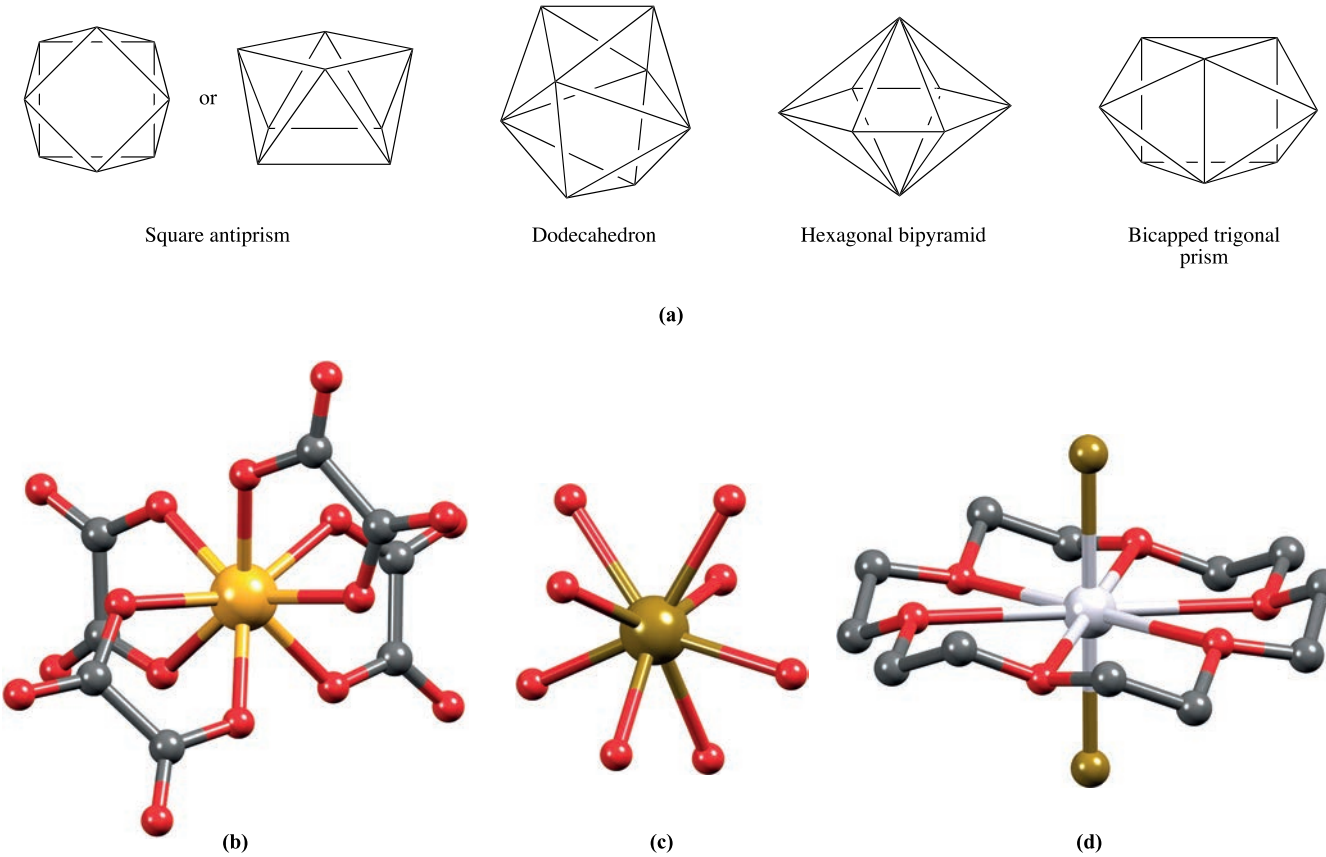
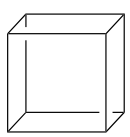
there is much distortion from these idealized structures, and this is apparent for the example of a capped octahedral complex shown in Fig. 19.9b. The anions in $[Li(OEt_2)]^+[MoMe_7]^-$ and $[Li(OEt_2)]^+[WMe_7]^-$ are further examples of capped octahedral structures. A problem in the chemical literature is that the distortions may lead to ambiguity in the way in which a given structure is described. Among binary metal halides and pseudohalides, 7-coordinate structures are exemplified by the pentagonal bipyramidal ions $[V(CN)_7]^{4-}$ (d^2) and $[NbF_7]^{3-}$ (d^1). In the ammonium salt, $[ZrF_7]^{3-}$ (d^0) is pentagonal bipyramidal, but in the guanidinium salt, it has a monocapped trigonal prismatic structure (Fig. 19.9c). Further examples of monocapped trigonal prismatic complexes are $[NbF_7]^{2-}$ and $[TaF_7]^{2-}$ (d^0). 7-Coordinate complexes containing oxido ligands may favour pentagonal bipyramidal structures with the oxido group in an axial site, e.g. $[Nb(O)(ox)_3]^{3-}$, $[Nb(O)(OH_2)_2(ox)_2]^-$ and $[Mo(O)(O_2)_2(ox)]^{2-}$ (all d^0). In this last example, two peroxido ligands are present, each in an η^2 mode (**19.13**). (The η-terminology is used to show the number of atoms in the ligand that interact directly with a metal centre; it is used widely in organometallic chemistry and is explained in Box 23.1.) Macrocyclic ligands containing five donor atoms (e.g. 15-crown-5) may dictate that the coordination geometry is pentagonal bipyramidal as shown in Fig. 19.9d.

(19.13)

Coordination number 8

As the number of vertices in a polyhedron increases, so does the number of possible structures (Fig. 19.10a). Probably, the best-known 8-vertex polyhedron is the cube, (**19.14**), but this is hardly ever observed as an arrangement of donor atoms in complexes. The few examples include the anions in the actinoid complexes $Na_3[PaF_8]$, $Na_3[UF_8]$ and





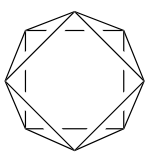


Fig. 19.10. (a) The coordination spheres defined by the donor atoms in idealized 8-coordinate structures. The left-hand drawing of the square antiprism emphasizes that the two square faces are mutually staggered. Examples of 8-coordinate complexes (X-ray diffraction): (b) the square antiprismatic structure of $[Nb(ox)_4]^{4-}$ in the salt $K_2[H_3NCH_2CH_2NH_3][Nb(ox)_4]\cdot 4H_2O$ [F.A. Cotton *et al.* (1987) *Inorg. Chem.*, vol. 26, p. 2889]; (c) the dodecahedral ion $[Y(OH_2)_8]^{3+}$ in the salt $[Y(OH_2)_8]Cl_3\cdot$(15-crown-5) [R.D. Rogers *et al.* (1986) *Inorg. Chim. Acta*, vol. 116, p. 171]; and (d) $[CdBr_2$(18-crown-6)] with the macrocyclic ligand occupying the equatorial plane of a hexagonal bipyramid [A. Hazell (1988) *Acta Crystallogr., Sect. C*, vol. 44, p. 88]. Hydrogen atoms have been omitted for clarity; colour code: Nb, yellow; O, red; Y, brown; Cd, silver; C, grey; Br, brown.

$[Et_4N]_4[U(NCS\text{-}N)_8]$. Steric hindrance between ligands can be reduced by converting a cubic into a square antiprismatic arrangement, i.e. on going from **19.14** to **19.15**.

Squares eclipsed

(19.14)

Squares staggered

(19.15)

Square antiprismatic coordination environments occur in $[Zr(acac)_4]$ (d^0) and in the anions in the salts $Na_3[TaF_8]$ (d^0), $K_2[ReF_8]$ (d^1) and $K_2[H_3NCH_2CH_2NH_3][Nb(ox)_4]$ (d^1) (Fig. 19.10b). Specifying the counter-ion is important since the energy difference between 8-coordinate structures tends to be small with the result that the preference between two structures may be altered by crystal packing forces in two different salts. Examples are seen in a range of salts of $[Mo(CN)_8]^{3-}$, $[W(CN)_8]^{3-}$, $[Mo(CN)_8]^{4-}$ or $[W(CN)_8]^{4-}$ which possess square antiprismatic or dodecahedral structures depending on the cation. Further examples of dodecahedral complexes include $[Y(OH_2)_8]^{3+}$ (Fig. 19.10c) and a number of complexes with bidentate ligands: $[Mo(O_2)_4]^{2-}$ (d^0), $[Ti(NO_3)_4]$ (d^0), $[Cr(O_2)_4]^{3-}$ (d^1), $[Mn(NO_3)_4]^{2-}$ (d^5) and $[Fe(NO_3)_4]^{-}$ (d^5).

The hexagonal bipyramid is a rare coordination environment, but may be favoured in complexes containing a hexadentate macrocyclic ligand, for example $[CdBr_2$(18-crown-6)], Fig. 19.10d. A bicapped trigonal prism is another option for 8-coordination, but is only rarely observed, e.g. in $[ZrF_8]^{4-}$ (d^0) and $[La(acac)_3(OH_2)_2]\cdot H_2O$ (d^0).

Coordination number 9

The anions $[ReH_9]^{2-}$ and $[TcH_9]^{2-}$ (both d^0) provide examples of 9-coordinate species in which the metal centre is in a tricapped trigonal prismatic environment (see Fig. 10.15c). A coordination number of 9 is most

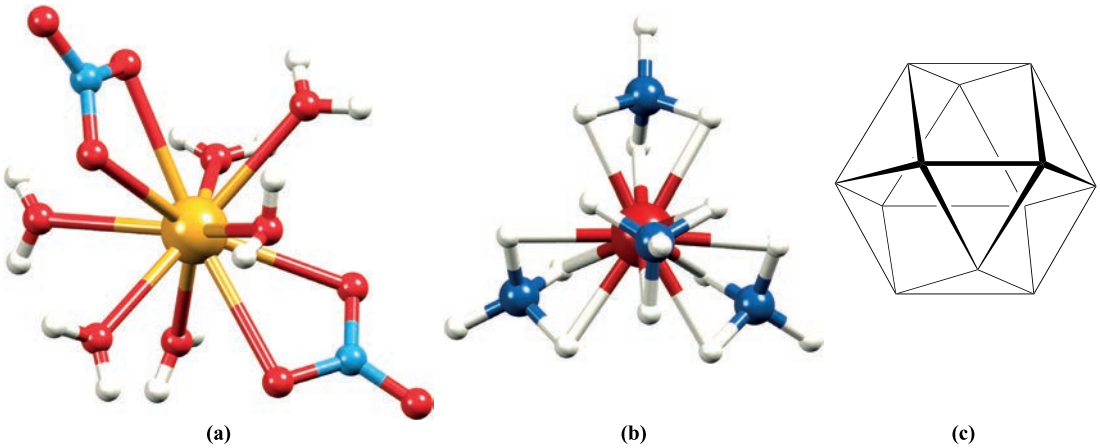

Fig. 19.11. (a) The structure (X-ray diffraction) of the $[La(NO_3\text{-}O,O')_2(OH_2)_6]^+$ cation in the nitrate salt [J.C. Barnes (2006) Private communication to the CSD]. Colour code: La, yellow; O, red; N, blue; H, white. (b) The structure of $[Hf(BH_4)_4]$ determined by neutron diffraction at low temperature [R.W. Broach *et al.* (1983) *Inorg. Chem.*, vol. 22, p. 1081]. Colour code: Hf, red; B, blue; H, white. (c) The 12-vertex cubeoctahedral coordination sphere of the Hf(IV) centre in $[Hf(BH_4)_4]$.

often associated with yttrium, lanthanum and the *f*-block elements. The tricapped trigonal prism is the only *regular* arrangement of donor atoms yet observed, e.g. in $[Sc(OH_2)_9]^{3+}$, $[Y(OH_2)_9]^{3+}$ and $[La(OH_2)_9]^{3+}$.

Coordination numbers of 10 and above

It is always dangerous to draw conclusions on the basis of the non-existence of structure types, but, from data available at the present time, it seems that a coordination of ≥ 10 is generally confined to the *f*-block metal ions (see Chapter 27). Lanthanum exhibits coordination numbers of 10 and 12, e.g. in $[La(NO_3\text{-}O,O')_2(OH_2)_6]^+$ (Fig. 19.11a) and $[La(NO_3\text{-}O,O')_6]^{3-}$. In both complexes, the nitrate ions are bidentate, as indicated by the nomenclature in the formulae. However, although La is in group 3, it is usually classed with the lanthanoid, rather than *d*-block, metals. Within the *d*-block, complexes containing $[BH_4]^-$ and related ligands provide rare examples of coordination numbers >9. For example, in $[Hf(BH_4)_4]$ and $[Zr(MeBH_3)_4]$ the ligands are tridentate (see structure **13.9**) and the metal centres are 12-coordinate. Figures 19.11b and c show the structure of $[Hf(BH_4)_4]$ and the cubeoctahedral arrangement of the 12 hydrogen atoms around the metal centre. The same coordination environment is found in $[Zr(MeBH_3)_4]$.

19.8 Isomerism in *d*-block metal complexes

In this book so far, most references to isomerism have been to *trans*- and *cis*-isomers, e.g. *trans*-$[CaI_2(THF)_4]$ (Section 12.5) and the *trans*- and *cis*-isomers of N_2F_2 (Section 15.7). These are *diastereoisomers* (see Section 2.9).

Stereoisomers possess the same connectivity of atoms, but differ in the spatial arrangement of atoms or groups. Examples include *trans*- and *cis*-isomers, and *mer*- and *fac*-isomers. If the stereoisomers are *not* mirror images of one another, they are called ***diastereoisomers***. Stereoisomers that *are* mirror images of one another are called ***enantiomers***.

Self-study exercises

All the answers can be found by reading Section 2.9.

1. Draw possible structures for the square planar complexes $[PtBr_2(NH_3)_2]$ and $[PtCl_3(PEt_3)]^-$ and give names to distinguish between any isomers that you have drawn.
2. In $[Ru(CO)_4(PPh_3)]$, the Ru centre is in a trigonal bipyramidal environment. Draw the structures of possible isomers and give names to distinguish between them.
3. Draw the structures and name the isomers of octahedral $[CrCl_2(NH_3)_4]^+$.
4. Octahedral $[RhCl_3(OH_2)_3]$ has two isomers. Draw their structures and give them distinguishing names.

Figure 19.12 classifies the types of isomers exhibited by coordination complexes. In the rest of this section, we introduce *structural* (or *constitutional*) *isomerism*, followed by a discussion of *enantiomers*.

Structural isomerism: ionization isomers

Ionization isomers result from the interchange of an anionic ligand within the first coordination sphere with an anion outside the coordination sphere.

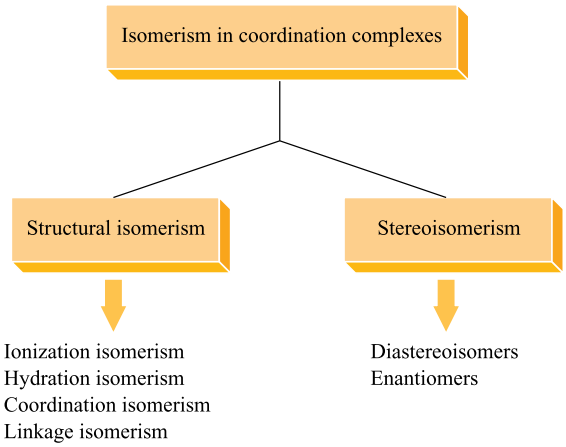

Fig. 19.12. Classification of types of isomerism in metal complexes.

Examples of ionization isomers are violet $[Co(NH_3)_5Br][SO_4]$ (prepared by reaction scheme 19.6) and red $[Co(NH_3)_5(SO_4)]Br$ (prepared by reaction sequence 19.7). These isomers can be readily distinguished by appropriate qualitative tests for *ionic* sulfate or bromide, respectively (eqs. 19.8 and 19.9). The isomers are also easily distinguished by IR spectroscopy. The free $[SO_4]^{2-}$ ion belongs to the T_d point group. The two T_2 vibrational modes are IR active (see Fig. 3.16) and strong absorptions are observed at $1104\,cm^{-1}$ (stretch) and $613\,cm^{-1}$ (deformation). In $[Co(NH_3)_5(SO_4)]Br$, the sulfate ion acts as a monodentate ligand and the symmetry of the $[SO_4]^{2-}$ group is lowered with respect to the free ion. As a result, the IR spectrum of $[Co(NH_3)_5(SO_4)]Br$ shows three absorptions (1040, 1120 and $970\,cm^{-1}$) arising from stretching modes of the coordinated $[SO_4]^{2-}$ ligand.

$$CoBr_2 \xrightarrow{[NH_4]Br,\ NH_3,\ O_2} [Co(NH_3)_5(OH_2)]Br_3 \xrightarrow{\Delta} [Co(NH_3)_5Br]Br_2 \xrightarrow{Ag_2SO_4} [Co(NH_3)_5Br][SO_4] \quad (19.6)$$

$$[Co(NH_3)_5Br]Br_2 \xrightarrow{\text{conc } H_2SO_4} [Co(NH_3)_5(SO_4)][HSO_4] \xrightarrow{BaBr_2} [Co(NH_3)_5(SO_4)]Br \quad (19.7)$$

$$BaCl_2(aq) + [SO_4]^{2-}(aq) \longrightarrow \underset{\text{white ppt}}{BaSO_4(s)} + 2Cl^-(aq) \quad (19.8)$$

$$AgNO_3(aq) + Br^-(aq) \longrightarrow \underset{\text{pale yellow ppt}}{AgBr(s)} + [NO_3]^-(aq) \quad (19.9)$$

Structural isomerism: hydration isomers

Hydration isomers result from the interchange of H_2O and another ligand between the first coordination sphere and the ligands outside it.

The classic example of hydrate isomerism is that of the compound of formula $CrCl_3{\cdot}6H_2O$. Green crystals of chromium(III) chloride formed from a hot solution obtained by reducing chromium(VI) oxide with concentrated hydrochloric acid are $[Cr(OH_2)_4Cl_2]Cl{\cdot}2H_2O$. When this is dissolved in water, the chloride ions in the complex are slowly replaced by water to give blue-green $[Cr(OH_2)_5Cl]Cl_2{\cdot}H_2O$ and finally violet $[Cr(OH_2)_6]Cl_3$. The complexes can be distinguished by precipitation of the *free* chloride ion using aqueous silver nitrate (eq. 19.10).

$$AgNO_3(aq) + Cl^-(aq) \longrightarrow \underset{\text{white ppt}}{AgCl(s)} + [NO_3]^-(aq) \quad (19.10)$$

Structural isomerism: coordination isomerism

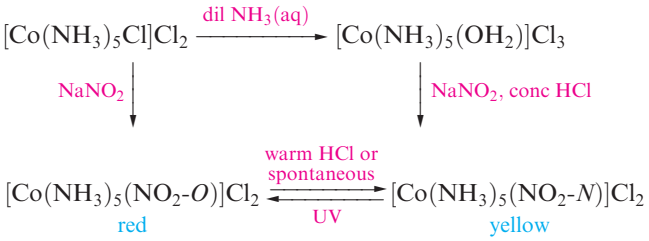
Coordination isomers are possible only for salts in which both cation and anion are complex ions. The isomers arise from interchange of ligands between the two metal centres.

Examples of coordination isomers are:

- $[Co(NH_3)_6][Cr(CN)_6]$ and $[Cr(NH_3)_6][Co(CN)_6]$;
- $[Co(NH_3)_6][Co(NO_2)_6]$ and $[Co(NH_3)_4(NO_2)_2][Co(NH_3)_2(NO_2)_4]$;
- $[Pt^{II}(NH_3)_4][Pt^{IV}Cl_6]$ and $[Pt^{IV}(NH_3)_4Cl_2][Pt^{II}Cl_4]$.

Structural isomerism: linkage isomerism

Linkage isomers may arise when one or more of the ligands can coordinate to the metal ion in more than one way, e.g. in $[SCN]^-$ (**19.16**), both the N and S atoms are potential donor sites. Such a ligand is ***ambidentate***. In a ligand such as $[SCN]^-$, the prefix κ is used in the name of the coordinated ligand to show which is the donor atom, e.g. thiocyanato-κ*N* versus thiocyanato-κ*S*.

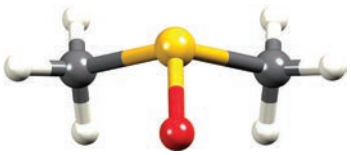


$$\left[S{=}C{=}N\right]^-$$

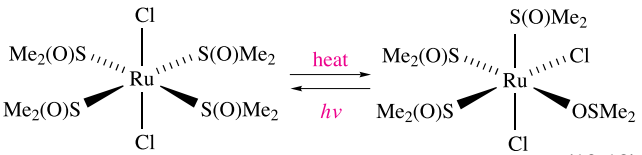
(19.16)

Because $[SCN]^-$ is ambidentate, the complex $[Co(NH_3)_5(NCS)]^{2+}$ has two isomers which are distinguished by using the following nomenclature:

- in $[Co(NH_3)_5(NCS\text{-}N)]^{2+}$, the thiocyanate ligand coordinates through the nitrogen donor atom;
- in $[Co(NH_3)_5(NCS\text{-}S)]^{2+}$, the thiocyanate ion is bonded to the metal centre through the sulfur atom.



Scheme 19.11 shows how linkage isomers of $[Co(NH_3)_5(NO_2)]^{2+}$ can be prepared.



(19.11)

In this example, the complexes $[Co(NH_3)_5(NO_2\text{-}O)]^{2+}$ and $[Co(NH_3)_5(NO_2\text{-}N)]^{2+}$ can be distinguished by using IR spectroscopy. For the *O*-bonded ligand, characteristic absorption bands at 1065 and 1470 cm^{-1} are observed, while for the *N*-bonded ligand, the corresponding vibrational wavenumbers are 1310 and 1430 cm^{-1}.

The DMSO ligand (dimethylsulfoxide, **19.17**) can coordinate to metal ions through either the *S*- or *O*-donor atom. These modes can be distinguished by using IR spectroscopy: $\bar{\nu}_{SO}$ for free DMSO is 1055 cm^{-1}, for *S*-bonded DMSO, $\bar{\nu}_{SO}$ = 1080–1150 cm^{-1}, and for *O*-bonded DMSO, $\bar{\nu}_{SO}$ = 890–950 cm^{-1}. An example of the interconversion of linkage isomers involving the DMSO ligand is shown in scheme 19.12. The isomerization also involves a *trans–cis* rearrangement of chlorido-ligands.

(19.17)

(19.12)

Stereoisomerism: diastereoisomers

Distinguishing between *cis*- and *trans*-isomers of a square planar complex or between *mer*- and *fac*-isomers of an octahedral complex is most unambiguously confirmed by structural determinations using single-crystal X-ray diffraction. Vibrational spectroscopy (applications of which were introduced in Section 3.7) may also be of assistance. For example, Fig. 19.13 illustrates that the asymmetric stretch for the $PtCl_2$ unit in $[Pt(NH_3)_2Cl_2]$ is IR active for both the *trans*- and *cis*-isomers, but the symmetric stretch is IR active only for the *cis*-isomer. In square planar complexes containing phosphane ligands, the ^{31}P NMR spectrum may be particularly diagnostic, as is illustrated in Box 19.1.

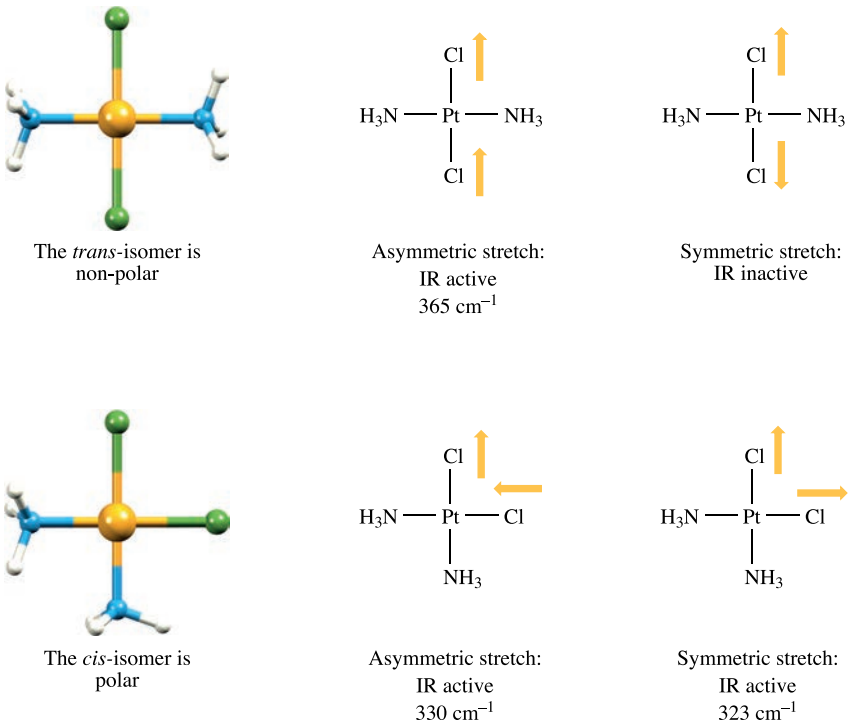


Fig. 19.13. The *trans*- and *cis*-isomers of the square planar complex $[PtCl_2(NH_3)_2]$ can be distinguished by IR spectroscopy. The selection rule for an IR active vibration is that it must lead to a *change in molecular dipole moment* (see Section 3.7).

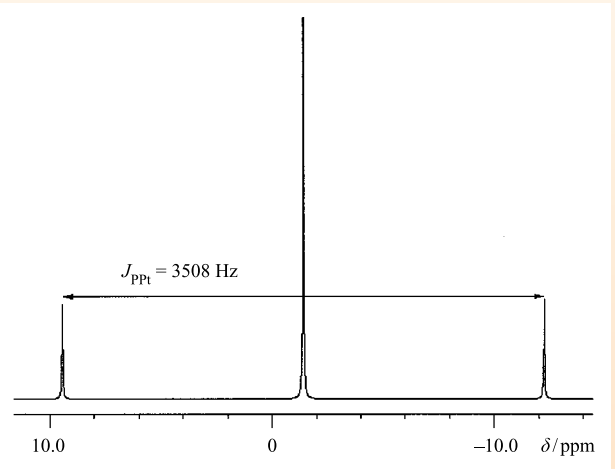


THEORY

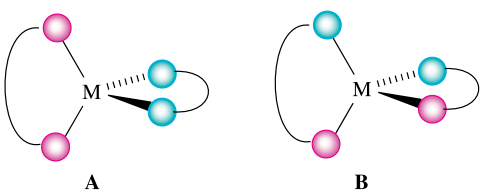
Box 19.1 *Trans*- and *cis*-isomers of square planar complexes: an NMR spectroscopic probe

In Section 4.8, we described how *satellite peaks* may arise in some NMR spectra. In square planar platinum(II) complexes containing two phosphane (PR_3) ligands, the ^{31}P NMR spectrum of the complex provides valuable information about the *cis*- or *trans*-arrangement of the ligands. Platinum possesses six naturally occurring isotopes (Appendix 5) but only one, ^{195}Pt, is NMR active. ^{195}Pt is 33.8% abundant and has a nuclear spin quantum number of value $I = \frac{1}{2}$. In a ^{31}P NMR spectrum of a complex such as $[PtCl_2(PPh_3)_2]$, there is spin–spin coupling between the ^{31}P and ^{195}Pt nuclei which gives rise to satellite peaks.

If the PR_3 ligands are mutually *trans*, the value of $J_{PPt} \approx 2000$–2500 Hz, but if the ligands are *cis*, the coupling constant is much larger, ≈3000–3500 Hz. While the values vary somewhat, comparison of the ^{31}P NMR spectra of *cis*- and *trans*-isomers of a given complex enables the isomers to be assigned. For example, for *cis*- and *trans*-$[PtCl_2(P^nBu_3)_2]$, values of J_{PPt} are 3508 and 2380 Hz, respectively. The figure on the right shows a 162 MHz ^{31}P NMR spectrum of *cis*-$[PtCl_2(P^nBu_3)_2]$, simulated using experimental data; (the chemical shift reference is 85% aqueous H_3PO_4).

Similar diagnostic information can be obtained from NMR spectroscopy for square planar complexes containing metal centres with spin-active isotopes. For example, rhodium is *monotopic* (i.e. 100% of one isotope) with ^{103}Rh having $I = \frac{1}{2}$. In square planar rhodium(I) complexes containing two phosphane ligands, values of J_{PRh} are ≈160–190 Hz for a *cis*-arrangement and ≈70–90 Hz for a *trans*-arrangement. Thus, the ^{31}P NMR spectrum of a complex of the type $[RhCl(PR_3)_2L]$ (L = neutral ligand) exhibits a *doublet* with a J_{PRh} coupling constant characteristic of a particular isomer.

The existence of ions or molecules in different structures (e.g. trigonal bipyramidal and square-based pyramidal $[Ni(CN)_5]^{3-}$) is just a special case of diastereoisomerism. In the cases of, for example, tetrahedral and square planar $[NiBr_2(PBzPh_2)_2]$ (Bz = benzyl), the two forms can be distinguished by the fact that they exhibit different magnetic properties as we discuss in Section 20.10. To complicate matters, square planar $[NiBr_2(PBzPh_2)_2]$ may exist as either *trans*- or *cis*-isomers.



Stereoisomerism: enantiomers

A pair of ***enantiomers*** consists of two molecular species which are non-superposable mirror images of each other; see also Section 3.8.

The occurrence of enantiomers (optical isomerism) is concerned with *chirality*, and some important terms relating to chiral complexes are defined in Box 19.2. Enantiomers of a coordination compound most often occur when chelating ligands are involved. Figure 19.14a shows $[Cr(acac)_3]$, an octahedral *tris-chelate* complex, and Fig. 19.14b shows *cis*-$[Co(en)_2Cl_2]^+$, an octahedral *bis-chelate* complex. In this case, only the *cis*-isomer possesses enantiomers; the *trans*-isomer is achiral. Enantiomers are distinguished by using the labels Δ and Λ (see Box 19.2).

Self-study exercises

1. Explain why *cis*-$[Co(en)_2Cl_2]^+$ is chiral while *trans*-$[Co(en)_2Cl_2]^+$ is achiral.
2. A chiral molecule lacks an inversion centre and a plane of symmetry. Use these criteria to show that species belonging to the C_2 and D_3 point groups are chiral. [*Hint*: see Appendix 3.]
3. The diagrams below represent two tetrahedral, bis-chelate complexes. Explain in terms of symmetry elements why **A** is achiral, but **B** is chiral. Draw the structure of the other enantiomer of **B**.

A **B**

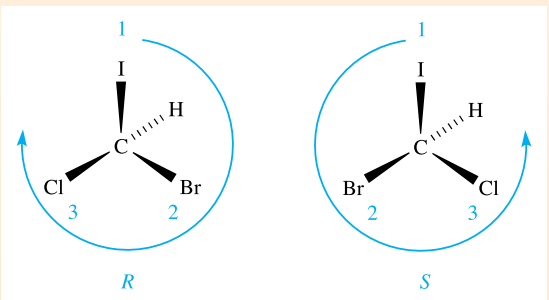
Chiral molecules rotate the plane of polarized light (Fig. 19.15). This property is known as *optical activity*. Enantiomers rotate the light to equal extents, but in opposite

THEORY

Box 19.2 Definitions and notation for chiral complexes

Chirality was introduced in Section 3.8. Here, we collect together some terms that are frequently encountered in discussing optically active complexes.

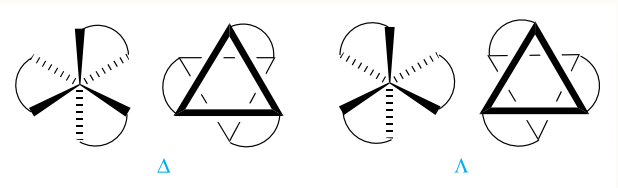
Enantiomers are a pair of stereoisomers that are non-superposable mirror images.



Diastereoisomers are stereoisomers that are not enantiomers.

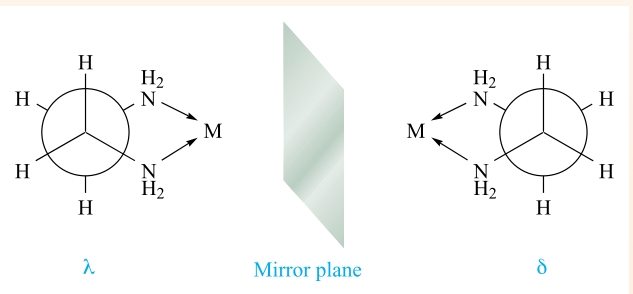
(+) and (−) prefixes: the specific rotation of enantiomers is equal and opposite, and a useful means of distinguishing between enantiomers is to denote the *sign* of $[\alpha]_D$. Thus, if two enantiomers of a compound A have $[\alpha]_D$ values of $+12^\circ$ and -12°, they are labelled (+)-A and (−)-A.

***d* and *l* prefixes**: sometimes (+) and (−) are denoted by *dextro*- and *laevo*- (derived from the Latin for right and left) and these refer to right- and left-handed rotation of the plane of polarized light respectively; *dextro* and *laevo* are generally abbreviated to *d* and *l*.

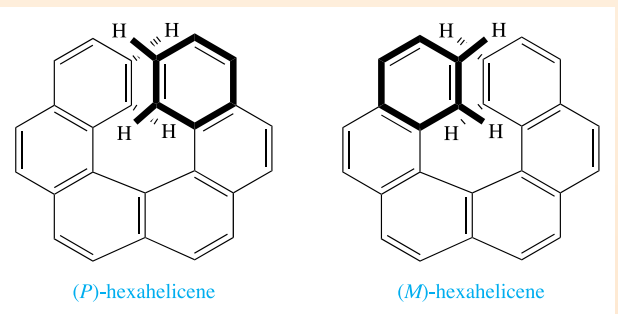


The +/− or *d*/*l* notation is not a direct descriptor of the *absolute configuration* of an enantiomer (the arrangement of the substituents or ligands) for which the following prefixes are used.

***R* and *S* prefixes**: the convention for labelling chiral carbon atoms (tetrahedral with four different groups attached) uses *sequence rules* (also called the Cahn–Ingold–Prelog notation). The four groups attached to the chiral carbon atom are prioritized according to the atomic number of the attached atoms, highest priority being assigned to highest atomic number, and the molecule then viewed down the C−X vector, where X has the lowest priority. The *R*- and *S*-labels for the enantiomers refer to a clockwise (*rectus*) and anticlockwise (*sinister*) sequence of the prioritized atoms, working from high to low. Example: CHClBrI, view down the C−H bond:



This notation is used for chiral organic ligands, and also for tetrahedral complexes.



Δ and Λ prefixes: enantiomers of octahedral complexes containing three equivalent bidentate ligands (tris-chelate complexes) are among those that are distinguished using Δ (delta) and Λ (lambda) prefixes. The octahedron is viewed down a 3-fold axis, and the chelates then define either a right- or a left-handed helix. The enantiomer with right-handedness is labelled Δ, and that with left-handedness is Λ.

δ and λ prefixes: the situation with chelating ligands is often more complicated than the previous paragraph suggests. Consider the chelation of 1,2-diaminoethane to a metal centre. The 5-membered ring so formed is not planar but adopts an envelope conformation. This is most easily seen by taking a Newman projection along the C−C bond of the ligand. Two enantiomers are possible and are distinguished by the prefixes δ and λ.

***P* and *M* descriptors:** a helical, propeller or screw-shaped structure (e.g. S_n has a helical chain) can be right- or left-handed and is termed *P* ('plus') or *M* ('minus'), respectively. This is illustrated with (*P*)- and (*M*)-hexahelicene:

For detailed information, see:

IUPAC Nomenclature of Inorganic Chemistry (*Recommendations 2005*), senior eds N.G. Connelly and T. Damhus, RSC Publishing, Cambridge, p. 189.

Basic terminology of stereochemistry: *IUPAC Recommendations 1996* (1996) *Pure Appl. Chem.*, vol. 68, p. 2193.

A. von Zelewsky (1996) *Stereochemistry of Coordination Compounds*, Wiley, Chichester.

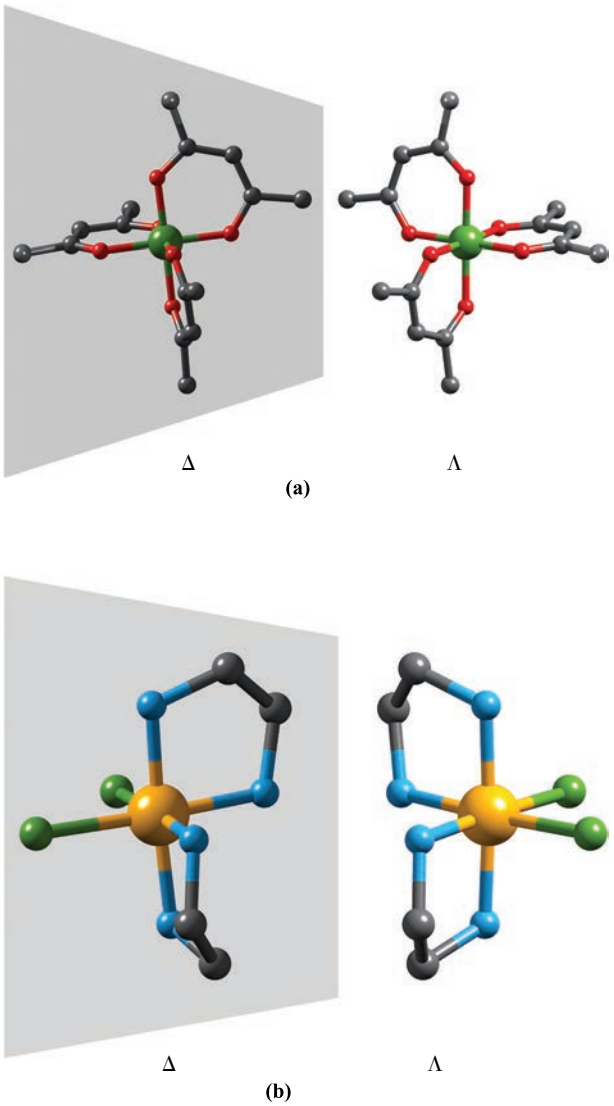


Fig. 19.14. The complexes (a) $[Cr(acac)_3]$ and (b) *cis*-$[Co(en)_2Cl_2]^+$ are chiral. The two enantiomers are non-superposable mirror images of one another. Hydrogen atoms are omitted from the diagrams for clarity. Colour code: Cr, green; Co yellow; Cl, green; N, blue; O, red; C, grey.

directions, the dextrorotatory (*d*) enantiomer to the right and the laevorotatory (*l*) enantiomer to the left. The amount of rotation *and* its sign depend upon the wavelength of the incident light. The observation of optical activity depends upon *chemical* properties of the chiral molecule. If the two enantiomers interconvert rapidly to give an equilibrium mixture containing equal amounts of the two forms, no overall rotation occurs. A mixture of equal amounts of two enantiomers is called a *racemate*.

The rotation, α, is measured in a *polarimeter* (Fig. 19.15). In practice, the amount of rotation depends upon the wavelength of the light, temperature and the concentration of compound present in solution. The *specific rotation*, $[\alpha]$, for a chiral compound in solution is given by eq. 19.13.

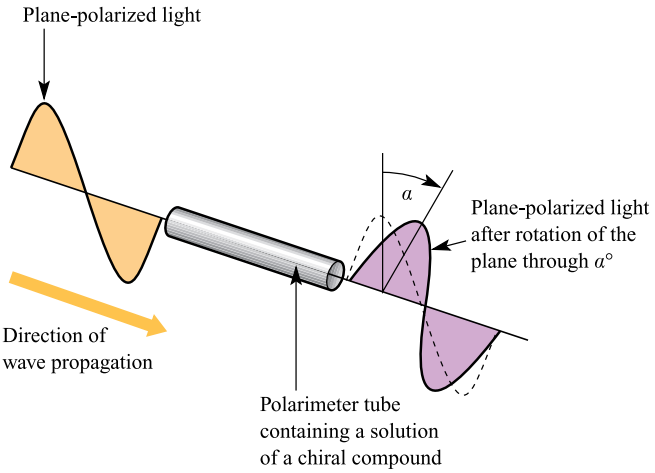

Fig. 19.15. One enantiomer of a chiral compound rotates the plane of linearly polarized light through a characteristic angle, α°; the instrument used to measure this rotation is called a polarimeter. The direction indicated (a clockwise rotation as you view the light as it emerges from the polarimeter) is designated as $+\alpha^\circ$. The other enantiomer of the same compound rotates the plane of polarized light through an angle $-\alpha^\circ$.

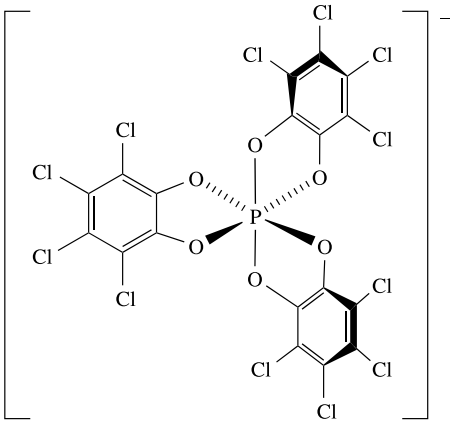
$$[\alpha] = \frac{\alpha}{c \times \ell} \qquad (19.13)$$

where: α = observed rotation

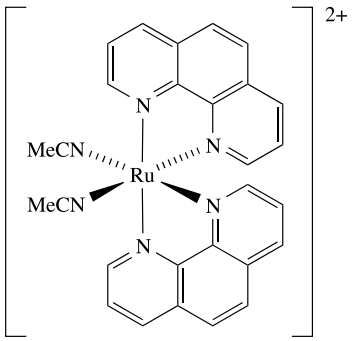
ℓ = path length of solution in polarimeter (in dm)



c = concentration (in g cm^{-3})

Light of a single frequency is used for specific rotation measurements and a common choice is the *sodium D-line* in the emission spectrum of atomic sodium. The specific rotation at this wavelength is denoted as $[\alpha]_D$.

Pairs of enantiomers such as Δ- and Λ-$[Cr(acac)_3]$ differ only in their action on polarized light. However, for ionic complexes such as $[Co(en)_3]^{3+}$, there is the opportunity to form salts with a chiral counter-ion A^-. These salts now contain two different types of chirality: the Δ- or Λ-chirality at the metal centre and the (+) or (−) chirality of the anion. Four combinations are possible of which the pair {Δ-(+)} and {Λ-(−)} is enantiomeric as is the pair {Δ-(−)} and {Λ-(+)}. However, with a given anion chirality, the pair of salts {Δ-(−)} and {Λ-(−)} are diastereoisomers (see Box 19.3) and may differ in the packing of the ions in the solid state, and separation by fractional crystallization is often possible.



Octahedral, phosphorus-containing anions (see p. 549) that are tris-chelates are chiral, and are used for resolving enantiomers and as NMR shift reagents.[†] We exemplify

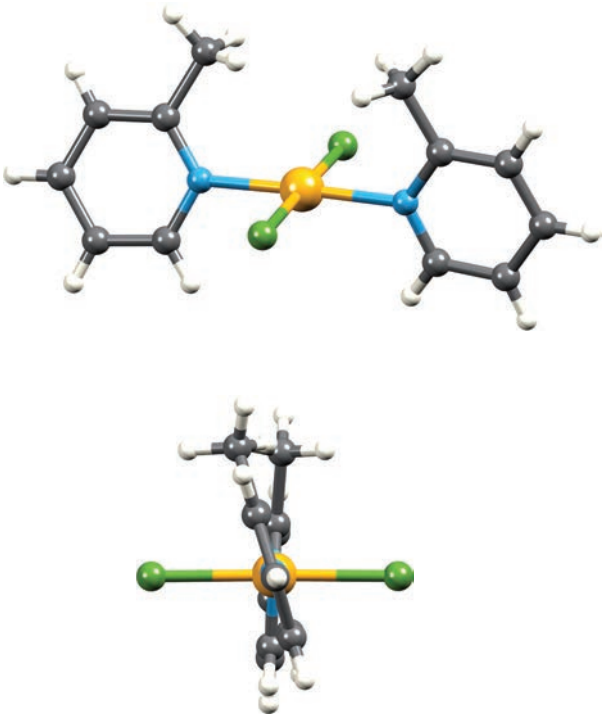
[†] For relevent reviews, see: J. Lacour and V. Hebbe-Viton (2003) *Chem. Soc. Rev.*, vol. 32, p. 373 – 'Recent developments in chiral anion mediated asymmetric chemistry'; J. Lacour (2010) *C. R. Chimie*, vol. 13, p. 985 – 'Chiral hexacoordinated phosphates: From pioneering studies to modern uses in stereochemistry'.

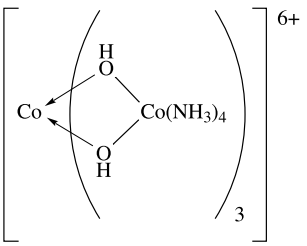
Δ-TRISPHAT

(19.18)

(19.19)

this with TRISPHAT (**19.18**). The presence of the electron-withdrawing substituents in TRISPHAT increases the configurational stability of the anion, i.e. the rate of interconversion of enantiomers is slow. Thus, salts of Δ- and Λ-TRISPHAT can be prepared enantiomerically pure. An example of its use is the resolution of the enantiomers of *cis*-$[Ru(phen)_2(NCMe)_2]^{2+}$ (**19.19**). This may conveniently be prepared as the $[CF_3SO_3]^-$ salt which is a racemate. Anion exchange using enantiomerically pure $[\Delta\text{-TRISPHAT}]^-$ gives a mixture of [Δ-**19.19**][Δ-TRISPHAT]$_2$ and [Λ-**19.19**][Δ-TRISPHAT]$_2$ which can be separated by chromatography. The salts [Δ-**19.19**][Δ-TRISPHAT]$_2$ and [Λ-**19.19**][Δ-TRISPHAT]$_2$ are diastereoisomers. When dissolved in non-coordinating or poorly solvating solvents, they form diastereoisomeric ion-pairs which can be distinguished in the ^{1}H NMR spectrum. For example, in CD_2Cl_2 solution, the signal for the methyl group of the MeCN ligands occurs at δ 2.21 ppm for [Δ-**19.19**][Δ-TRISPHAT]$_2$, and at δ 2.24 ppm for [Λ-**19.19**][Δ-TRISPHAT]$_2$. This illustrates the use of TRISPHAT as a *diamagnetic* NMR chiral shift reagent. We look at the use of *paramagnetic* NMR shift reagents in Box 27.3.





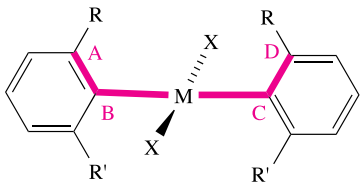


Fig. 19.16. Two views of the structure (X-ray diffraction) of *trans*-$[PdCl_2(2\text{-Mepy})_2]$ (2-Mepy = 2-methylpyridine) showing the square planar environment of the Pd(II) centre and the mutual twisting of the 2-methylpyridine ligands. The torsion angle between the rings is 18.6° [M.C. Biagini (1999) *J. Chem. Soc., Dalton Trans.*, p. 1575]. Colour code: Pd, yellow; N, blue; Cl, green; C, grey; H, white.

The first purely inorganic complex to be resolved into its enantiomers was $[CoL_3]^{6+}$ (**19.20**) in which each L^+ ligand is the complex *cis*-$[Co(NH_3)_4(OH)_2]^+$ which chelates through the two *O*-donor atoms.[†]

(19.20)

(19.21)

[†]For elucidation of a related species, see: W.G. Jackson, J.A. McKeon, M. Zehnder and M. Neuburger (2004) *Chem. Commun.*, p. 2322 – 'The rediscovery of Alfred Werner's second hexol'.

Chirality is not usually associated with square planar complexes but there are some special cases where chirality is introduced as a result of, for example, steric interactions between two ligands. In **19.21**, steric repulsions between the two R groups may cause the aromatic substituents to twist so that the plane of each C_6-ring is no longer orthogonal to the plane that defines the square planar environment around M. Such a twist is defined by the torsion angle A–B–C–D in structure **19.21**, and renders the molecule chiral. The chirality can be recognized in terms of a handedness, as in a helix, and the terms *P* and *M* (see Box 19.2) can be used to distinguish between related chiral molecules. If, in **19.21**, the sequence rules priority of R is higher than R' (e.g. R = Me, R' = H), then a positive torsion angle corresponds to *P*-chirality. An example is *trans*-$[PdCl_2(2\text{-Mepy})_2]$ (2-Mepy = 2-methylpyridine), for which the *P*-isomer is shown in Fig. 19.16. End-of-chapter problem 19.28 is concerned with the incorporation of chiral ligands into square planar platinum(II) complexes.

KEY TERMS

The following terms were introduced in this chapter. Do you know what they mean?

- ❑ *d*-block metal
- ❑ transition element
- ❑ platinum-group metal
- ❑ chromophore
- ❑ electroneutrality principle
- ❑ Kepert model
- ❑ tripodal ligand
- ❑ structural isomerism
- ❑ stereoisomerism
- ❑ ionization isomerism
- ❑ hydration isomerism
- ❑ linkage isomerism
- ❑ enantiomer
- ❑ diastereoisomer
- ❑ specific rotation
- ❑ racemate
- ❑ resolution of enantiomers

PROBLEMS

Ligand abbreviations: see Table 7.8.

19.1 Comment on (a) the observation of variable oxidation states among elements of the *s*- and *p*-blocks, and (b) the statement that 'variable oxidation states are a characteristic feature of any *d*-block metal'.

19.2 (a) Write down, in order, the metals that make up the first row of the *d*-block and give the ground state valence electronic configuration of each element. (b) Which triads of metals make up groups 4, 8 and 11 in the first three rows? (c) Which metals are collectively known as the platinum-group metals?

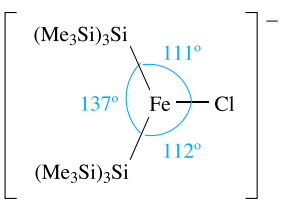
19.3 Comment on the reduction potential data in Table 19.1.

19.4 By referring to relevant sections earlier in the book, write a brief account of the formation of hydrides, borides, carbides and nitrides of the *d*-block metals.

19.5 Give a brief overview of properties that characterize a *d*-block metal.

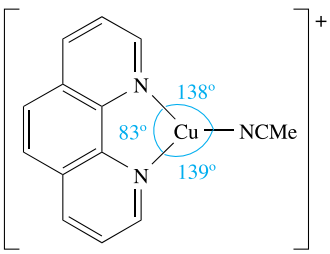
19.6 Suggest why (a) high coordination numbers are not usual for first row *d*-block metals, (b) in early *d*-block metal complexes the combination of a high oxidation state and high coordination number is common, and (c) in first row *d*-block metal complexes, high oxidation states are stabilized by fluorido or oxido ligands.

19.7 For each of the following complexes, give the oxidation state of the metal and its d^n configuration:



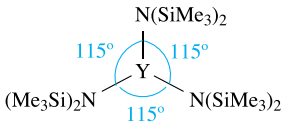
(a) $[Mn(CN)_6]^{4-}$; (b) $[FeCl_4]^{2-}$; (c) $[CoCl_3(py)_3]$; (d) $[ReO_4]^-$; (e) $[Ni(en)_3]^{2+}$; (f) $[Ti(OH_2)_6]^{3+}$; (g) $[VCl_6]^{3-}$; (h) $[Cr(acac)_3]$.

19.8 Within the Kepert model, what geometries do you associate with the following coordination numbers: (a) 2; (b) 3; (c) 4; (d) 5; (e) 6?



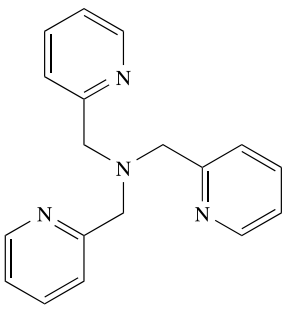
19.9 Show that the trigonal bipyramid, square-based pyramid, square antiprism and dodecahedron belong to the point groups D_{3h}, C_{4v}, D_{4d} and D_{2d} respectively.

19.10 (a) In the solid state, $Fe(CO)_5$ possesses a trigonal bipyramidal structure. How many carbon environments are there? (b) Explain why only one signal is observed in the ^{13}C NMR spectrum of solutions of $Fe(CO)_5$, even at low temperature.



19.11 Structures **19.22–19.24** show bond angle data (determined by X-ray diffraction) for some complexes with low coordination numbers. Comment on these data, suggesting reasons for deviations from regular geometries.

(19.22)



(19.23)

(19.24)

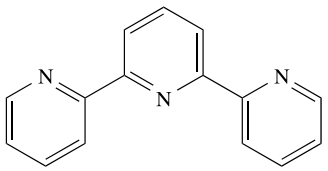
19.12 Suggest a structure for the complex $[CuCl(\mathbf{19.25})]^+$ assuming that all donor atoms are coordinated to the Cu(II) centre.

(19.25)

19.13 What chemical tests would you use to distinguish between (a) $[Co(NH_3)_5Br][SO_4]$ and $[Co(NH_3)_5(SO_4)]Br$, and (b) $[CrCl_2(OH_2)_4]Cl{\cdot}2H_2O$ and $[CrCl(OH_2)_5]Cl_2{\cdot}H_2O$? (c) What is the relationship between these pairs of compounds? (d) What isomers are possible for $[CrCl_2(OH_2)_4]^+$?

19.14 (a) Give formulae for compounds that are coordination isomers of $[Co(bpy)_3]^{3+}[Fe(CN)_6]^{3-}$. (b) What other types of isomerism could be exhibited by any of the complex ions given in your answer to part (a)?

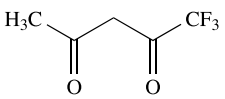
19.15 What isomers would you expect to exist for the platinum(II) compounds:



(a) $[Pt(H_2NCH_2CHMeNH_2)_2]Cl_2$, and
(b) $[Pt(H_2NCH_2CMe_2NH_2)(H_2NCH_2CPh_2NH_2)]Cl_2$?

19.16 How many different forms of $[Co(en)_3]^{3+}$ are possible in principle? Indicate how they are related as enantiomers or diastereoisomers.

19.17 State the types of isomerism that may be exhibited by the following complexes, and draw structures of the isomers: (a) $[Co(en)_2(ox)]^+$, (b) $[Cr(ox)_2(OH_2)_2]^-$, (c) $[PtCl_2(PPh_3)_2]$, (d) $[PtCl_2(Ph_2PCH_2CH_2PPh_2)]$ and (e) $[Co(en)(NH_3)_2Cl_2]^+$.



19.18 Using spectroscopic methods, how would you distinguish between the pairs of isomers (a) *cis*- and *trans*-$[PdCl_2(PPh_3)_2]$, (b) *cis*- and *trans*-$[PtCl_2(PPh_3)_2]$ and (c) *fac*- and *mer*-$[RhCl_3(PMe_3)_3]$?

19.19 Structure **19.26** shows the ligand tpy (2,2':6',2"-terpyridine). What conformational changes does the ligand undergo when it coordinates to a metal ion? Comment on possible isomer formation in the following complexes: (a) $[Ru(py)_3Cl_3]$, (b) $[Ru(bpy)_2Cl_2]^+$ and (c) $[Ru(tpy)Cl_3]$.

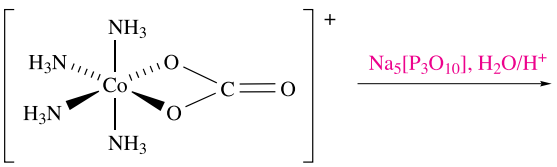
(19.26)

19.20 The conjugate base of **19.27** forms the complex $[CoL_3]$ which has *mer*- and *fac*-isomers. (a) Draw the structures of these isomers, and explain why the labels *mer* and *fac* are used. (b) What other type of isomerism does $[CoL_3]$ exhibit? (c) When a freshly prepared sample of $[CoL_3]$ is chromatographed, two fractions, **A** and **B**, are collected. The ^{19}F NMR spectrum of **A** exhibits a singlet, while that of **B** shows three signals with relative integrals of 1 : 1 : 1. Rationalize these data.

HL

(19.27)

19.21 The reaction of $[RuCl_2(PPh_3)(dppb)]$ with phen leads to the loss of PPh_3 and the formation of an octahedral complex, **X**. The structure of dppb is as follows:



dppb

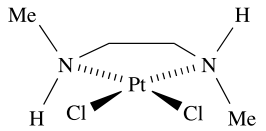
The solution $^{31}P\{^1H\}$ NMR spectrum of a freshly made sample of **X** shows a singlet at δ 33.2 ppm. The sample is left standing in the light for a few hours, after which time the $^{31}P\{^1H\}$ NMR spectrum is again recorded. The signal at δ 33.2 ppm has diminished in intensity, and two doublets at δ 44.7 and 32.4 ppm (relative integrals 1 : 1, each signal with $J = 31$ Hz) have appeared. Rationalize these data.

19.22 One isomer of $[PdBr_2(NH_3)_2]$ is unstable with respect to a second isomer, and the isomerization process can be followed by IR spectroscopy. The IR spectrum of the first isomer shows absorptions at 480 and 460 cm^{-1} assigned to ν(PdN) modes. During isomerization, the band at 460 cm^{-1} gradually disappears and that at 480 cm^{-1} shifts to 490 cm^{-1}. Rationalize these data.

19.23 Consider the following reaction in which $[P_3O_{10}]^{5-}$ (see Fig. 15.21) displaces the carbonate ion to give a mixture of linkage isomers:

(a) Suggest possible coordination modes for the $[P_3O_{10}]^{5-}$ ion in the products, given that an octahedral metal centre is retained. (b) How might the products formed in the reaction be influenced by the pH of the solution?

OVERVIEW PROBLEMS



19.24 (a) In each of the following complexes, determine the overall charge, *n*, which may be positive or negative: $[Fe^{II}(bpy)_3]^n$, $[Cr^{III}(ox)_3]^n$, $[Cr^{III}F_6]^n$, $[Ni^{II}(en)_3]^n$, $[Mn^{II}(ox)_2(OH_2)_2]^n$, $[Zn^{II}(py)_4]^n$, $[Co^{III}Cl_2(en)_2]^n$.

(b) If the bonding in $[MnO_4]^-$ were 100% ionic, what would be the charges on the Mn and O atoms? Is this model realistic? By applying Pauling's electroneutrality principle, redistribute the charge in $[MnO_4]^-$ so that Mn has a resultant charge of +1. What are the charges on each O atom? What does this charge distribution tell you about the degree of covalent character in the Mn–O bonds?

19.25 (a) Which of the following octahedral complexes are chiral: *cis*-$[CoCl_2(en)_2]^+$, $[Cr(ox)_3]^{3-}$, *trans*-$[PtCl_2(en)_2]^{2+}$, $[Ni(phen)_3]^{2+}$, $[RuBr_4(phen)]^-$, *cis*-$[RuCl(py)(phen)_2]^+$?

(b) The solution ^{31}P NMR spectrum of a mixture of isomers of the square planar complex $[Pd(SCN)_2(Ph_2PCH_2PPh_2)]$ shows one broad signal at 298 K. At 228 K, two singlets and two doublets ($J = 82$ Hz) are observed and the relative integrals of these signals are solvent-dependent. Draw the structures of the possible isomers of $[Pd(SCN)_2(Ph_2PCH_2PPh_2)]$ and rationalize the NMR spectroscopic data.

19.26 (a) Explain why complex **19.28** is chiral.

(19.28)

(b) In each of the following reactions, the left-hand sides are balanced. Suggest possible products and give the structures of each complex formed.

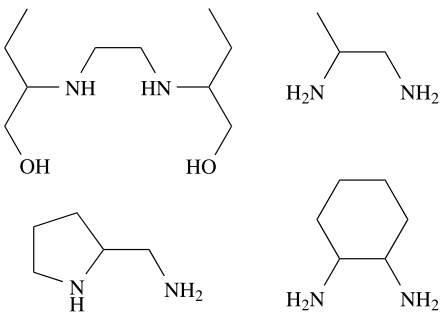
$$AgCl(s) + 2NH_3(aq) \longrightarrow$$

$$Zn(OH)_2(s) + 2KOH(aq) \longrightarrow$$

(c) What type of isomerism relates the Cr(III) complexes $[Cr(en)_3][Cr(ox)_3]$ and $[Cr(en)(ox)_2]$ $[Cr(en)_2(ox)]$?

19.27 (a) The following complexes each possess one of the structures listed in Table 19.4. Use the point group to deduce each structure: $[ZnCl_4]^{2-}$ (T_d); $[AgCl_3]^{2-}$ (D_{3h}); $[ZrF_7]^{3-}$ (C_{2v}); $[ReH_9]^{2-}$ (D_{3h}); $[PtCl_4]^{2-}$ (D_{4h}); $[AuCl_2]^-$ ($D_{\infty h}$).

(b) How does the coordination environment of Cs^+ in CsCl differ from that of typical, discrete 8-coordinate complexes? Give examples to illustrate the latter, commenting on factors that may influence the preference for a particular coordination geometry.



INORGANIC CHEMISTRY MATTERS

19.28 Interactions between DNA and metal complexes are the basis for the use of square planar platinum(II)-containing anti-cancer drugs. (a) Explain how the interaction of right-handed DNA with chiral complexes leads to diastereoisomeric species. (b) How does the replacement of the two NH_3 ligands in cisplatin (see below) by two $PhMeCHNH_2$ ligands affect the chirality of the complex?

cisplatin

(c) The bidentate ligands drawn opposite may be used to prepare analogues of cisplatin. Draw the structures of the complexes formed and indicate all asymmetric centres. For a given ligand, which pairs of complexes are related by being enantiomers or diastereoisomers?

20.1 Introduction

In this chapter, we discuss complexes of the *d*-block metals and consider bonding theories that rationalize experimental facts such as electronic spectra and magnetic properties. Most of the discussion centres on first row *d*-block metals, for which theories of bonding are most successful. The bonding in *d*-block metal complexes is not fundamentally different from that in other compounds, and we shall show applications of valence bond theory, the electrostatic model and molecular orbital theory.

Fundamental to discussions about *d*-block chemistry of the first three rows of elements are, respectively, the 3*d*, 4*d* or 5*d* orbitals. We introduced *d*-orbitals in Section 1.6, and showed that a *d*-orbital is characterized by having a value of the quantum number $l = 2$. The conventional representation of a set of five degenerate *d*-orbitals is shown in Fig. 20.1b.[†] The lobes of the d_{yz}, d_{xy} and d_{xz} orbitals point *between* the Cartesian axes and each orbital lies in one of the three planes defined by the axes. The $d_{x^2-y^2}$ orbital is related to d_{xy}, but the lobes of the $d_{x^2-y^2}$ orbital point *along* (rather than between) the x and y axes. We could envisage being able to draw two more atomic orbitals which are related to the $d_{x^2-y^2}$ orbital, i.e. the $d_{z^2-y^2}$ and $d_{z^2-x^2}$ orbitals (Fig. 20.1c). However, this would give a total of six *d*-orbitals. For $l = 2$, there are only five real solutions to the Schrödinger equation ($m_l = +2, +1, 0, -1, -2$). The problem is solved by taking a linear combination of the $d_{z^2-x^2}$ and $d_{z^2-y^2}$ orbitals. This means that the two orbitals are combined (Fig. 20.1c), with the result that the fifth real solution to the Schrödinger equation corresponds to what is traditionally labelled the d_{z^2} orbital (although this is actually shorthand notation for $d_{2z^2-y^2-x^2}$).

The fact that three of the five *d*-orbitals have their lobes directed *between* the Cartesian axes, while the other two are directed along these axes (Fig. 20.1b), is a key point in the understanding of bonding models for and physical properties of *d*-block metal complexes. As a consequence of there being a distinction in their directionalities, the *d* orbitals in the presence of ligands are split into groups of different energies, the type of splitting and the magnitude of the energy differences depending on the arrangement and nature of the ligands. Magnetic properties and electronic absorption spectra, both of which are observable properties, reflect the splitting of *d* orbitals.

High- and low-spin states

In Section 19.5, we stated that paramagnetism is a characteristic of some *d*-block metal compounds. In Section 20.10 we consider magnetic properties in detail, but for now, let us simply state that magnetic data allow us to determine the number of unpaired electrons. In an isolated first row *d*-block metal ion, the 3*d* orbitals are degenerate and the electrons occupy them according to Hund's rules: e.g. diagram **20.1** shows the arrangement of six electrons.

(20.1)

[†] Although we refer to the *d* orbitals in these 'pictorial' terms, it is important not to lose sight of the fact that these orbitals are *not real* but merely mathematical solutions of the Schrödinger wave equation (see Section 1.5).

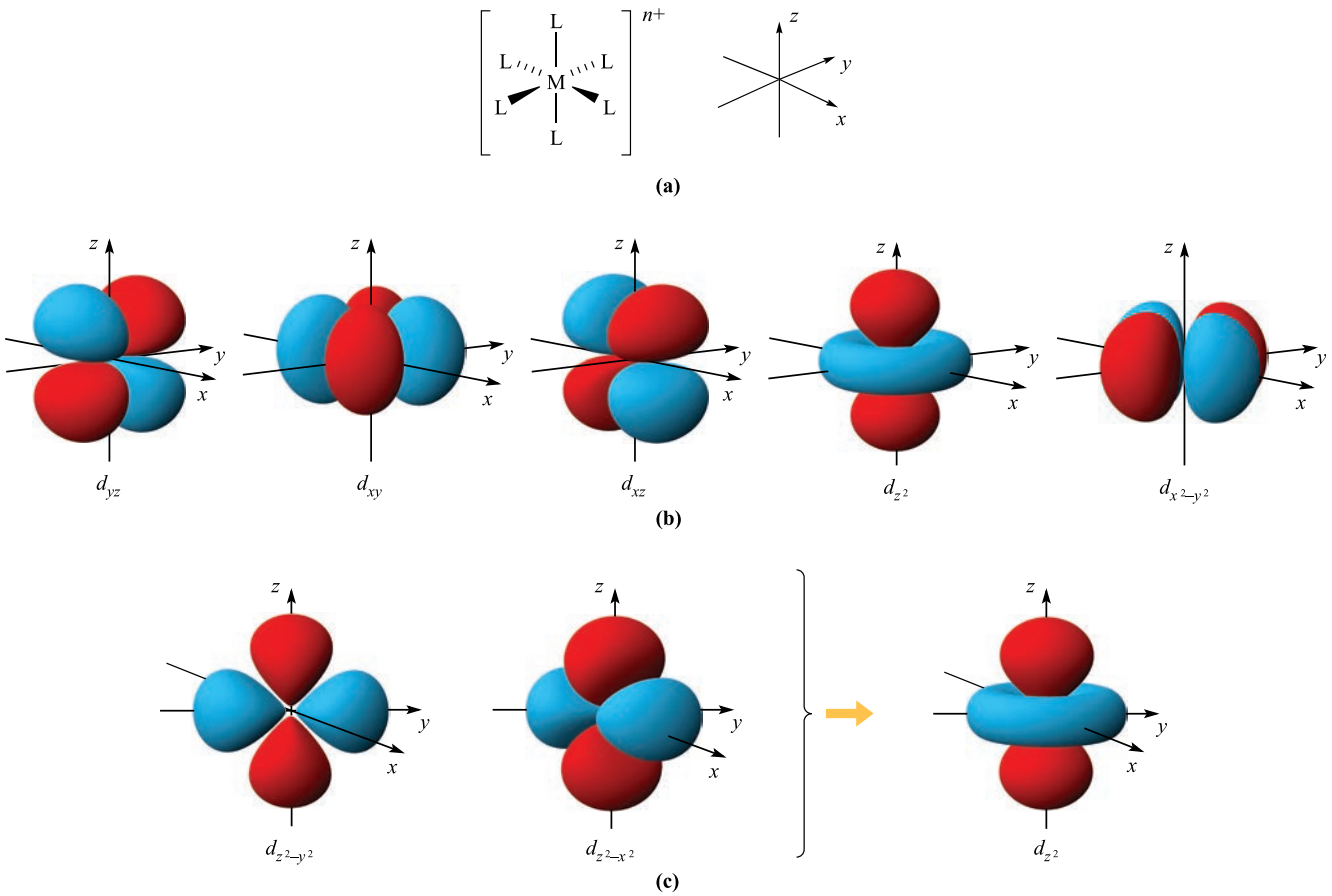

Fig. 20.1. (a) The six M–L vectors of an octahedral complex $[ML_6]^{n+}$ can be defined to lie along the x, y and z axes. (b) The five d orbitals; the d_{z^2} and $d_{x^2-y^2}$ atomic orbitals point directly along the axes, but the d_{xy}, d_{yz} and d_{xz} atomic orbitals point between them. (c) The formation of a d_{z^2} orbital from a linear combination of $d_{z^2-y^2}$ and $d_{z^2-x^2}$ orbitals. The orbitals have been generated using the program *Orbital Viewer* [David Manthey, www.orbitals.com/orb/index.html].

However, magnetic data for a range of octahedral d^6 *complexes* show that they fall into two categories: paramagnetic or diamagnetic. The former are called *high-spin complexes* and the diamagnetic d^6 complexes are termed *low-spin*. High- and low-spin complexes exist for octahedral d^4, d^5, d^6 and d^7 metal complexes. For a d^6 configuration, low-spin corresponds to a diamagnetic complex and high-spin to a paramagnetic one. For d^4, d^5 and d^7 configurations, both high- and low-spin complexes of a given configuration are paramagnetic, but with different numbers of unpaired electrons. We return to high- and low-spin complexes in Section 20.3, and discuss magnetic properties of *d*-block metal complexes in detail in Section 20.10.

20.2 Bonding in *d*-block metal complexes: valence bond theory

Hybridization schemes

Although VB theory (see Sections 2.1, 2.2 and 5.2) in the form developed by Pauling in the 1930s is not much used now in discussing *d*-block metal complexes, the terminology and many of the ideas have been retained and some knowledge of the theory remains useful. In Section 5.2, we described the use of sp^3d, sp^3d^2 and sp^2d hybridization schemes in trigonal pyramidal, square-based pyramidal, octahedral and square planar molecules. Applications of these hybridization schemes to describe the bonding in *d*-block metal complexes are given in Table 20.1. An *empty* hybrid orbital on the metal centre can accept a pair of electrons from a ligand to form a σ-bond. The choice of particular p or d atomic orbitals may depend on the definition of the axes with respect to the molecular framework, e.g. in linear ML_2, the M–L vectors are usually defined to lie along the z axis. We have included the cube in Table 20.1 only to point out the required use of an f orbital.

While Table 20.1 serves as a reference point, hybridization schemes for *d*-block metal coordination compounds are not commonly used now that modern MO approaches are widely accessible. The use of MO theory in octahedral complexes is described in Section 20.5.

Table 20.1 Hybridization schemes for the σ-bonding frameworks of different geometrical configurations of ligand donor atoms.

Coordination number	Arrangement of donor atoms	Orbitals hybridized*	Hybrid orbital description for σ-bonding	Example
2	Linear	s, p_z	sp	$[Ag(NH_3)_2]^+$
3	Trigonal planar	s, p_x, p_y	sp^2	$[HgI_3]^-$
4	Tetrahedral	s, p_x, p_y, p_z	sp^3	$[FeBr_4]^{2-}$
4	Square planar	s, p_x, p_y, $d_{x^2-y^2}$	sp^2d	$[Ni(CN)_4]^{2-}$
5	Trigonal bipyramidal	s, p_x, p_y, p_z, d_{z^2}	sp^3d	$[CuCl_5]^{3-}$
5	Square-based pyramidal	s, p_x, p_y, p_z, $d_{x^2-y^2}$	sp^3d	$[Ni(CN)_5]^{3-}$
6	Octahedral	s, p_x, p_y, p_z, d_{z^2}, $d_{x^2-y^2}$	sp^3d^2	$[Co(NH_3)_6]^{3+}$
6	Trigonal prismatic	s, d_{xy}, d_{yz}, d_{xz}, d_{z^2}, $d_{x^2-y^2}$ or s, p_x, p_y, p_z, d_{xz}, d_{yz}	sd^5 or sp^3d^2	$[ZrMe_6]^{2-}$
7	Pentagonal bipyramidal	s, p_x, p_y, p_z, d_{xy}, $d_{x^2-y^2}$, d_{z^2}	sp^3d^3	$[V(CN)_7]^{4-}$
7	Monocapped trigonal prismatic	s, p_x, p_y, p_z, d_{xy}, d_{xz}, d_{z^2}	sp^3d^3	$[NbF_7]^{2-}$
8	Cubic	s, p_x, p_y, p_z, d_{xy}, d_{xz}, d_{yz}, f_{xyz}	sp^3d^3f	$[PaF_8]^{3-}$
8	Dodecahedral	s, p_x, p_y, p_z, d_{z^2}, d_{xy}, d_{xz}, d_{yz}	sp^3d^4	$[Mo(CN)_8]^{4-}$
8	Square antiprismatic	s, p_x, p_y, p_z, d_{xy}, d_{xz}, d_{yz}, $d_{x^2-y^2}$	sp^3d^4	$[TaF_8]^{3-}$
9	Tricapped trigonal prismatic	s, p_x, p_y, p_z, d_{xy}, d_{xz}, d_{yz}, d_{z^2}, $d_{x^2-y^2}$	sp^3d^5	$[ReH_9]^{2-}$

* These are not unique orbital hybridization schemes. For example, the choice of $d_{x^2-y^2}$ as the d orbital in a square planar MX_4 arrangement follows only if the X atoms lie on the x and y axes.

20.3 Crystal field theory

Crystal field theory is an important approach to the bonding in coordination compounds of *d*-block metals. It is an *electrostatic model* and uses the electrons from the ligands to create an electric field around the metal centre. Ligands are considered as point charges and there are *no* metal–ligand covalent interactions.

Crystal field theory is an electrostatic model which predicts that the *d* orbitals in a metal complex are not degenerate. The pattern of splitting of the *d* orbitals depends on the crystal field, this being determined by the arrangement and type of ligands.

The octahedral crystal field

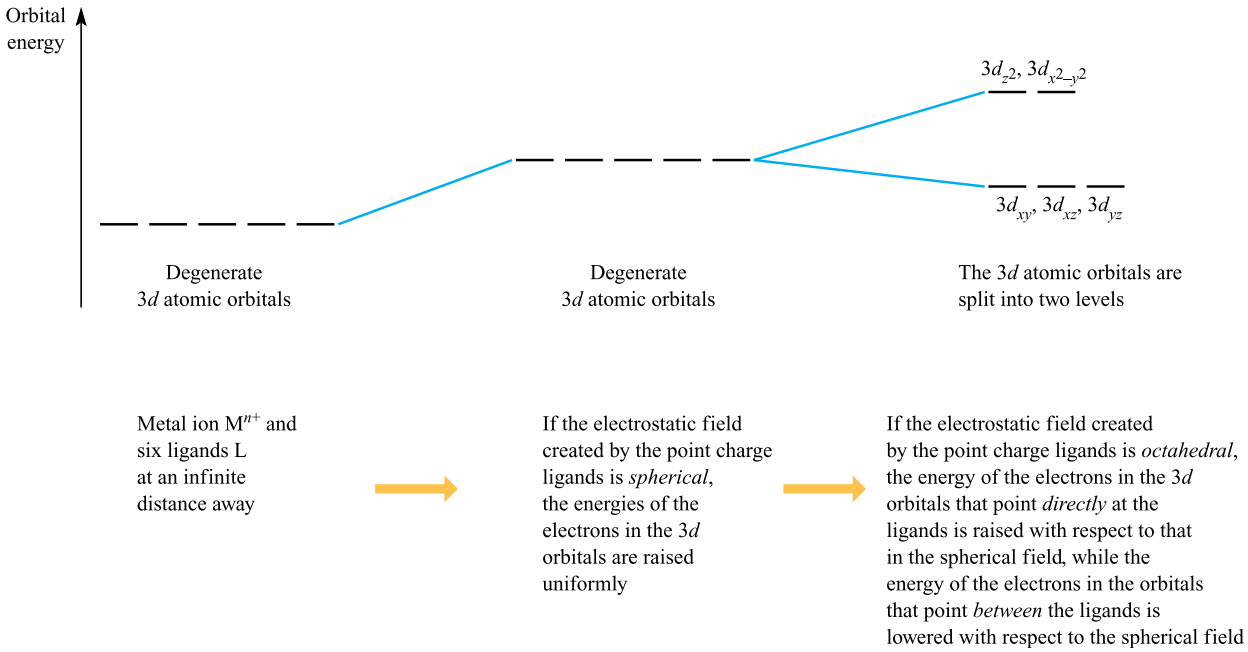
Consider a first row metal cation, M^{n+}, surrounded by six ligands placed on the Cartesian axes at the vertices of an octahedron (Fig. 20.1a). Each ligand is treated as a negative point charge and there is an electrostatic attraction between the metal ion and ligands. As the ligands approach the M^{n+} ion, the electrons in the *d* orbitals are *repelled* by the point charges (the ligands) and crystal field theory only considers these repulsive interactions. *If* the electrostatic field (the *crystal field*) were spherical, then the energies of the five *d* orbitals would be raised (destabilized) by the same amount (Fig. 20.2, left). However, since the d_{z^2} and $d_{x^2-y^2}$ atomic orbitals point *directly at* the ligands while the d_{xy}, d_{yz} and d_{xz} atomic orbitals point *between* them, the d_{z^2} and $d_{x^2-y^2}$ atomic orbitals are destabilized to a greater extent than the d_{xy}, d_{yz} and d_{xz} atomic orbitals (Fig. 20.2, right). Thus, with respect to their energy in a spherical field (the *barycentre*, a kind of 'centre of gravity'), the d_{z^2} and $d_{x^2-y^2}$ atomic orbitals are destabilized while the d_{xy}, d_{yz} and d_{xz} atomic orbitals are stabilized.

From the O_h character table (Appendix 3), it can be deduced (see Chapter 5) that the d_{z^2} and $d_{x^2-y^2}$ orbitals have e_g symmetry, while the d_{xy}, d_{yz} and d_{xz} orbitals possess t_{2g} symmetry (Fig. 20.3). The energy separation between them is Δ_{oct} ('delta oct') or $10Dq$. The overall stabilization of the t_{2g} orbitals equals the overall destabilization of the e_g set. Thus, the two orbitals in the e_g set are raised by $0.6\Delta_{oct}$ with respect to the barycentre while the three in the t_{2g} set are lowered by $0.4\Delta_{oct}$. Figure 20.3 also shows these energy differences in terms of $10Dq$. Both Δ_{oct} and $10Dq$ notations are in common use, but we use Δ_{oct} in this book.† The stabilization and destabilization of the t_{2g} and e_g sets, respectively, are given *in terms of* Δ_{oct}. The magnitude of Δ_{oct} is determined by the *strength of the crystal field*, the two extremes being called *weak field* and *strong field* (eq. 20.1).

$$\Delta_{oct}(\text{weak field}) < \Delta_{oct}(\text{strong field}) \qquad (20.1)$$

It is a merit of crystal field theory that, in principle at least, values of Δ_{oct} can be evaluated from electronic absorption spectroscopic data (see Section 20.7). Consider the d^1 complex $[Ti(OH_2)_6]^{3+}$, for which the ground state is represented by diagram **20.2** or the notation $t_{2g}{}^1e_g{}^0$.

† The notation Dq has mathematical origins in crystal field theory. We prefer the use of Δ_{oct} because of its experimentally determined origins (see Section 20.7).



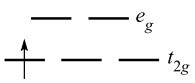


Fig. 20.2. The changes in the energies of the electrons occupying the 3*d* orbitals of a first row M^{n+} ion when the latter is in an octahedral crystal field. The energy changes are shown in terms of the orbital energies. Similar diagrams can be drawn for second (4*d*) and third (5*d*) row metal ions.

(20.2)

The absorption spectrum of the ion (Fig. 20.4) exhibits one broad band for which $\lambda_{max} = 20\,300\,cm^{-1}$ corresponding to an energy change of $243\,kJ\,mol^{-1}$. (The conversion is $1\,cm^{-1} = 11.96 \times 10^{-3}\,kJ\,mol^{-1}$.) The absorption results from a change in electronic configuration from $t_{2g}^{\ 1}e_g^{\ 0}$ to $t_{2g}^{\ 0}e_g^{\ 1}$, and the value of λ_{max} (see Fig. 20.16) gives a measure of Δ_{oct}. For systems with more than one *d* electron, the evaluation of Δ_{oct} is more complicated. It is important to remember that Δ_{oct} is an *experimental* quantity.

Factors governing the magnitude of Δ_{oct} (Table 20.2) are the identity and oxidation state of the metal ion and the nature of the ligands. We shall see later that Δ parameters are also defined for other ligand arrangements (e.g. Δ_{tet}). For octahedral complexes, Δ_{oct} increases along the following *spectrochemical series* of ligands. The $[NCS]^-$ ion may coordinate through the *N*- or *S*-donor (distinguished in red below) and accordingly, it has two positions in the series:

$$I^- < Br^- < [NCS]^- < Cl^- < F^- < [OH]^- < [ox]^{2-}$$
$$\approx H_2O < [NCS]^- < NH_3 < en < bpy < phen < [CN]^- \approx CO$$

weak field ligands ⟶ strong field ligands increasing Δ_{oct}

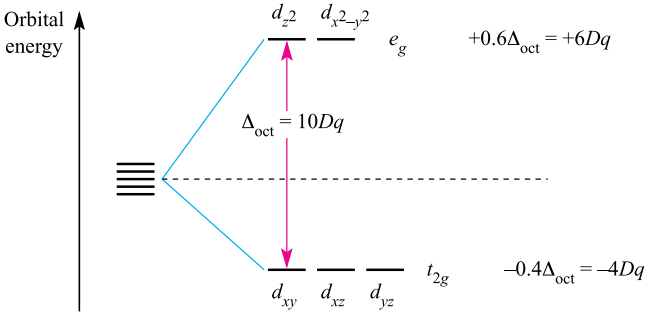

Fig. 20.3. Splitting of the *d* orbitals in an octahedral crystal field, with the energy changes measured with respect to the barycentre, the energy level shown by the hashed line.

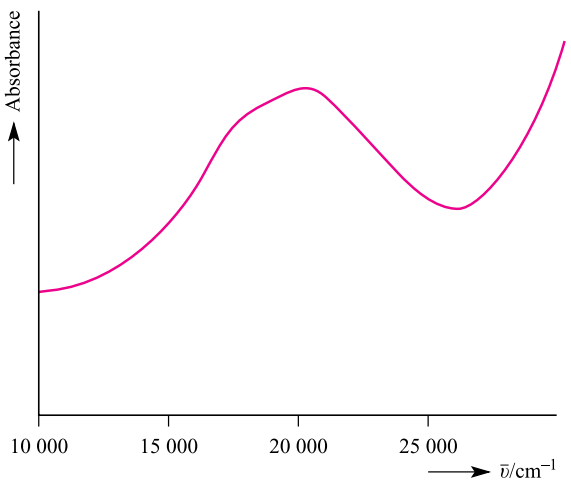

Fig. 20.4. The electronic absorption spectrum of $[Ti(OH_2)_6]^{3+}$ in aqueous solution.

Table 20.2 Values of Δ_{oct} for some *d*-block metal complexes.

Complex	Δ / cm^{-1}	Complex	Δ / cm^{-1}
$[TiF_6]^{3-}$	17 000	$[Fe(ox)_3]^{3-}$	14 100
$[Ti(OH_2)_6]^{3+}$	20 300	$[Fe(CN)_6]^{3-}$	35 000
$[V(OH_2)_6]^{3+}$	17 850	$[Fe(CN)_6]^{4-}$	33 800
$[V(OH_2)_6]^{2+}$	12 400	$[CoF_6]^{3-}$	13 100
$[CrF_6]^{3-}$	15 000	$[Co(NH_3)_6]^{3+}$	22 900
$[Cr(OH_2)_6]^{3+}$	17 400	$[Co(NH_3)_6]^{2+}$	10 200
$[Cr(OH_2)_6]^{2+}$	14 100	$[Co(en)_3]^{3+}$	24 000
$[Cr(NH_3)_6]^{3+}$	21 600	$[Co(OH_2)_6]^{3+}$	18 200
$[Cr(CN)_6]^{3-}$	26 600	$[Co(OH_2)_6]^{2+}$	9 300
$[MnF_6]^{2-}$	21 800	$[Ni(OH_2)_6]^{2+}$	8 500
$[Fe(OH_2)_6]^{3+}$	13 700	$[Ni(NH_3)_6]^{2+}$	10 800
$[Fe(OH_2)_6]^{2+}$	9 400	$[Ni(en)_3]^{2+}$	11 500

The spectrochemical series is reasonably general. Ligands with the same donor atoms are close together in the series. If we consider octahedral complexes of *d*-block metal ions, a number of points arise which can be illustrated by the following examples:

- the complexes of Cr(III) listed in Table 20.2 illustrate the effects of different ligand field strengths for a given M^{n+} ion;
- the complexes of Fe(II) and Fe(III) in Table 20.2 illustrate that for a given ligand and a given metal, Δ_{oct} increases with increasing oxidation state;
- where analogous complexes exist for a series of M^{n+} metals ions (constant *n*) in a triad, Δ_{oct} increases significantly down the triad (e.g. Fig. 20.5);
- for a given ligand and a given oxidation state, Δ_{oct} varies *irregularly* across the first row of the *d*-block, e.g. over the range 8000 to 14 000 cm^{-1} for the $[M(OH_2)_6]^{2+}$ ions.

Trends in values of Δ_{oct} lead to the conclusion that metal ions can be placed in a spectrochemical series which is independent of the ligands:

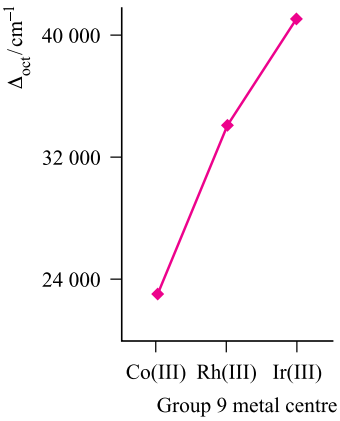
$$\text{Mn(II)} < \text{Ni(II)} < \text{Co(II)} < \text{Fe(III)} < \text{Cr(III)} < \text{Co(III)} < \text{Ru(III)} < \text{Mo(III)} < \text{Rh(III)} < \text{Pd(II)} < \text{Ir(III)} < \text{Pt(IV)}$$

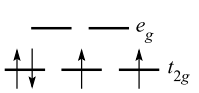
$$\xrightarrow[\text{increasing field strength}]{}$$

Spectrochemical series are empirical generalizations and simple crystal field theory *cannot* account for the magnitudes of Δ_{oct} values.

Crystal field stabilization energy: high- and low-spin octahedral complexes

We now consider the effects of different numbers of electrons occupying the *d* orbitals in an octahedral crystal field. For a d^1 system, the ground state corresponds to the configuration $t_{2g}{}^1$ (**20.2**). With respect to the barycentre, there is a stabilization energy of $-0.4\Delta_{oct}$ (Fig. 20.3). This is the so-called *crystal field stabilization energy*, *CFSE*.[†] For a d^2 ion, the ground state configuration is $t_{2g}{}^2$ and the CFSE $= -0.8\Delta_{oct}$ (eq. 20.2). A d^3 ion ($t_{2g}{}^3$) has a CFSE $= -1.2\Delta_{oct}$.





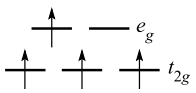


Fig. 20.5. The trend in values of Δ_{oct} for the complexes $[M(NH_3)_6]^{3+}$ where M = Co, Rh, Ir.

$$\text{CFSE} = -(2 \times 0.4)\Delta_{oct} = -0.8\Delta_{oct} \qquad (20.2)$$

(20.3)

(20.4)

For a ground state d^4 ion, two arrangements are possible: the four electrons may occupy the t_{2g} set with the configuration $t_{2g}{}^4$ (**20.3**), or may singly occupy four *d* orbitals, $t_{2g}{}^3e_g{}^1$ (**20.4**). Configuration **20.3** corresponds to a low-spin arrangement, and **20.4** to a high-spin case. The preferred configuration is that with the lower energy and depends on whether it is energetically preferable to pair the fourth electron or promote it to the e_g level. Two terms contribute to the electron-pairing energy, *P*, which is the energy required to transform two electrons with parallel spin in different degenerate orbitals into spin-paired electrons in the same orbital:

- the loss in the *exchange energy* (see Box 1.7) which occurs upon pairing the electrons;
- the coulombic repulsion between the spin-paired electrons.

For a given d^n configuration, the CFSE is the *difference* in energy between the *d* electrons in an octahedral crystal field and the *d* electrons in a spherical crystal field (see Fig. 20.2). To exemplify this, consider a d^4 configuration. In a spherical crystal field, the *d* orbitals are degenerate and each of four orbitals is singly occupied. In an octahedral

[†] The sign convention used here for CFSE follows the thermodynamic convention.

Table 20.3 Octahedral crystal field stabilization energies (CFSE) for d^n configurations; pairing energy, P, terms are included where appropriate (see text). High- and low-spin octahedral complexes are shown only where the distinction is appropriate.

d^n	High-spin = weak field		Low-spin = strong field	
	Electronic configuration	CFSE	Electronic configuration	CFSE
d^1	$t_{2g}^1 e_g^0$	$-0.4\Delta_{oct}$		
d^2	$t_{2g}^2 e_g^0$	$-0.8\Delta_{oct}$		
d^3	$t_{2g}^3 e_g^0$	$-1.2\Delta_{oct}$		
d^4	$t_{2g}^3 e_g^1$	$-0.6\Delta_{oct}$	$t_{2g}^4 e_g^0$	$-1.6\Delta_{oct} + P$
d^5	$t_{2g}^3 e_g^2$	0	$t_{2g}^5 e_g^0$	$-2.0\Delta_{oct} + 2P$
d^6	$t_{2g}^4 e_g^2$	$-0.4\Delta_{oct}$	$t_{2g}^6 e_g^0$	$-2.4\Delta_{oct} + 2P$
d^7	$t_{2g}^5 e_g^2$	$-0.8\Delta_{oct}$	$t_{2g}^6 e_g^1$	$-1.8\Delta_{oct} + P$
d^8	$t_{2g}^6 e_g^2$	$-1.2\Delta_{oct}$		
d^9	$t_{2g}^6 e_g^3$	$-0.6\Delta_{oct}$		
d^{10}	$t_{2g}^6 e_g^4$	0		

crystal field, eq. 20.3 shows how the CFSE is determined for a high-spin d^4 configuration (**20.4**).

$$\text{CFSE} = -(3 \times 0.4)\Delta_{oct} + 0.6\Delta_{oct} = -0.6\Delta_{oct} \qquad (20.3)$$

For a low-spin d^4 configuration (**20.3**), the CFSE consists of two terms: the four electrons in the t_{2g} orbitals give rise to a $-1.6\Delta_{oct}$ term, and a pairing energy, P, must be included to account for the spin-pairing of two electrons. Now consider a d^6 ion. In a spherical crystal field (Fig. 20.2), one d orbital contains spin-paired electrons, and each of four orbitals is singly occupied. On going to the high-spin d^6 configuration in the octahedral field ($t_{2g}^4 e_g^2$), no change occurs to the number of spin-paired electrons and the CFSE is given by eq. 20.4.

$$\text{CFSE} = -(4 \times 0.4)\Delta_{oct} + (2 \times 0.6)\Delta_{oct} = -0.4\Delta_{oct} \qquad (20.4)$$

For a low-spin d^6 configuration ($t_{2g}^6 e_g^0$) the six electrons in the t_{2g} orbitals give rise to a $-2.4\Delta_{oct}$ term. Added to this is a pairing energy term of $2P$ which accounts for the spin-pairing associated with the two pairs of electrons in excess of the one in the high-spin configuration. Table 20.3 lists values of the CFSE for all d^n configurations in an octahedral crystal field. Inequalities 20.5 and 20.6 show the requirements for high- or low-spin configurations. Inequality 20.5 holds when the crystal field is weak, whereas expression 20.6 is true for a strong crystal field. Figure 20.6 summarizes the preferences for low- and high-spin d^5 octahedral complexes.

$$\text{For high-spin:} \quad \Delta_{oct} < P \qquad (20.5)$$

$$\text{For low-spin:} \quad \Delta_{oct} > P \qquad (20.6)$$

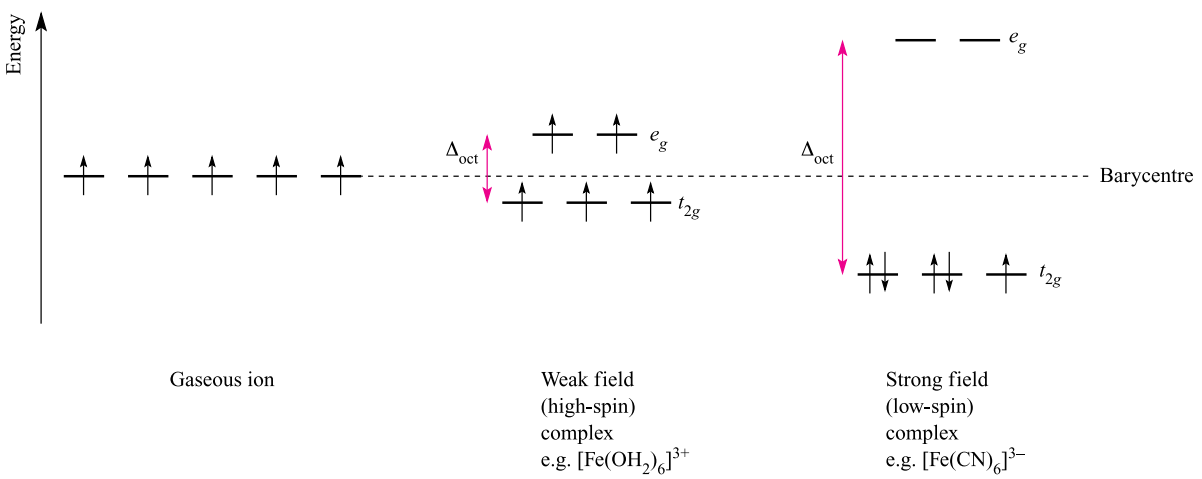

Fig. 20.6. The occupation of the 3*d* orbitals in weak and strong field Fe^{3+} (d^5) complexes.

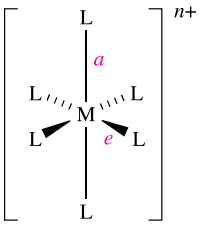
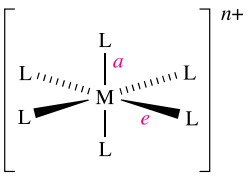
We can now relate types of ligand with a preference for high- or low-spin complexes. Strong field ligands such as $[CN]^-$ favour the formation of low-spin complexes, while weak field ligands such as halides tend to favour high-spin complexes. However, we cannot predict whether high- or low-spin complexes will be formed unless we have accurate values of Δ_{oct} and P. On the other hand, with some experimental knowledge in hand, we can make some comparative predictions. For example, if we know from magnetic data that $[Co(OH_2)_6]^{3+}$ is low-spin, then from the spectrochemical series we can say that $[Co(ox)_3]^{3-}$ and $[Co(CN)_6]^{3-}$ will be low-spin. The only common high-spin cobalt(III) complex is $[CoF_6]^{3-}$.



Self-study exercises

All questions refer to ground state electronic configurations.

1. Draw energy level diagrams to represent a high-spin d^6 electronic configuration for an octahedral (O_h) complex. Confirm that the diagram is consistent with a value of CFSE $= -0.4\Delta_{oct}$.
2. Why does Table 20.3 not list high- and low-spin cases for all d^n configurations?
3. Explain why the CFSE for a low-spin d^5 configuration contains a $2P$ term (Table 20.3).
4. Given that $[Co(OH_2)_6]^{3+}$ is low-spin, explain why it is possible to predict that $[Co(bpy)_3]^{3+}$ is also low-spin.



Jahn–Teller distortions

Octahedral complexes of d^9 and high-spin d^4 ions are often distorted, e.g. CuF_2 (the solid state structure of which contains octahedrally sited Cu^{2+} centres, see Section 21.12) and $[Cr(OH_2)_6]^{2+}$, so that two metal–ligand bonds (axial) are different lengths from the remaining four (equatorial). This is shown in structures **20.5** (elongated octahedron) and **20.6** (compressed octahedron).† For a high-spin d^4 ion, one of the e_g orbitals contains one electron while the other is vacant. If the singly occupied orbital is the d_{z^2}, most of the electron density in this orbital will be concentrated between the cation and the two ligands on the z axis. Thus, there will be greater electrostatic repulsion associated with these ligands than with the other four, and therefore the complex suffers elongation (**20.5**). Conversely, occupation of the $d_{x^2-y^2}$ orbital would lead to elongation along the x and y axes as in structure **20.6**. A similar argument can be put forward for the d^9 configuration in which the two orbitals in the e_g set are occupied by one and two electrons respectively. Electron-density measurements confirm that the electronic configuration of the Cr^{2+} ion in $[Cr(OH_2)_6]^{2+}$ is *approximately* $d_{xy}^1 d_{yz}^1 d_{xz}^1 d_{z^2}^1$. The corresponding effect when the t_{2g} set is unequally occupied is expected to be very much smaller since the orbitals are not pointing directly at the ligands. This expectation is usually, but not invariably, confirmed experimentally. Distortions of this kind are called *Jahn–Teller* or *tetragonal distortions*.

Bond length $a > e$

(20.5)

Bond length $a < e$

(20.6)

The ***Jahn–Teller theorem*** states that any non-linear molecular system in a degenerate electronic state will be unstable and will undergo distortion to form a system of lower symmetry and lower energy, thereby removing the degeneracy.

The observed tetragonal distortion of an octahedral $[ML_6]^{n+}$ complex is accompanied by a change in symmetry (O_h to D_{4h}) and a splitting of the e_g and t_{2g} sets of orbitals (see Fig. 20.10). Elongation of the complex (**20.5**) is accompanied by the stabilization of each d orbital that has a z component, while the d_{xy} and $d_{x^2-y^2}$ orbitals are destabilized.

The tetrahedral crystal field

Now we consider the tetrahedral crystal field. Figure 20.7 shows a convenient and very useful way of relating a tetrahedron to a Cartesian axis set. With the complex in this orientation, none of the metal d orbitals points exactly at the ligands, but the d_{xy}, d_{yz} and d_{xz} orbitals come nearer to

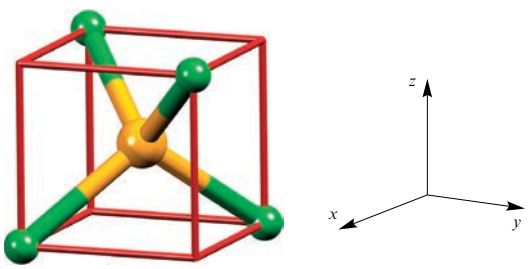


Fig. 20.7. The relationship between a tetrahedral ML_4 complex and a cube; the cube is readily related to a Cartesian axis set. The ligands lie *between* the x, y and z axes. Compare this with an octahedral complex, where the ligands lie on the axes.

† Other distortions may arise and these are exemplified for Cu(II) complexes in Section 21.12.

doing so than the d_{z^2} and $d_{x^2-y^2}$ orbitals. For a regular tetrahedron, the splitting of the *d* orbitals is therefore inverted compared with that for a regular octahedral structure, and the energy difference (Δ_{tet}) is smaller. If all other things are equal (and of course, they never are), the relative splittings Δ_{oct} and Δ_{tet} are related by eq. 20.7.

$$\Delta_{tet} = \tfrac{4}{9}\Delta_{oct} \approx \tfrac{1}{2}\Delta_{oct} \qquad (20.7)$$

Figure 20.8 compares crystal field splitting for octahedral and tetrahedral fields. The subscript *g* in the symmetry labels (see Box 20.1) is not needed in the tetrahedral case.

Since Δ_{tet} is significantly smaller than Δ_{oct}, tetrahedral complexes are high-spin. Also, since smaller amounts of energy are needed for $t_2 \leftarrow e$ transitions (tetrahedral) than for $e_g \leftarrow t_{2g}$ transitions (octahedral), corresponding octahedral and tetrahedral complexes often have different colours. (The notation for electronic transitions is given in Section 4.7.)

Tetrahedral complexes are almost always ***high-spin***.

While one can anticipate that tetrahedral complexes will be high-spin, the effects of a strong field ligand which also lowers the symmetry of the complex can lead to a low-spin 'distorted tetrahedral' system. This is a rare situation, and is observed in the cobalt(II) complex shown in

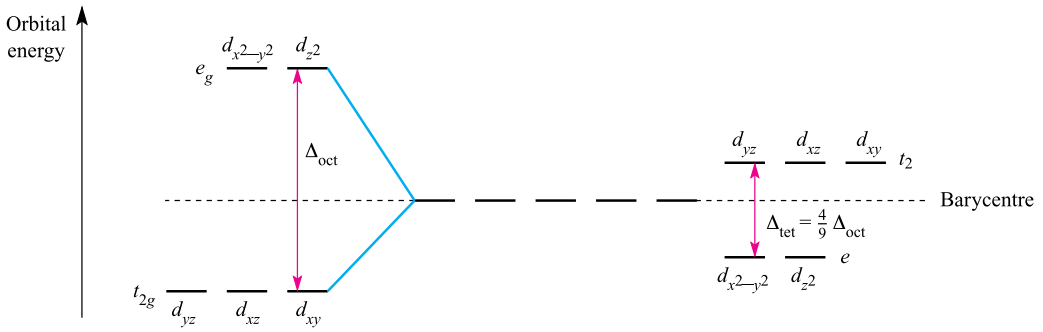

Fig. 20.8. Crystal field splitting diagrams for octahedral (left-hand side) and tetrahedral (right-hand side) fields. The splittings are referred to a common barycentre. See also Fig. 20.2.

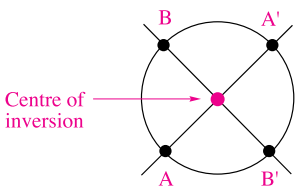
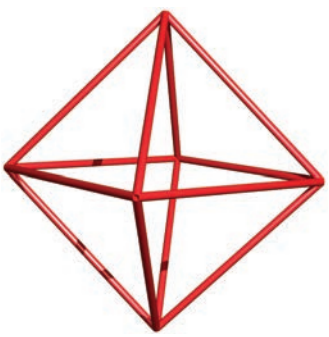


THEORY

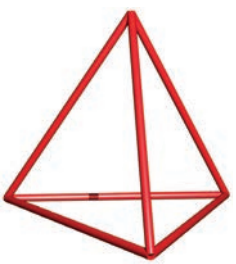
Box 20.1 A reminder about symmetry labels

The two sets of *d* orbitals in an octahedral field are labelled e_g and t_{2g} (Fig. 20.3). In a tetrahedral field (Fig. 20.8), the labels become *e* and t_2. The symbols *t* and *e* refer to the degeneracy of the level:



- a triply degenerate level is labelled *t*;
- a doubly degenerate level is labelled *e*.

The subscript *g* means *gerade* and the subscript *u* means *ungerade*. *Gerade* and *ungerade* designate the behaviour of the wavefunction under the operation of *inversion*, and denote the *parity* (even or odd) of an orbital.



Point A is related to A' by passing through the centre of inversion. Similarly, B is related to B'.

The *u* and *g* labels are applicable *only* if the system possesses a centre of symmetry (centre of inversion) and thus are used for the octahedral field, but not for the tetrahedral one:

Octahedron has a centre of symmetry

Tetrahedron has no centre of symmetry

For more on the origins of symmetry labels: see Chapter 5.

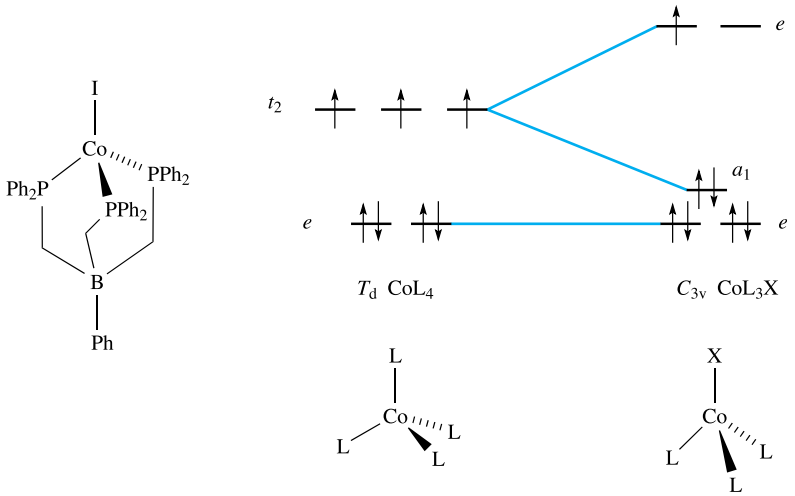


Fig. 20.9. [PhB(CH_2PPh_2)$_3$CoI] is a rare example of a low-spin, distorted tetrahedral complex. The tripodal tris(phosphane) is a strong-field ligand.

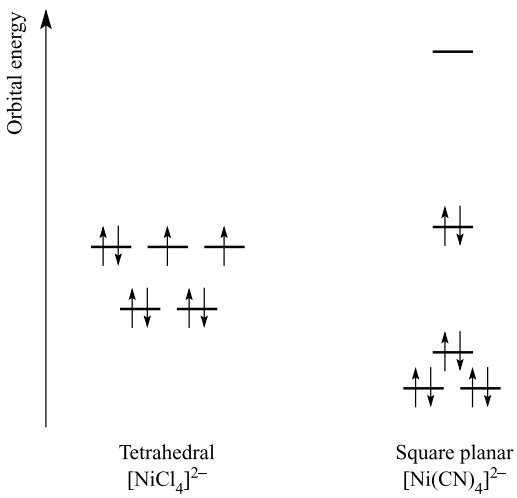
Fig. 20.9. The lowering in symmetry from a model T_d CoL_4 complex to C_{3v} CoL_3X results in the change in orbital energy levels (Fig. 20.9). If the a_1 orbital is sufficiently stabilized and the e set is significantly destabilized, a low-spin system is energetically favoured.

Jahn–Teller effects in tetrahedral complexes are illustrated by distortions in d^9 (e.g. $[CuCl_4]^{2-}$) and high-spin d^4 complexes. A particularly strong structural distortion is observed in $[FeO_4]^{4-}$ (see structure **21.37**).



The square planar crystal field

A square planar arrangement of ligands can be formally derived from an octahedral array by removal of two *trans*-ligands (Fig. 20.10). If we remove the ligands lying along the z axis, then the d_{z^2} orbital is greatly stabilized; the energies of the d_{yz} and d_{xz} orbitals are also lowered (Fig. 20.10). The fact that square planar d^8 complexes such as $[Ni(CN)_4]^{2-}$ are diamagnetic is a consequence of the relatively large energy difference between the d_{xy} and $d_{x^2-y^2}$ orbitals. Worked example 20.1 shows an experimental means (other than single-crystal X-ray diffraction) by which square planar and tetrahedral d^8 complexes can be distinguished.

Worked example 20.1 Square planar and tetrahedral d^8 complexes

The d^8 complexes $[Ni(CN)_4]^{2-}$ and $[NiCl_4]^{2-}$ are square planar and tetrahedral respectively. Will these complexes be paramagnetic or diamagnetic?

Consider the splitting diagrams shown in Fig. 20.11. For $[Ni(CN)_4]^{2-}$ and $[NiCl_4]^{2-}$, the eight electrons occupy the d orbitals as follows:

Thus, $[NiCl_4]^{2-}$ is paramagnetic while $[Ni(CN)_4]^{2-}$ is diamagnetic.

Self-study exercises

The answer to each question is closely linked to the theory in worked example 20.1.

1. The complexes $[NiCl_2(PPh_3)_2]$ and $[PdCl_2(PPh_3)_2]$ are paramagnetic and diamagnetic respectively. What does this tell you about their structures?
2. The anion $[Ni(SPh)_4]^{2-}$ is tetrahedral. Explain why it is paramagnetic.
3. Diamagnetic *trans*-$[NiBr_2(PEtPh_2)_2]$ converts to a form which is paramagnetic. Suggest a reason for this observation.

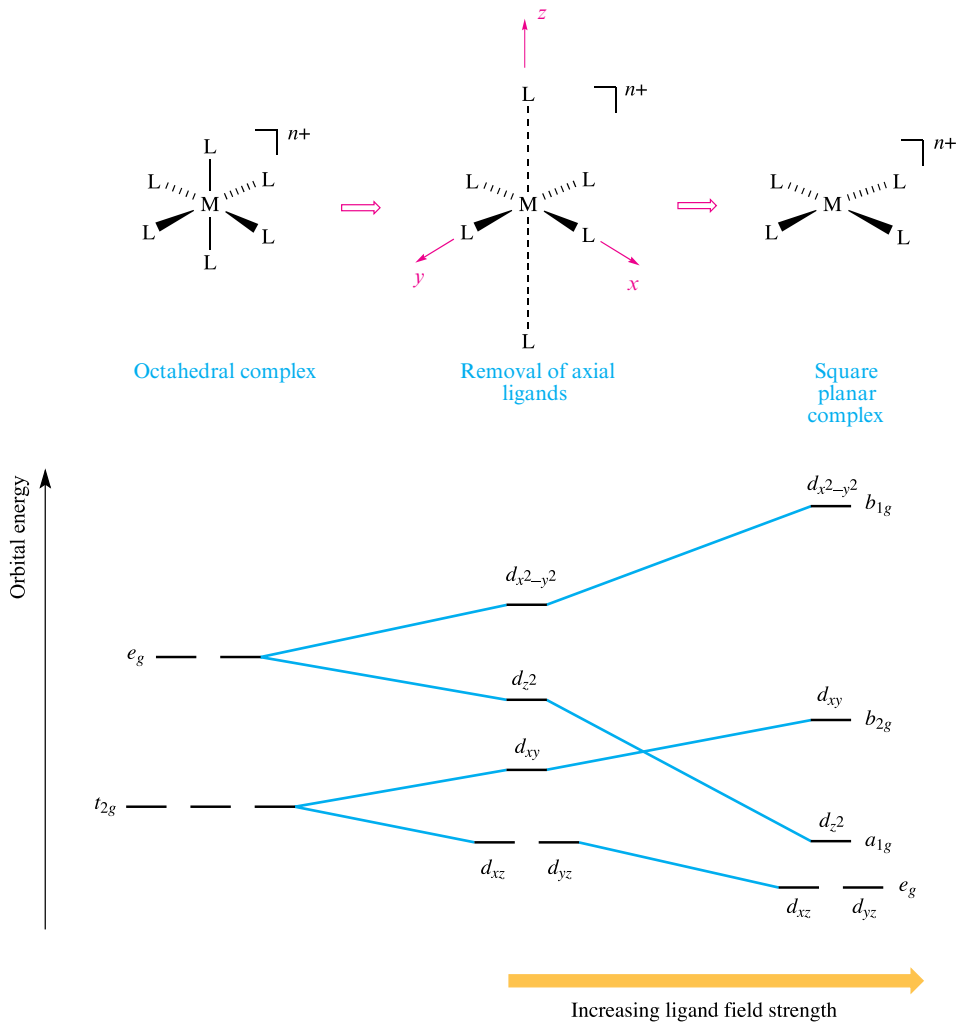


Fig. 20.10. A square planar complex can be derived from an octahedral complex by the removal of two ligands, e.g. those on the *z* axis. The intermediate stage is analogous to a Jahn–Teller distorted (elongated) octahedral complex.

Although $[NiCl_4]^{2-}$ (d^8) is tetrahedral and paramagnetic, $[PdCl_4]^{2-}$ and $[PtCl_4]^{2-}$ (also d^8) are square planar and diamagnetic. This difference is a consequence of the larger crystal field splitting observed for second and third row metal ions compared with their first row congener. Palladium(II) and platinum(II) complexes are invariably square planar.

Second and third row metal d^8 complexes (e.g. Pt(II), Pd(II), Rh(I), Ir(I)) are invariably ***square planar***.

Other crystal fields

Figure 20.11 shows crystal field splittings for some common geometries with the relative splittings of the *d* orbitals with respect to Δ_{oct}. By using these splitting diagrams, it is possible to rationalize the magnetic properties of a given complex (see Section 20.9). However, a word of caution: Fig. 20.11 refers to ML_x complexes containing *like* ligands, and so *only* applies to simple complexes.

Crystal field theory: uses and limitations

Crystal field theory can bring together structures, magnetic properties and electronic properties, and we shall expand upon the last two topics later in the chapter. Trends in CFSEs provide some understanding of thermodynamic and kinetic aspects of *d*-block metal complexes (see Sections 20.11–20.13 and 26.4). Crystal field theory is surprisingly useful when one considers its simplicity. However, it has limitations. For example, although we can interpret the contrasting magnetic properties of high- and low-spin octahedral complexes on the basis of the positions of weak- and strong-field ligands in the spectrochemical series, crystal field theory provides no explanation as to *why* particular ligands are placed where they are in the series.

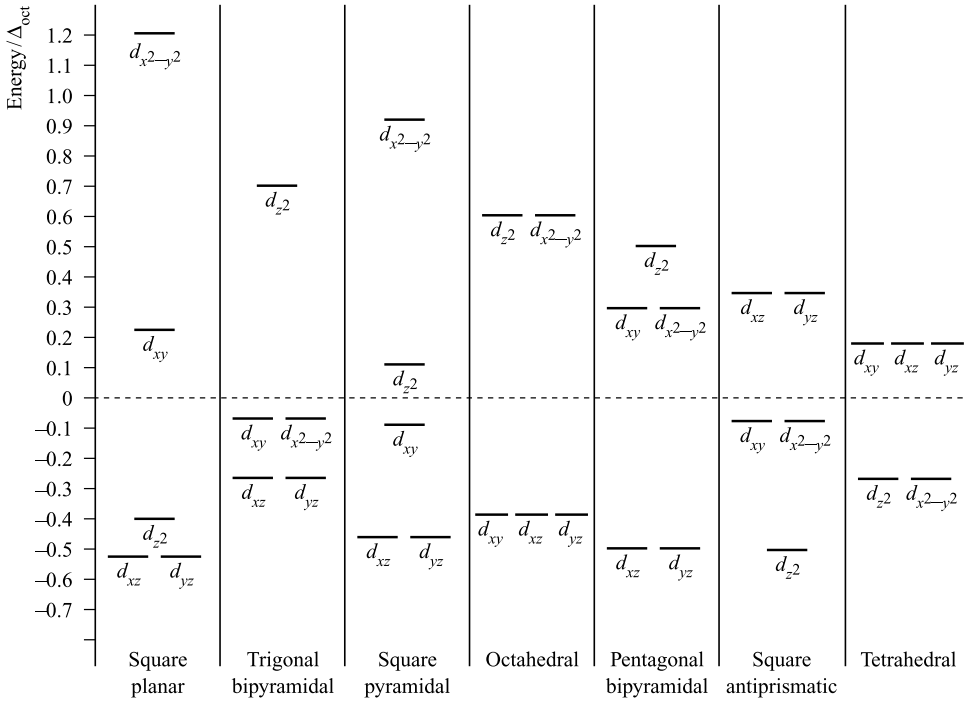

Fig. 20.11. Crystal field splitting diagrams for some common fields referred to a common barycentre. Splittings are given with respect to Δ_{oct}.

20.4 Molecular orbital theory: octahedral complexes

In this section, we consider another approach to the bonding in metal complexes: the use of molecular orbital theory. In contrast to crystal field theory, the molecular orbital model considers covalent interactions between the metal centre and ligands. Before starting Section 20.4, you may wish to review approaches to the bonding in diatomic molecules (Sections 2.2, 2.3 and 2.7) and the use of ligand group orbitals in polyatomic molecules (Sections 5.4, 5.5 and 5.6).

Complexes with *no* metal–ligand π-bonding

We illustrate the application of MO theory to *d*-block metal complexes first by considering an octahedral complex such as $[Co(NH_3)_6]^{3+}$ in which metal–ligand σ-bonding is dominant. In the construction of an MO energy level diagram for such a complex, many approximations are made and the result is only *qualitatively* accurate. Even so, the results are useful for an understanding of metal–ligand bonding.

By following the procedures detailed in Chapter 5, an MO diagram can be constructed to describe the bonding in an O_h $[ML_6]^{n+}$ complex. For a first row metal, the valence shell atomic orbitals are 3*d*, 4*s* and 4*p*. Under O_h symmetry (see Appendix 3), the *s* orbital has a_{1g} symmetry, the *p* orbitals are degenerate with t_{1u} symmetry, and the *d* orbitals split into two sets with e_g (d_{z^2} and $d_{x^2-y^2}$ orbitals) and t_{2g} (d_{xy}, d_{yz} and d_{xz} orbitals) symmetries, respectively (Fig. 20.12). Each ligand, L, provides one orbital and derivation of the ligand group orbitals for the O_h L_6 fragment is analogous to those for the F_6 fragment in SF_6 (see Fig. 5.27, eqs. 5.26–5.31 and accompanying text). These LGOs have a_{1g}, t_{1u} and e_g symmetries (Fig. 20.12). Symmetry matching between metal orbitals and LGOs allows the construction of the MO diagram shown in Fig. 20.13. Combinations of the metal and ligand orbitals generate six bonding and six antibonding molecular orbitals. The metal d_{xy}, d_{yz} and d_{xz} atomic orbitals have t_{2g} symmetry and are non-bonding (Fig. 20.13). The overlap between the ligand and metal *s* and *p* orbitals is greater than that involving the metal *d* orbitals, and so the a_{1g} and t_{1u} MOs are stabilized to a greater extent than the e_g MOs. In an octahedral complex *with no π-bonding*, the energy difference between the t_{2g} and e_g^* levels corresponds to Δ_{oct} in crystal field theory (Fig. 20.13).

Having constructed the MO diagram in Fig. 20.13, we are able to describe the bonding in a range of octahedral σ-bonded complexes. For example:

- in low-spin $[Co(NH_3)_6]^{3+}$, 18 electrons (six from Co^{3+} and two from each ligand) occupy the a_{1g}, t_{1u}, e_g and t_{2g} MOs;
- in high-spin $[CoF_6]^{3-}$, 18 electrons are available, 12 occupying the a_{1g}, t_{1u} and e_g MOs, four the t_{2g} level, and two the e_g^* level.

Whether a complex is high- or low-spin depends upon the energy separation of the t_{2g} and e_g^* levels. *Notionally*, in a σ-bonded octahedral complex, the 12 electrons supplied by the ligands are considered to occupy the a_{1g}, t_{1u} and e_g

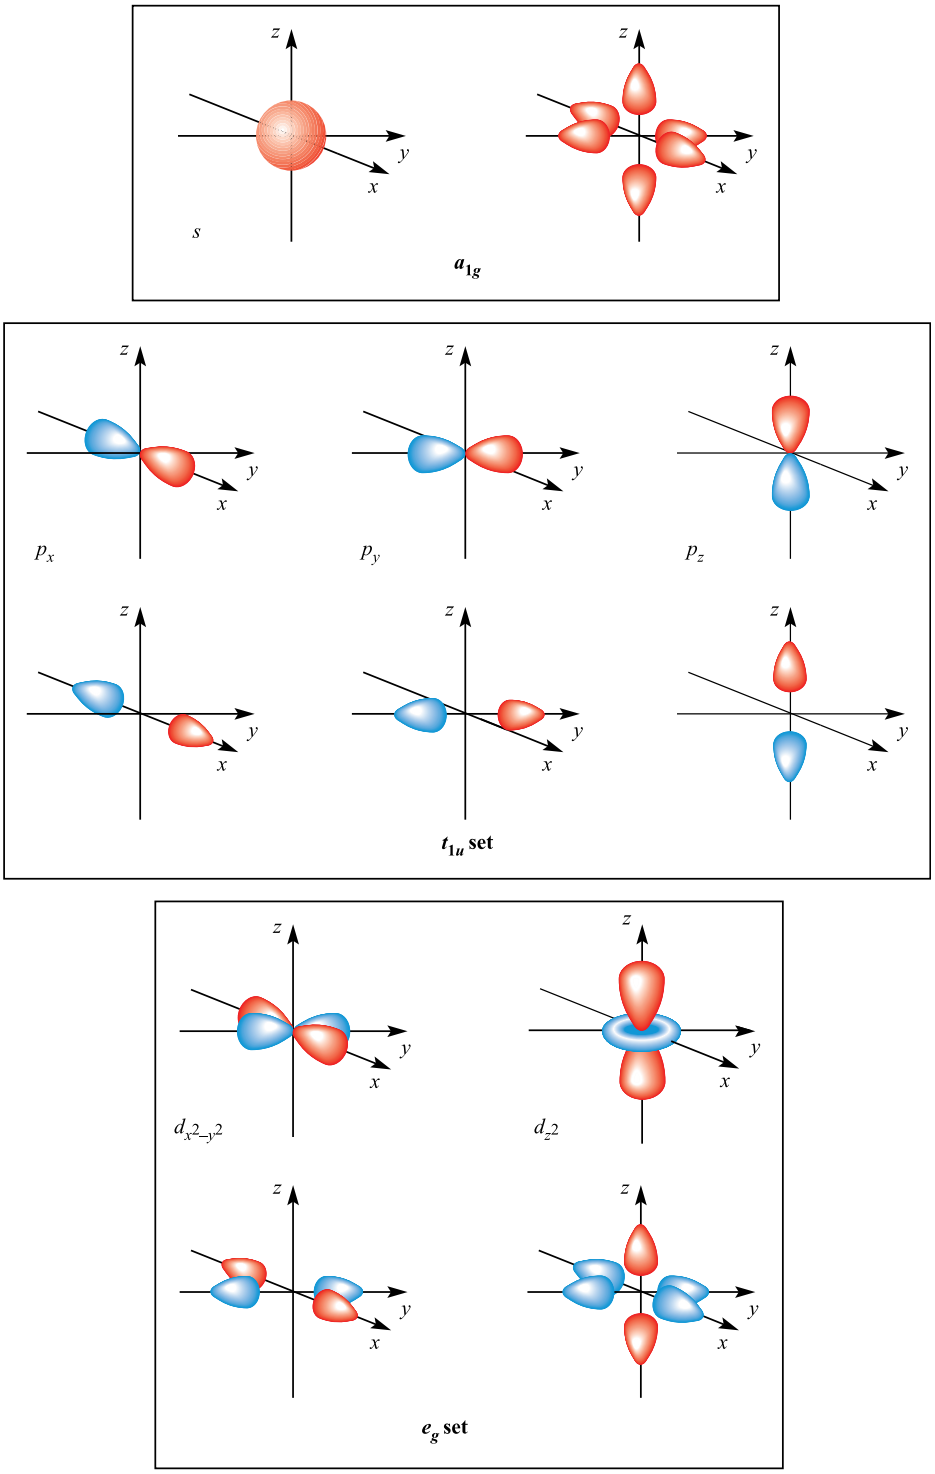

Fig. 20.12. Metal atomic orbitals s, p_x, p_y, p_z, $d_{x^2-y^2}$, d_{z^2} matched by symmetry with ligand group orbitals for an octahedral (O_h) complex with only σ-bonding.

orbitals. Occupancy of the t_{2g} and e_g^* levels corresponds to the number of valence electrons of the metal ion, just as in crystal field theory. The molecular orbital model of bonding in octahedral complexes gives much the same results as crystal field theory. It is when we move to complexes with M–L π-bonding that distinctions between the models emerge.

Complexes with metal–ligand π-bonding

The metal d_{xy}, d_{yz} and d_{xz} atomic orbitals (the t_{2g} set) are non-bonding in an $[ML_6]^{n+}$, σ-bonded complex (Fig. 20.13) and these orbitals may overlap with ligand orbitals of the correct symmetry to give π-interactions (Fig. 20.14).

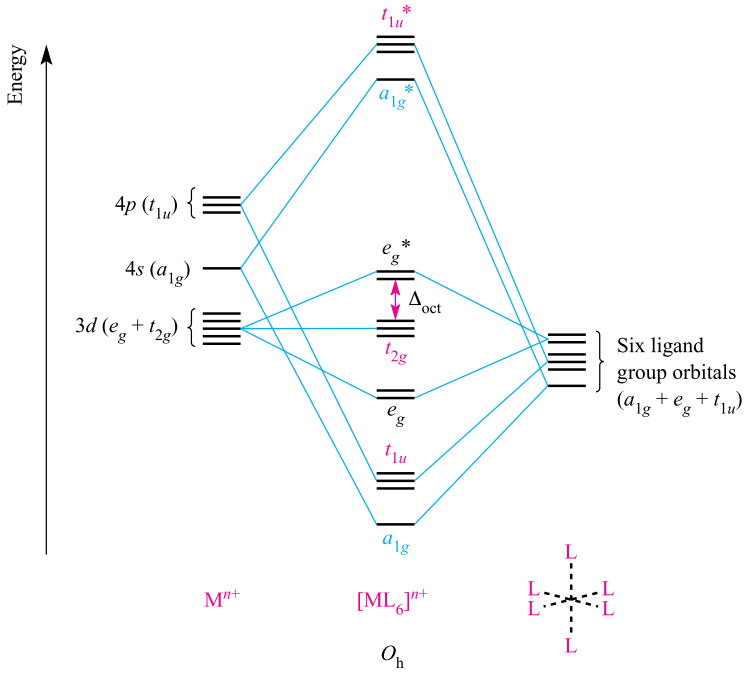

Fig. 20.13. An approximate MO diagram for the formation of $[ML_6]^{n+}$ (where M is a first row metal) using the ligand group orbital approach; the orbitals are shown pictorially in Fig. 20.12. The bonding only involves M–L σ-interactions.

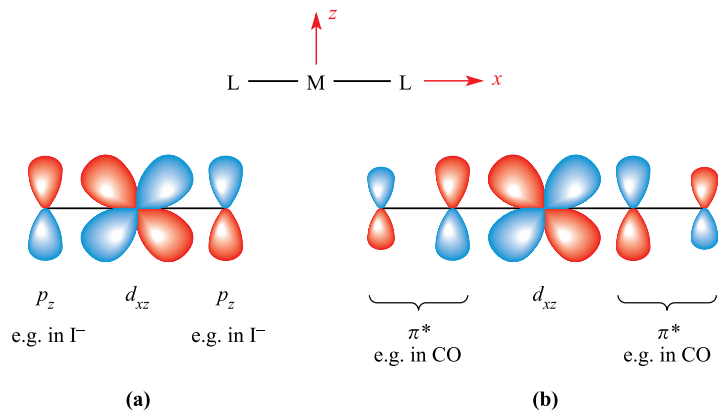

Fig. 20.14. π-Bond formation in a linear L–M–L unit in which the metal and ligand donor atoms lie on the x axis: (a) between metal d_{xz} and ligand p_z orbitals as for L = I^-, an example of a π-donor ligand, and (b) between metal d_{xz} and ligand π^*-orbitals as for L = CO, an example of a π-acceptor ligand.

Although π-bonding between metal and ligand d orbitals is sometimes considered for interactions between metals and phosphane ligands (e.g. PR_3 or PF_3), it is more realistic to consider the roles of ligand σ^*-orbitals as the acceptor orbitals.[†] Two types of ligand must be differentiated: π-donor and π-acceptor ligands.

A ***π-donor ligand*** donates electrons to the metal centre in an interaction that involves a filled ligand orbital and an empty metal orbital.

A ***π-acceptor ligand*** accepts electrons from the metal centre in an interaction that involves a filled metal orbital and an empty ligand orbital.

π-Donor ligands include Cl^-, Br^- and I^- and the metal–ligand π-interaction involves transfer of electrons from filled ligand p orbitals to the metal centre (Fig. 20.14a). Examples of π-acceptor ligands are CO, N_2, NO and alkenes, and the metal–ligand π-bonds arise from the

[†] For further discussion, see: A.G. Orpen and N.G. Connelly (1985) *J. Chem. Soc., Chem. Commun.*, p. 1310; T. Leyssens, D. Peeters, A. G. Orpen and J.N. Harvey (2007) *Organometallics*, vol. 26, p. 2637. See also the discussion of *negative hyperconjugation* at the end of Section 14.6.

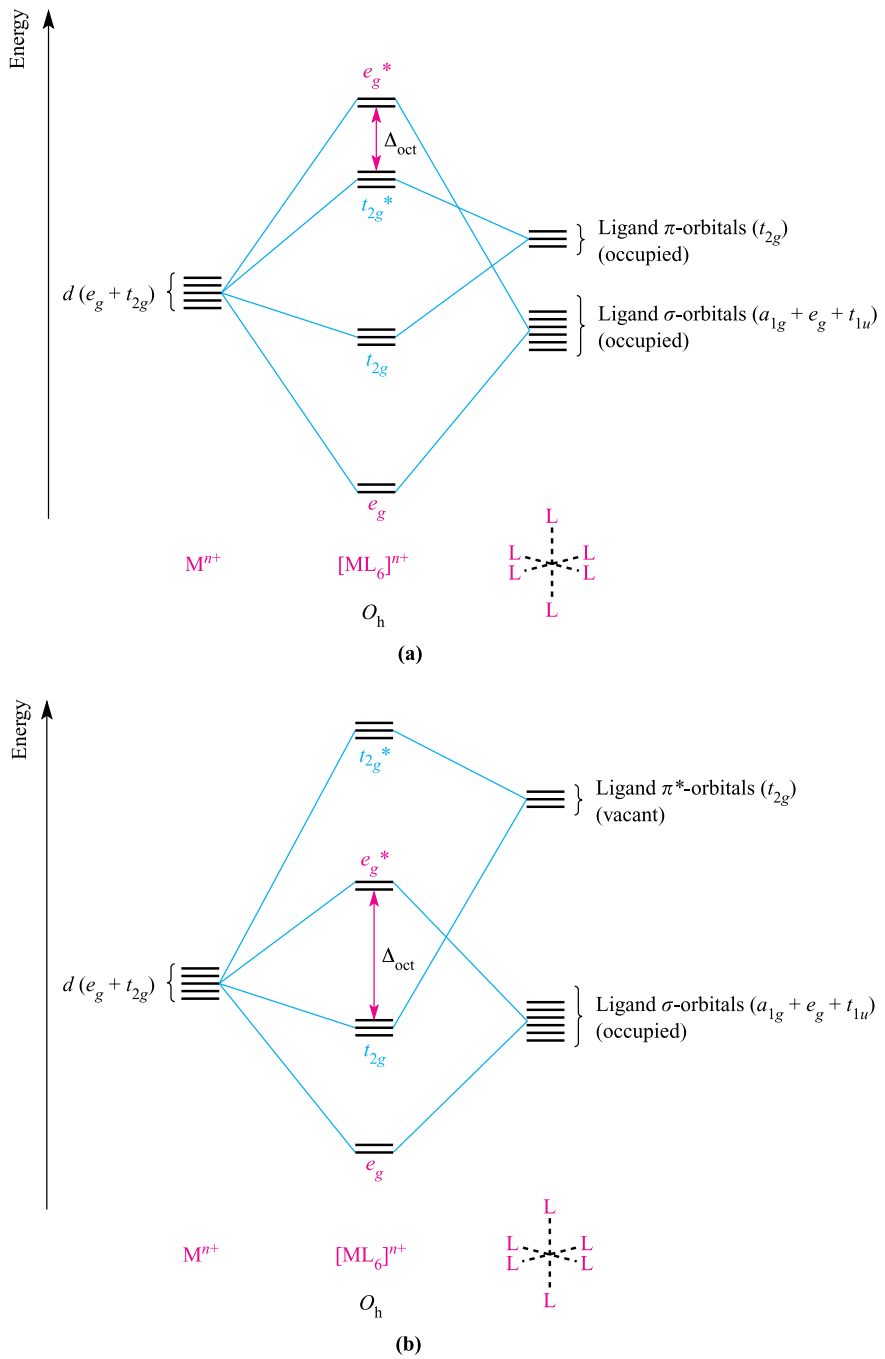

Fig. 20.15. Approximate partial MO diagrams for metal–ligand π-bonding in an octahedral complex: (a) with π-donor ligands and (b) with π-acceptor ligands. In addition to the MOs shown, σ-bonding in the complex involves the a_{1g} and t_{1u} MOs (see Fig. 20.13). Electrons are omitted from the diagram, because we are dealing with a general M^{n+} ion. Compared with Fig. 20.13, the energy scale is expanded.

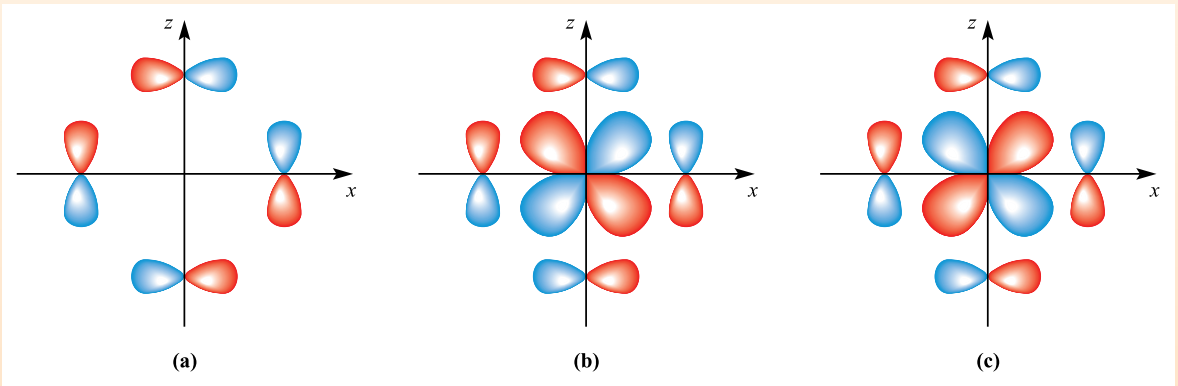
back-donation of electrons from the metal centre to vacant antibonding orbitals on the ligand (for example, Fig. 20.14b). π-Acceptor ligands can stabilize low oxidation state metal complexes (see Chapter 24). Figure 20.15 shows partial MO diagrams which describe metal–ligand π-interactions in octahedral complexes; the metal *s* and *p* orbitals which are involved in σ-bonding (see Fig. 20.13) have been omitted. Figure 20.15a shows the interaction between a metal ion and six π-donor ligands; electrons are omitted from the diagram, and we return to them later. The ligand group π-orbitals (see Box 20.2) are filled and lie above, but relatively close to, the ligand σ-orbitals, and interaction with the metal d_{xy}, d_{yz} and d_{xz} atomic orbitals leads to bonding (t_{2g}) and antibonding (t_{2g}^*) MOs. The energy separation between the t_{2g}^* and e_g^* levels corresponds to Δ_{oct}. Figure 20.15b shows the interaction between a metal ion and six π-acceptor ligands. The vacant ligand π^*-orbitals lie significantly higher in energy than the ligand σ-orbitals.

THEORY



Box 20.2 The t_{2g} set of ligand π-orbitals for an octahedral complex

Figure 20.15 shows *three* ligand group π-orbitals and you may wonder how these arise from the combination of six ligands, especially since we show a simplistic view of the π-interactions in Fig. 20.14. In an octahedral $[ML_6]^{n+}$ complex with six π-donor or -acceptor ligands lying on the x, y and z axes, each ligand provides *two* π-orbitals, e.g. for ligands on the x axis, both p_y and p_z orbitals are available for π-bonding. Now consider just one plane containing four ligands of the octahedral complex, e.g. the xz plane. Diagram (a) below shows a ligand group orbital (LGO) comprising the p_z orbitals of two ligands and the p_x orbitals of the other two. Diagram (b) shows how the LGO in (a) combines with the metal d_{xz} orbital to give a bonding MO, while (c) shows the antibonding combination.

Three LGOs of the type shown in (a) can be constructed, one in each plane, and these can, respectively, overlap with the metal d_{xy}, d_{yz} and d_{xz} atomic orbitals to give the t_{2g} and t_{2g}^* MOs shown in Fig. 20.15.

Self-study exercise

Show that, under O_h symmetry, the LGO in diagram (a) belongs to a t_{2g} set.

Orbital interaction leads to bonding (t_{2g}) and antibonding (t_{2g}^*) MOs as before, but now the t_{2g}^* MOs are at high energy and Δ_{oct} is identified as the energy separation between the t_{2g} and e_g^* levels (Fig. 20.15b).

Although Figs. 20.13 and 20.15 are qualitative, they reveal important differences between octahedral $[ML_6]^{n+}$ complexes containing σ-donor, π-donor and π-acceptor ligands:

- Δ_{oct} *decreases* on going from a σ-complex to one containing π-donor ligands;
- for a complex with π-donor ligands, increased π-donation stabilizes the t_{2g} level and destabilizes the t_{2g}^*, thus decreasing Δ_{oct};
- Δ_{oct} values are relatively large for complexes containing π-acceptor ligands, and such complexes are likely to be low-spin;
- for a complex with π-acceptor ligands, increased π-acceptance stabilizes the t_{2g} level, increasing Δ_{oct}.

The above points are consistent with the positions of the ligands in the spectrochemical series; π-donors such as I^- and Br^- are weak-field, while π-acceptor ligands such as CO and $[CN]^-$ are strong-field ligands.

We complete this section by considering the occupancies of the MOs in Figs. 20.15a and b. Six π-donor ligands provide 18 electrons (12 σ- and six π-electrons) and these can *notionally* be considered to occupy the a_{1g}, t_{1u}, e_g and t_{2g} orbitals of the complex. The occupancy of the t_{2g}^* and e_g^* levels corresponds to the number of valence electrons of the metal ion. Six π-acceptor ligands provide 12 electrons (i.e. 12 σ-electrons since the π^*-ligand orbitals are empty) and, *formally*, we can place these in the a_{1g}, t_{1u} and e_g orbitals of the complex. The number of electrons supplied by the metal centre then corresponds to the occupancy of the t_{2g} and e_g^* levels. Since occupying *antibonding* MOs lowers the metal–ligand bond order, it follows that, for example, octahedral complexes with π-accepting ligands will not be favoured for metal centres with d^7, d^8, d^9 or d^{10} configurations. This last point brings us back to some fundamental observations in experimental inorganic chemistry: *d*-block metal organometallic and related complexes tend to obey the *effective atomic number rule* or *18-electron rule*. Worked example 20.2 illustrates this rule, and we return to its applications in Chapter 24.

A low oxidation state organometallic complex contains π-acceptor ligands and the metal centre tends to acquire 18 electrons in its valence shell (the ***18-electron rule***), thus filling the valence orbitals, e.g. Cr in $Cr(CO)_6$, Fe in $Fe(CO)_5$, and Ni in $Ni(CO)_4$.

Worked example 20.2 18-Electron rule

Show that $Cr(CO)_6$ obeys the 18-electron rule.

The Cr(0) centre has six valence electrons.

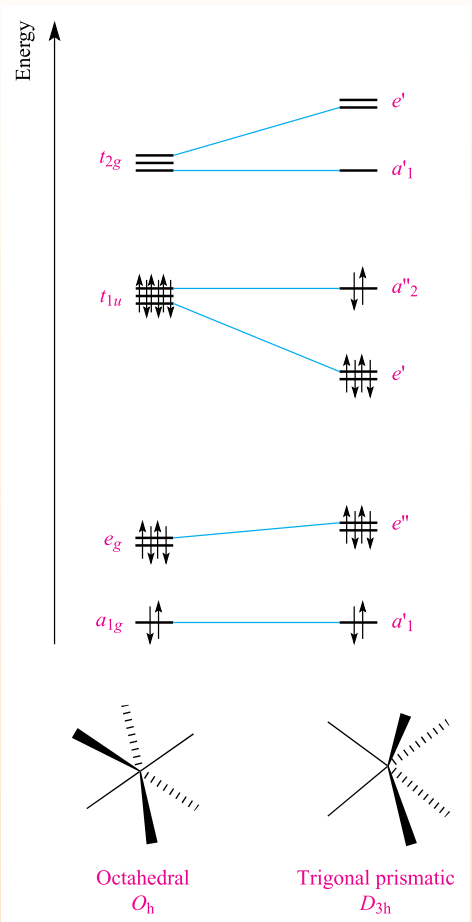
CO is a π-acceptor ligand, and each CO ligand is a 2-electron donor.

The total electron count at the metal centre in $Cr(CO)_6 = 6 + (6 \times 2) = 18$.

Self-study exercises

1. Show that the metal centre in each of the following obeys the 18-electron rule: (a) $Fe(CO)_5$; (b) $Ni(CO)_4$; (c) $[Mn(CO)_5]^-$; (d) $Mo(CO)_6$.
2. (a) How many electrons does a PPh_3 ligand donate? (b) Use your answer to (a) to confirm that the Fe centre in $Fe(CO)_4(PPh_3)$ obeys the 18-electron rule.
3. What is the oxidation state of each metal centre in the complexes in question (1)?

[*Ans.* (a) 0; (b) 0; (c) −1; (d) 0]



In applying the 18-electron rule, one clearly needs to know the number of electrons donated by a ligand, e.g. CO is a

THEORY

Box 20.3 Octahedral versus trigonal prismatic d^0 and d^1 metal complexes

In Section 19.7, we stated that there is a small group of d^0 or d^1 metal complexes in which the metal centre is in a trigonal prismatic (e.g. $[TaMe_6]^-$ and $[ZrMe_6]^{2-}$) or distorted trigonal prismatic (e.g. $[MoMe_6]$ and $[WMe_6]$) environment. The methyl groups in these d^0 complexes form M–C σ-bonds, and 12 electrons are available for the bonding: one electron from each ligand and six electrons from the metal, including those from the negative charge where applicable. (In counting electrons, we assume a zero-valent metal centre: see Section 24.3.) The qualitative energy level diagram drawn opposite shows that, in a model MH_6 complex with an octahedral structure, these 12 electrons occupy the a_{1g}, e_g and t_{1u} MOs. Now consider what happens if we change the geometry of the model MH_6 complex from octahedral to trigonal prismatic. The point group changes from O_h to D_{3h}, and as a consequence, the properties of the MOs change as shown in the figure. The number of electrons stays the same, but there is a net gain in energy. This stabilization explains why d^0 (and also d^1) complexes of the MMe_6 type show a preference for a trigonal prismatic structure. However, the situation is further complicated because of the observation that $[MoMe_6]$ and $[WMe_6]$, for example, exhibit structures with C_{3v} symmetry (i.e. distorted trigonal prismatic): three of the M–C bonds are normal but three are elongated and have smaller angles between them. This distortion can also be explained in terms of MO theory, since additional orbital stabilization for the 12-electron system is achieved with respect to the D_{3h} structure.

K. Seppelt (2003) *Acc. Chem. Res.*, vol. 36, p. 147 – 'Non-octahedral structures'.

2-electron donor. An ambiguity arises over NO groups in complexes. Nitrosyl complexes fall into two classes:

- NO as a 3-electron donor: crystallographic data show linear M−N−O (observed range ∠M−N−O = 165–180°) and short M−N and N−O bonds indicating multiple bond character; IR spectroscopic data give ν(NO) in the range 1650–1900 cm^{-1}; the bonding mode is represented as **20.7** with the N atom taken to be *sp* hybridized.
- NO as a 1-electron donor: crystallographic data reveal a bent M−N−O group (observed range ∠M−N−O ≈ 120–140°), and N−O bond length typical of a double bond; IR spectroscopic data show ν(NO) in the range 1525–1690 cm^{-1}; the bonding mode is represented as **20.8** with the N atom considered as sp^2 hybridized.

(20.7)

(20.8)

Although the 18-electron rule is quite widely obeyed for low oxidation state organometallic compounds containing π-acceptor ligands, it is useless for higher oxidation state metals. This is clear from examples of octahedral complexes cited in Section 19.7, and can be rationalized in terms of the smaller energy separations between bonding and antibonding orbitals illustrated in Figs. 20.13 and 20.15a compared with that in Fig. 20.15b.

We could extend our arguments to complexes such as $[CrO_4]^{2-}$ and $[MnO_4]^-$ showing how π-donor ligands help to stabilize high oxidation state complexes. However, for a valid discussion of these examples, we need to construct new MO diagrams appropriate to tetrahedral species. To do so would not provide much more insight than we have gained from considering the octahedral case, and interested readers are directed to more specialized texts.[†]

20.5 Ligand field theory

Although we shall not be concerned with the mathematics of ligand field theory, it is important to comment upon it briefly since we shall be using ligand field stabilization energies (LFSEs) later in this chapter.

Ligand field theory is an extension of crystal field theory which is freely parameterized rather than taking a localized field arising from point charge ligands.

Ligand field, like crystal field, theory is *confined* to the role of *d* orbitals, but unlike the crystal field model, the ligand field approach is *not* a purely electrostatic model. It is a freely parameterized model, and uses Δ_{oct} and *Racah parameters* (to which we return later) which are obtained from electronic spectroscopic (i.e. *experimental*) data. Most importantly, although (as we showed in the last section) it is possible to approach the bonding in *d*-block metal complexes by using molecular orbital theory, it is *incorrect* to state that ligand field theory is simply the application of MO theory.[‡]

20.6 Describing electrons in multi-electron systems

In crystal field theory, the splitting of the *d*-orbitals is a result of the repulsions between *d*-electrons and ligand electrons. We ignore interactions between *d*-electrons on the metal centre. This is actually an aspect of a more general question about how we describe the interactions between electrons in multi-electron systems. We will now show why simple electron configurations such as $2s^2 2p^1$ or $4s^2 3d^2$ do not uniquely define the arrangement of the electrons. This leads us to an introduction of term symbols for free atoms and ions. For the most part, use of these symbols is confined to our discussions of the electronic spectra of *d*- and *f*-block complexes. In Section 1.7, we showed how to assign a set of quantum numbers to a given electron. For many purposes, this level of discussion is adequate. However, for an understanding of electronic spectra, a more detailed discussion is required. Before studying this section, you should review Box 1.4.

Quantum numbers *L* and M_L for multi-electron species

In the answer to worked example 1.7, we ignored a complication. In assigning quantum numbers to the four 2*p* electrons, how do we indicate whether the last electron is in an orbital with $m_l = +1$, 0 or −1? This, and related questions, can be answered only by considering the interaction of electrons, primarily by means of the *coupling* of magnetic fields generated by their spin or orbital motion: hence the importance of spin and orbital angular momentum (see Section 1.6).

For any system containing more than one electron, the energy of an electron with principal quantum number *n* depends on the value of *l*, and this also determines the orbital angular momentum which is given by eq. 20.8 (see Box 1.4).

[†] For application of MO theory to geometries other than octahedral, see Chapter 9 in: J.K. Burdett (1980) *Molecular Shapes: Theoretical Models of Inorganic Stereochemistry*, Wiley, New York.

[‡] For a more detailed introduction to ligand field theory, see: M. Gerloch and E.C. Constable (1994) *Transition Metal Chemistry: The Valence Shell in d-Block Chemistry*, VCH, Weinheim, pp. 117–120; also see the further reading list at the end of the chapter.

$$\text{Orbital angular momentum} = \left(\sqrt{l(l+1)}\right)\frac{h}{2\pi} \qquad (20.8)$$

The energy and the orbital angular momentum of a multi-electron species are determined by a new quantum number, L, which is related to the values of l for the individual electrons. Since the orbital angular momentum has magnitude *and* $(2l+1)$ spatial orientations with respect to the z axis (i.e. the number of values of m_l), *vectorial* summation of individual l values is necessary. The value of m_l for any electron denotes the component of its orbital angular momentum, $m_l(h/2\pi)$, along the z axis (see Box 1.4). Summation of m_l values for individual electrons in a multi-electron system therefore gives the resultant orbital magnetic quantum number M_L:

$$M_L = \sum m_l$$

Just as m_l may have the $(2l+1)$ values $l, (l-1) \ldots 0 \ldots -(l-1), -l$, so M_L can have $(2L+1)$ values $L, (L-1) \ldots 0 \ldots -(L-1), -L$. If we can find all possible values of M_L for a multi-electron species, we can determine the value of L for the system.

As a means of cross-checking, it is useful to know what values of L are possible. The allowed values of L can be determined from l for the individual electrons in the multi-electron system. For two electrons with values of l_1 and l_2:

$$L = (l_1 + l_2), (l_1 + l_2 - 1), \ldots \ |l_1 - l_2|$$

The *modulus* sign around the last term indicates that $|l_1 - l_2|$ may only be zero or a positive value. As an example, consider a p^2 configuration. Each electron has $l = 1$, and so the allowed values of L are 2, 1 or 0. Similarly, for a d^2 configuration, each electron has $l = 2$, and so the allowed values of L are 4, 3, 2, 1 or 0. For systems with three or more electrons, the electron–electron coupling must be considered in sequential steps: couple l_1 and l_2 as above to give a resultant L, and then couple L with l_3, and so on.

Energy states for which $L = 0, 1, 2, 3, 4 \ldots$ are known as S, P, D, F, $G \ldots$ terms, respectively. These are analogous to the $s, p, d, f, g \ldots$ labels used to denote atomic orbitals with $l = 0$, 1, 2, 3, 4... in the 1-electron case. By analogy with eq. 20.8, eq. 20.9 gives the resultant orbital angular momentum for a multi-electron system.

$$\text{Orbital angular momentum} = \left(\sqrt{L(L+1)}\right)\frac{h}{2\pi} \qquad (20.9)$$

Quantum numbers S and M_S for multi-electron species

Now let us move from the orbital quantum number to the spin quantum number. In Section 1.6, we stated that the spin quantum number, s, determines the magnitude of the spin angular momentum of an electron and has a value of $\frac{1}{2}$. For a 1-electron species, m_s is the magnetic spin angular momentum and has a value of $+\frac{1}{2}$ or $-\frac{1}{2}$. We now need to define the quantum numbers S and M_S for multi-electron species. The spin angular momentum for a multi-electron species is given by eq. 20.10, where S is the total spin quantum number.

$$\text{Spin angular momentum} = \left(\sqrt{S(S+1)}\right)\frac{h}{2\pi} \qquad (20.10)$$

The quantum number M_S is obtained by algebraic summation of the m_s values for individual electrons:

$$M_S = \sum m_s$$

For a system with n electrons, each having $s = \frac{1}{2}$, possible values of S fall into two series depending on the total number of electrons:

- $S = \frac{1}{2}, \frac{3}{2}, \frac{5}{2} \ldots$ for an odd number of electrons;
- $S = 0, 1, 2 \ldots$ for an even number of electrons.

S cannot take negative values. The case of $S = \frac{1}{2}$ clearly corresponds to a 1-electron system, for which values of m_s are $+\frac{1}{2}$ or $-\frac{1}{2}$, and values of M_S are also $+\frac{1}{2}$ or $-\frac{1}{2}$. For each value of S, there are $(2S+1)$ values of M_S :

$$\text{Allowed values of } M_S: \quad S, (S-1), \ldots -(S-1), -S$$

Thus, for $S = 0$, $M_S = 0$, for $S = 1$, $M_S = 1, 0$ or -1, and for $S = \frac{3}{2}$, $M_S = \frac{3}{2}, \frac{1}{2}, -\frac{1}{2}$ or $-\frac{3}{2}$.

Microstates and term symbols

With sets of quantum numbers in hand, the electronic states (*microstates*) that are possible for a given electronic configuration can be determined. This is best achieved by constructing a table of microstates, remembering that:

- no two electrons may possess the same set of quantum numbers (the Pauli exclusion principle);
- only *unique* microstates may be included.

Let us start with the case of two electrons in s orbitals. There are two general electronic configurations which describe this: ns^2 and $ns^1n's^1$. Our aim is to determine the possible arrangements of electrons within these two configurations. This will give us a general result which relates all ns^2 states (regardless of n) and another which relates all $ns^1n's^1$ states (regardless of n and n'). An extension of these results leads to the conclusion that a single electronic configuration (e.g. $2s^22p^2$) does *not* define a unique arrangement of electrons.

Case 1: ns^2 configuration

An electron in an s atomic orbital must have $l = 0$ and $m_l = 0$, and for each electron, m_s can be $+\frac{1}{2}$ or $-\frac{1}{2}$. The ns^2 configuration is described in Table 20.4. Applying the Pauli exclusion principle means that the two electrons in a given

Table 20.4 Table of microstates for an ns^2 configuration; an electron with $m_s = +\frac{1}{2}$ is denoted as ↑, and an electron with $m_s = -\frac{1}{2}$ is denoted as ↓. The two microstates are identical and so one row can be discounted (see text for explanation).

First electron: $m_l = 0$	Second electron: $m_l = 0$	$M_L = \Sigma m_l$	$M_S = \Sigma m_s$	
↑	↓	0	0	$L = 0, S = 0$
~~↓~~	~~↑~~			

microstate must have different values of m_s, i.e. ↑ and ↓ in one row in Table 20.4. A second arrangement of electrons is given in Table 20.4, but now we must check whether this is the same as or different from the first arrangement. We cannot physically distinguish the electrons, so must use sets of quantum numbers to decide if the microstates (i.e. rows in the table) are the same or different:

- first microstate: $l=0$, $m_l=0$, $m_s=+\frac{1}{2}$; $l=0$, $m_l=0$, $m_s=-\frac{1}{2}$;
- second microstate: $l=0$, $m_l=0$, $m_s=-\frac{1}{2}$; $l=0$, $m_l=0$, $m_s=+\frac{1}{2}$.

The microstates are identical (the electrons have simply been switched around) and so one microstate is discounted. Hence, for the ns^2 configuration, only one microstate is possible. The values of M_S and M_L are obtained by reading across the table. The result in Table 20.4 is represented as a *term symbol* which has the form ${}^{(2S+1)}L$, where $(2S + 1)$ is called the *multiplicity* of the term:

Multiplicity of the term → $(2S + 1)L$ ←
- $L = 0$ S term
- $L = 1$ P term
- $L = 2$ D term
- $L = 3$ F term
- $L = 4$ G term

Terms for which $(2S + 1) = 1, 2, 3, 4$ ... (corresponding to $S = 0, \frac{1}{2}, 1, \frac{3}{2}$ ...) are called *singlet*, *doublet*, *triplet*, *quartet* ... terms, respectively. Hence, the ns^2 configuration in Table 20.4 corresponds to a ${}^1S$ term (a 'singlet S term').†

Case 2: $ns^1n's^1$ configuration

Table 20.5 shows allowed microstates for an $ns^1n's^1$ configuration. It is important to check that the three microstates are indeed different from one another:

- first microstate: $l = 0$, $m_l = 0$, $m_s = +\frac{1}{2}$; $l = 0$, $m_l = 0$, $m_s = +\frac{1}{2}$;
- second microstate: $l = 0$, $m_l = 0$, $m_s = +\frac{1}{2}$; $l = 0$, $m_l = 0$, $m_s = -\frac{1}{2}$;
- third microstate: $l = 0$, $m_l = 0$, $m_s = -\frac{1}{2}$; $l = 0$, $m_l = 0$, $m_s = -\frac{1}{2}$.

† S is used for the resultant spin quantum number as well as a term with $L = 0$, but, in practice, this double usage rarely causes confusion.

Table 20.5 Table of microstates for an $ns^1n's^1$ configuration. An electron with $m_s = +\frac{1}{2}$ is denoted as ↑, and an electron with $m_s = -\frac{1}{2}$ as ↓. Each row in the table corresponds to a different microstate.

First electron: $m_l = 0$	Second electron: $m_l = 0$	$M_L = \Sigma m_l$	$M_S = \Sigma m_s$	
↑	↑	0	+1	} $L = 0$, $S = 1$
↑	↓	0	0	
↓	↓	0	−1	

Values of M_S and M_L are obtained by reading across the table. Values of L and S are obtained by fitting the values of M_S and M_L to the series:

M_L : L, $(L - 1)$ ... 0, ... $-(L - 1)$, $-L$
M_S : S, $(S - 1)$ ... $-(S - 1)$, $-S$

and are shown in the right-hand column of Table 20.5. A value of $S = 1$ corresponds to a multiplicity of $(2S + 1) = 3$. This gives rise to a ${}^3S$ term (a 'triplet S term').

Self-study exercises

1. Show that an s^1 configuration corresponds to a ${}^2S$ term.
2. Show that a d^1 configuration corresponds to a ${}^2D$ term.
3. In Table 20.5, why is there not a microstate in which the first electron has $m_s=-\frac{1}{2}$, and the second electron has $m_s=+\frac{1}{2}$?

The quantum numbers J and M_J

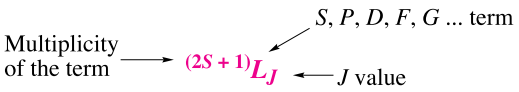
Before moving to further examples, we must address the interaction between the total angular orbital momentum, L, and the total spin angular momentum, S. To do so, we define the total angular momentum quantum number, J. Equation 20.11 gives the relationship for the total angular momentum for a multi-electron species.

$$\text{Total angular momentum} = \left(\sqrt{J(J+1)}\right)\frac{h}{2\pi} \qquad (20.11)$$

The quantum number J takes values $(L + S)$, $(L + S - 1)$ ... $|L - S|$, and these values fall into the series 0, 1, 2 ... or $\frac{1}{2}, \frac{3}{2}, \frac{5}{2}$ ... (like j for a single electron, J for the multi-electron system must be positive or zero). It follows that there are:

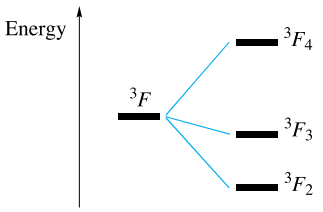
$(2S + 1)$ possible values of J for $S < L$;

$(2L + 1)$ possible values of J for $L < S$.



The value of M_J denotes the component of the total angular momentum along the z axis. Just as there are relationships

between S and M_S, and between L and M_L, there is one between J and M_J:



Allowed values of M_J : J, $(J-1)$ ... $-(J-1)$, $-J$

The method of obtaining J from L and S is based on LS (or *Russell–Saunders*) *coupling*, i.e. *spin–orbit coupling*. Although it is the only form of coupling of orbital and spin angular momentum that we shall consider in this book, it is not valid for all elements (especially those with high atomic numbers). In an alternative method of coupling, l and s for all the individual electrons are first combined to give j, and the individual j values are combined in a *j–j coupling* scheme.[†] The difference in coupling schemes arises from whether the spin–orbit interaction is greater or smaller than the orbit–orbit and spin–spin interactions between electrons.

We are now in a position to write *full* term symbols which include information about S, L and J. The notation for a full term symbol is:

A term symbol $^3P_0$ ('triplet P zero') signifies a term with $L=1$, $(2S+1)=3$ (i.e. $S=1$), and $J=0$. Different values of J denote different *levels* within the term, i.e. $^{(2S+1)}L_{J_1}$, $^{(2S+1)}L_{J_2}$ ..., for example:

The degeneracy of any J level is $(2J+1)$. This follows from the allowed M_J values being J, $(J-1)$ ... $-(J-1)$, $-J$. The J levels have different energies and we illustrate their importance when we discuss magnetic properties (see Fig. 20.28). In inorganic chemistry, it is often sufficient to write the term symbol without the J value, and refer simply to a $^{(2S+1)}L$ term as in the ns^2 and $ns^1n's^1$ examples that we described earlier.

Ground states of elements with Z = 1–10

In this section, we look in detail at the electronic ground states of atoms with $Z=1$ to 10. This allows you to practise writing tables of microstates, placing the microstates in groups so as to designate terms, and finally assigning ground or excited states. An understanding of this process is essential before we can proceed to a discussion of electronic spectroscopy. An important point to note is that *only electrons in open (incompletely filled) shells* (e.g. ns^1, np^2, nd^4) *contribute to the term symbol.*

When constructing tables of microstates, it is all too easy to write down a duplicate set, or to miss a microstate. The ns^2 and $ns^1n'p^1$ examples above are relatively simple, but for other systems, it is useful to follow a set of guidelines. Book-keeping of microstates is extremely important, if extremely tedious!

Follow these 'rules' when constructing a ***table of microstates***:

1. Write down the electron configuration (e.g. d^2).
2. Ignore closed shell configurations (e.g. ns^2, np^6, nd^{10}) as these will always give a $^1S_0$ term. This is totally symmetric and makes no contribution to the angular momentum.
3. Determine the number of microstates: for x electrons in a sub-level of $(2l+1)$ orbitals, this is given by:[‡]
$$\frac{\{2(2l+1)\}!}{x!\{2(2l+1)-x\}!}$$
4. Tabulate microstates by m_l and m_s, and sum to give M_L and M_S on each row. Check that the number of microstates in the table is the same as that expected from rule (3).
5. Collect the microstates into groups based on values of M_L.

Hydrogen ($Z=1$)

The electronic configuration for an H atom in its ground state is $1s^1$. For one electron in an s orbital ($l=0$):

$$\text{Number of microstates} = \frac{\{2(2l+1)\}!}{x!\{2(2l+1)-x\}!} = \frac{2!}{1!\times 1!} = 2$$

The table of microstates is as follows:

$m_l = 0$	$M_L = \Sigma m_l$	$M_S = \Sigma m_s$	
↑	0	$+\frac{1}{2}$	} $L = 0$, $S = \frac{1}{2}$
↓	0	$-\frac{1}{2}$	

Since $S = \frac{1}{2}$, the multiplicity of the term, $(2S+1)$, is 2 (a doublet term). Since $L=0$, this is a ^2S term. To determine J, look at the values: use $J = (L+S)$, $(L+S-1)$ ... $|L-S|$. The only possible value of J is $\frac{1}{2}$, so the complete term symbol for the H atom is $^2S_{1/2}$.

[†] For details of *j–j* coupling, see: M. Gerloch (1986) *Orbitals, Terms and States*, Wiley, Chichester, p. 74; H. Orofino and R.B. Faria (2010) *J. Chem. Educ.*, vol. 87, p. 1451.

[‡] The ! sign means *factorial*: $x! = x \times (x-1) \times (x-2) \ldots \times 1$.

Helium ($Z = 2$)

The electronic configuration of a ground state He atom is $1s^2$ ($l = 0$) and hence the table of microstates is like that in Table 20.4:

$m_l = 0$	$m_l = 0$	$M_L = \Sigma m_l$	$M_S = \Sigma m_s$	
↑	↓	0	0	$L = 0, S = 0$

Since $M_L = 0$ and $M_S = 0$, it follows that $L = 0$ and $S = 0$. The only value of J is 0, and so the term symbol is $^1S_0$.

Lithium ($Z = 3$)

Atomic Li has the ground state electronic configuration $1s^2 2s^1$. Since only the $2s^1$ configuration contributes to the term symbol, the term symbol for Li is the same as that for H (both in their ground states): $^2S_{1/2}$.

Beryllium ($Z = 4$)

The ground state electronic configuration of Be is $1s^2 2s^2$, and contains only closed configurations. Therefore, the term symbol for the ground state of Be is like that of He: $^1S_0$.

Boron ($Z = 5$)

When we consider boron ($1s^2 2s^2 2p^1$), a new complication arises. Only the $2p^1$ configuration contributes to the term symbol, but because there are three distinct p orbitals ($m_l = +1$, 0 or -1), the p^1 configuration cannot be represented by a unique term symbol. For one electron in a p orbital ($l = 1$):

$$\text{Number of microstates} = \frac{\{2(2l+1)\}!}{x!\{2(2l+1)-x\}!}$$
$$= \frac{6!}{1! \times 5!} = 6$$

A table of microstates for the $2p^1$ configuration is as follows:

$m_l = +1$	$m_l = 0$	$m_l = -1$	M_L	M_S	
↑			+1	$+\frac{1}{2}$	$L = 1, S = \frac{1}{2}$
	↑		0	$+\frac{1}{2}$	
		↑	−1	$+\frac{1}{2}$	
		↓	−1	$-\frac{1}{2}$	$L = 1, S = \frac{1}{2}$
	↓		0	$-\frac{1}{2}$	
↓			+1	$-\frac{1}{2}$	

The microstates fall into two sets with $M_L = +1, 0, -1$, and therefore with $L = 1$ (a P term); $S = \frac{1}{2}$ and so $(2S+1) = 2$ (a doublet term). J can take values $(L+S)$, $(L+S-1)$ … $|L-S|$, and so $J = \frac{3}{2}$ or $\frac{1}{2}$. The term symbol for boron may be $^2P_{3/2}$ or $^2P_{1/2}$.

Providing that Russell–Saunders coupling holds, the relative energies of the terms for a given configuration can be found by stating Hund's rules in a formal way:

For the ***relative energies of terms*** for a given electronic configuration:

1. The term with the highest spin multiplicity has the lowest energy.
2. If two or more terms have the same multiplicity (e.g. ^3F and ^3P), the term having the highest value of L has the lowest energy (e.g. ^3F is lower than ^3P).
3. For terms having the same multiplicity and the same values of L (e.g. $^3P_0$ and $^3P_1$), the level with the lowest value of J is the lowest in energy if the sub-level is less than half-filled (e.g. p^2), and the level with the highest value of J is the more stable if the sub-level is more than half-filled (e.g. p^4). If the level is half-filled with maximum spin multiplicity (e.g. p^3 with $S = \frac{3}{2}$), L must be zero, and $J = S$.

For boron, there are two terms to consider: $^2P_{3/2}$ or $^2P_{1/2}$. These are both doublet terms, and both have $L = 1$. For the p^1 configuration, the p level is less than half-filled, and therefore the ground state level is the one with the lower value of J, i.e. $^2P_{1/2}$.

Carbon ($Z = 6$)

The electron configuration of carbon is $1s^2 2s^2 2p^2$, but only the $2p^2$ ($l = 1$) configuration contributes to the term symbol:

$$\text{Number of microstates} = \frac{\{2(2l+1)\}!}{x!\{2(2l+1)-x\}!}$$
$$= \frac{6!}{2! \times 4!} = 15$$

The table of microstates for a p^2 configuration is given in Table 20.6. The microstates have been grouped according

Table 20.6 Table of microstates for a p^2 configuration. An electron with $m_s = +\frac{1}{2}$ is denoted as ↑, and an electron with $m_s = -\frac{1}{2}$ by ↓.

$m_l = +1$	$m_l = 0$	$m_l = -1$	M_L	M_S	
↑↓			2	0	$L = 2, S = 0$
↑	↓		1	0	
	↑↓		0	0	
	↑	↓	−1	0	
		↑↓	−2	0	
↑	↑		1	1	$L = 1, S = 1$
↑		↑	0	1	
	↑	↑	−1	1	
↓	↑		1	0	
↓		↑	0	0	
	↓	↑	−1	0	
↓	↓		1	−1	
↓		↓	0	−1	
	↓	↓	−1	−1	
↑		↓	0	0	$L = 0, S = 0$

to values of M_L and M_S. Remember that values of L and S are derived by looking for sets of M_L and M_S values:

Allowed values of M_L : $L, (L-1), ..., 0, ... -(L-1), -L$
Allowed values of M_S : $S, (S-1), ... -(S-1), -S$

There is no means of telling which entry with $M_L = 0$ and $M_S = 0$ should be assigned to which term (or similarly, how entries with $M_L = 1$ and $M_S = 0$, or $M_L = -1$ and $M_S = 0$ should be assigned). *Indeed, it is not meaningful to do so*. Term symbols are now assigned as follows:

- $L = 2$, $S = 0$ gives the singlet term, ^1D; J can take values $(L + S), (L + S - 1) ... |L - S|$, so only $J = 2$ is possible; the term symbol is $^1D_2$.
- $L = 1$, $S = 1$ corresponds to a triplet term; possible values of J are 2, 1, 0 giving the terms $^3P_2$, $^3P_1$ and $^3P_0$.
- $L = 0$, $S = 0$ corresponds to a singlet term, and only $J = 0$ is possible; the term symbol is $^1S_0$.

The predicted energy ordering (from the rules above) is $^3P_0 < {}^3P_1 < {}^3P_2 < {}^1D_2 < {}^1S_0$, and the ground state is the $^3P_0$ term.

Nitrogen to neon ($Z = 7$–10)

A similar treatment for the nitrogen atom shows that the $2p^3$ configuration gives rise to ^4S, ^2P and ^2D terms. For the $2p^4$ configuration (oxygen), we introduce a useful simplification by considering the $2p^4$ case in terms of microstates arising from two positrons. This follows from the fact that a positron has the same spin and angular momentum properties as an electron, and differs only in charge. Hence, the terms arising from the np^4 and np^2 configurations are the same. Similarly, np^5 is equivalent to np^1. This positron or *positive hole* concept is very useful and we shall later extend it to *nd* configurations.

Self-study exercises

1. Show that the terms for the $3s^2 3p^2$ configuration of Si are $^1D_2$, $^3P_2$, $^3P_1$, $^3P_0$ and $^1S_0$, and that the ground term is $^3P_0$.
2. Show that the ground term for the $2s^2 2p^5$ configuration of an F atom is $^2P_{3/2}$.
3. Confirm that a p^3 configuration has 20 possible microstates.
4. Show that the $2s^2 2p^3$ configuration of nitrogen leads to ^4S, ^2D and ^2P terms, and that the ground term is $^4S_{3/2}$.

The d^2 configuration

Finally in this section, we move to d electron configurations. With $l = 2$, and up to 10 electrons, tables of microstates soon become large. We consider only the d^2 configuration for which:

$$\text{Number of microstates} = \frac{\{2(2l+1)\}!}{x!\{2(2l+1)-x\}!}$$

$$= \frac{10!}{2! \times 8!} = 45$$

Table 20.7 shows the 45 microstates which have been arranged according to values of M_L and M_S. Once again, remember that for microstates such as those with $M_L = 0$ and $M_S = 0$, there is no means of telling which entry should be assigned to which term. The terms arising from the microstates in Table 20.7 are determined as follows:

- $L = 3$, $S = 1$ gives a ^3F term with J values of 4, 3 or 2 ($^3F_4$, $^3F_3$, $^3F_2$);
- $L = 4$, $S = 0$ gives a ^1G term with only $J = 4$ possible ($^1G_4$);
- $L = 2$, $S = 0$ gives a ^1D term with only $J = 2$ possible ($^1D_2$);
- $L = 1$, $S = 1$ gives a ^3P term with J values of 2, 1 or 0 ($^3P_2$, $^3P_1$, $^3P_0$);
- $L = 0$, $S = 0$ gives a ^1S term with only $J = 0$ possible ($^1S_0$).

The relative energies of these terms are determined by considering Hund's rules. The terms with the highest spin multiplicity are the ^3F and ^3P, and of these, the term with higher value of L has the lower energy. Therefore, ^3F is the ground term. The remaining terms are all singlets and so their relative energies depend on the values of L. Hund's rules therefore predict the energy ordering of the terms for a d^2 configuration to be $^3F < {}^3P < {}^1G < {}^1D < {}^1S$.

The d^2 configuration is less than a half-filled level and so, if we include the J values, a more detailed description of the predicted ordering of the terms is $^3F_2 < {}^3F_3 < {}^3F_4 < {}^3P_0 < {}^3P_1 < {}^3P_2 < {}^1G_4 < {}^1D_2 < {}^1S_0$. We return to this ordering when we discuss Racah parameters in Section 20.7, and magnetism. Note that the predicted ordering of higher levels needs to be viewed with caution (compare the predicted order above with that in Fig. 20.24 and see the discussion of Racah parameters).

Self-study exercises

Further explanations for the answers can be found by reading Section 20.6.

1. Set up a table of microstates for a d^1 configuration and show that the term symbol is ^2D, and that the ground term is $^2D_{3/2}$.
2. Explain why a value of $S = 1$ corresponds to a triplet state.
3. The terms for a d^2 configuration are ^1D, ^3F, ^1G, ^3P and ^1S. Which is the ground state term? Rationalize your answer.

Table 20.7 Table of microstates for a d^2 configuration. An electron with $m_s = +\frac{1}{2}$ is denoted as ↑, and an electron with $m_s = -\frac{1}{2}$ by ↓.

$m_l = +2$	$m_l = +1$	$m_l = 0$	$m_l = -1$	$m_l = -2$	M_L	M_S	
↑	↑				+3	+1	
↑		↑			+2	+1	
↑			↑		+1	+1	
↑				↑	0	+1	
	↑			↑	−1	+1	
		↑		↑	−2	+1	
			↑	↑	−3	+1	
↑	↓				+3	0	
↑		↓			+2	0	
↑			↓		+1	0

	↓		↓		0	−1	
		↓	↓		−1	−1	
		↑↓			0	0	$L = 0, S = 0$

4. Explain why a d^9 configuration has the same ground state term as a d^1 configuration.

5. Set up a table of microstates for a d^5 configuration, considering *only* those microstates with the highest possible spin multiplicity (the *weak field limit*). Show that the term symbol for the ground term is $^6S_{5/2}$.

20.7 Electronic spectra: absorption

Spectral features

A characteristic feature of many *d*-block metal complexes is their colours, which arise because they absorb light in the visible region (e.g. Fig. 20.4). Studies of electronic spectra of metal complexes provide information about structure

Table 20.8 Typical ε_{max} values for electronic absorptions. A large ε_{max} corresponds to an intense absorption and, if the absorption is in the visible region, a highly coloured complex.

Type of transition	Typical ε_{max} / dm^3 mol^{-1} cm^{-1}	Example
Spin-forbidden '*d*–*d*'	<1	$[Mn(OH_2)_6]^{2+}$ (high-spin d^5)
Laporte-forbidden, spin-allowed '*d*–*d*'	1–10 10–1000	Centrosymmetric complexes, e.g. $[Ti(OH_2)_6]^{3+}$ (d^1) Non-centrosymmetric complexes, e.g. $[NiCl_4]^{2-}$
Charge transfer (fully allowed)	1000–50 000	$[MnO_4]^-$

and bonding, although interpretation of the spectra is not always straightforward. Absorptions arise from transitions between electronic energy levels:

- transitions between metal-centred orbitals possessing *d*-character ('*d*–*d*' transitions);
- transitions between metal- and ligand-centred MOs which transfer charge from metal to ligand or ligand to metal (charge transfer bands).

Electronic absorption spectra and the notation for electronic transitions were introduced in Section 4.7, along with the Beer–Lambert law which relates absorbance to the concentration of the solution. The molar extinction coefficient, ε_{max}, is determined from the Beer–Lambert law (eq. 20.12) and indicates the intensity of an absorption. Values of ε_{max} range from close to zero to >10 000 dm^3 mol^{-1} cm^{-1} (Table 20.8).

$$\varepsilon_{max} = \frac{A_{max}}{c \times \ell} \qquad (\varepsilon_{max} \text{ in dm}^3\,\text{mol}^{-1}\,\text{cm}^{-1}) \qquad (20.12)$$

An absorption band is characterized by both the wavelength, λ_{max}, of the absorbed electromagnetic radiation and ε_{max}. An absorption spectrum may be represented as a plot of absorbance (A) against wavelength (Fig. 20.16), ε against wavelength, A against wavenumber ($\bar{\nu}$), or ε against wavenumber (see Section 4.7). Wavelength is usually quoted in nm and wavenumber in cm^{-1}.

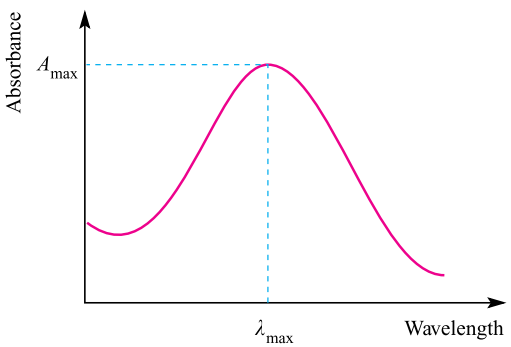

Fig. 20.16. Absorptions in the electronic spectrum of a molecule or molecular ion are often broad, and cover a range of wavelengths. The absorption is characterized by values of λ_{max} and ε_{max} (see eq. 20.12 to relate ε_{max} to A_{max}).

$$\bar{\nu} = \frac{1}{\lambda} = \frac{\nu}{c}$$

where: $\bar{\nu}$ = wavenumber; λ = wavelength; ν = frequency; c = speed of light

400 nm corresponds to 25 000 cm^{-1}; 200 nm corresponds to 50 000 cm^{-1}.

Some important points (for which explanations will be given later in the section) are that the electronic absorption spectra of:

- d^1, d^4, d^6 and d^9 complexes consist of one broad absorption;
- d^2, d^3, d^7 and d^8 complexes consist of three broad absorptions;
- d^5 complexes consist of a series of very weak, relatively sharp absorptions.

Self-study exercises

1. Show that 20 000 cm^{-1} = 500 nm.
2. Figure 20.4 shows the absorption spectrum of aqueous $[Ti(OH_2)_6]^{3+}$ as a plot of A against $\bar{\nu}$. How will the appearance of the plot change if it is redrawn as (a) A against λ, and (b) ε against $\bar{\nu}$? (c) What other information do you require to generate a plot of ε against $\bar{\nu}$?

Charge transfer absorptions

In Section 17.4, we introduced charge transfer bands in the context of their appearance in the UV region of the spectra of halogen-containing charge transfer complexes. In metal complexes, intense absorptions (typically in the UV or visible part of the electronic spectrum) may arise from

ligand-centred n–π^* or π–π^* transitions, or from the transfer of electronic charge between ligand and metal orbitals. The latter fall into two categories:

- transfer of an electron from an orbital with primarily ligand character to one with primarily metal character (ligand-to-metal charge transfer, LMCT).
- transfer of an electron from an orbital with primarily metal character to one with primarily ligand character (metal-to-ligand charge transfer, MLCT).

Charge transfer transitions are not restricted by the selection rules that govern '*d*–*d*' transitions (see later). The probability of these electronic transitions is therefore high, and the absorption bands are therefore intense (Table 20.8).

Since electron transfer from metal to ligand corresponds to metal oxidation and ligand reduction, an MLCT transition occurs when a ligand that is easily reduced is bound to a metal centre that is readily oxidized. Conversely, LMCT occurs when a ligand that is easily oxidized is bound to a metal centre (usually one in a high oxidation state) that is readily reduced. There is, therefore, a correlation between the energies of charge transfer absorptions and the electrochemical properties of metals and ligands.

Ligand-to-metal charge transfer may give rise to absorptions in the UV or visible region of the electronic spectrum. One of the most well-known examples is observed for $KMnO_4$. The deep purple colour of aqueous solutions of $KMnO_4$ arises from an intense LMCT absorption in the visible part of the spectrum (Fig. 20.17). This transition corresponds to the promotion of an electron from an orbital that is mainly oxygen lone pair in character to a low-lying, mainly Mn-centred orbital. The following series of complexes illustrate the effects of the metal, ligand and oxidation state of the metal on the position (λ_{max}) of the LMCT band:

- $[MnO_4]^-$ (528 nm), $[TcO_4]^-$ (286 nm), $[ReO_4]^-$ (227 nm);
- $[CrO_4]^{2-}$ (373 nm), $[MoO_4]^{2-}$ (225 nm), $[WO_4]^{2-}$ (199 nm);
- $[FeCl_4]^{2-}$ (220 nm), $[FeBr_4]^{2-}$ (244 nm);
- $[OsCl_6]^{3-}$ (282 nm), $[OsCl_6]^{2-}$ (370 nm).

Across the first two series above, the LMCT band moves to lower wavelength (higher energy) as the metal centre becomes harder to reduce (see Fig. 22.14). The values of the absorption maxima for $[FeX_4]^{2-}$ with different halido-ligands illustrate a shift to longer wavelength (lower energy) as the ligand becomes easier to oxidize (I^- easier than Br^-, easier than Cl^-). Finally, a comparison of two osmium complexes that differ only in the oxidation state of the metal centre illustrates that the observed ordering of the λ_{max} values is consistent with Os(IV) being easier to reduce than Os(III).

Metal-to-ligand charge transfer typically occurs when the ligand has a vacant, low-lying π^* orbital, for example, CO (see Fig. 2.15), py, bpy, phen and other heterocyclic, aromatic ligands. Often, the associated absorption occurs in the UV region of the spectrum and is not responsible for producing intensely coloured species. In addition, for ligands where a ligand-centred $\pi^* \leftarrow \pi$ transition is possible (e.g. heterocyclic aromatics such as bpy), the MLCT band may be obscured by the $\pi^* \leftarrow \pi$ absorption. For $[Fe(bpy)_3]^{2+}$ and $[Ru(bpy)_3]^{2+}$, the MLCT bands appear in the visible region at 520 and 452 nm, respectively. These are both metal(II) complexes, and the metal *d*-orbitals are relatively close in energy to the ligand π^* orbitals, giving rise to an MLCT absorption energy corresponding to the visible part of the spectrum.

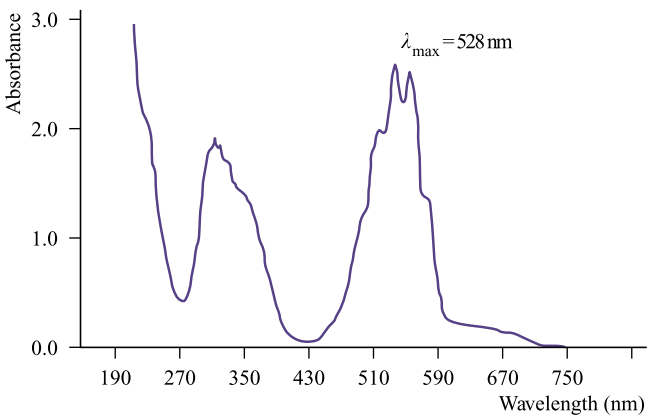

Fig. 20.17. Part of the electronic absorption spectrum of an aqueous solution of $KMnO_4$. Both absorptions arise from LMCT, but it is the band at 528 nm that gives rise to the observed purple colour. Very dilute solutions (here, 1.55×10^{-3} mol dm^{-3}) must be used so that the absorptions remain within the absorption scale.

Self-study exercises

1. Explain why aqueous solutions of $[MnO_4]^-$ are purple whereas those of $[ReO_4]^-$ are colourless.
2. Explain the origin of an absorption at 510 nm ($\varepsilon = 11\,000$ dm^3 mol^{-1} cm^{-1}) in the electronic absorption spectrum of $[Fe(phen)_3]^{2+}$ (phen, see Table 7.8).

Selection rules

As we saw in Section 20.6, electronic energy levels are labelled with term symbols. For the most part, we shall use the simplified form of these labels, omitting the *J* states. Thus, the term symbol is written in the general form:

Multiplicity of the term → $^{(2S+1)}L$ ←

$L = 0$	*S* term
$L = 1$	*P* term
$L = 2$	*D* term
$L = 3$	*F* term
$L = 4$	*G* term

Electronic transitions between energy levels obey the following selection rules:

Spin selection rule: $\Delta S = 0$

Transitions may occur from singlet to singlet, or from triplet to triplet states, and so on, but a change in spin multiplicity is *forbidden*.

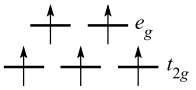
Laporte selection rule: There must be a change in parity:

allowed transitions:	$g \leftrightarrow u$	
forbidden transitions:	$g \leftrightarrow g$	$u \leftrightarrow u$

This leads to the selection rule:

$\Delta l = \pm 1$

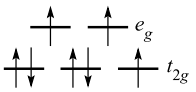
and, thus, *allowed* transitions are $s \rightarrow p$, $p \rightarrow d$, $d \rightarrow f$; *forbidden* transitions are $s \rightarrow s$, $p \rightarrow p$, $d \rightarrow d$, $f \rightarrow f$, $s \rightarrow d$, $p \rightarrow f$ etc.



Since these selection rules *must* be *strictly obeyed*, why do many *d*-block metal complexes exhibit '*d–d*' bands in their electronic absorption spectra?

A spin-forbidden transition becomes 'allowed' if, for example, a singlet state mixes to some extent with a triplet state. This is possible by *spin–orbit coupling* (see Section 20.6) but for first row metals, the degree of mixing is small and so bands associated with 'spin-forbidden' transitions are very weak (Table 20.8). Spin-allowed '*d–d*' transitions remain Laporte-forbidden and their observation is explained by a mechanism called '*vibronic coupling*'. An octahedral complex possesses a centre of symmetry, but molecular vibrations result in its temporary loss. At an instant when the molecule does *not* possess a centre of symmetry, mixing of *d* and *p* orbitals can occur. Since the lifetime of the vibration ($\approx 10^{-13}$ s) is longer than that of an electronic transition ($\approx 10^{-18}$ s), a '*d–d*' transition involving an orbital of mixed *pd* character can occur although the absorption is still relatively weak (Table 20.8). In a molecule which is non-centrosymmetric (e.g. tetrahedral), *p–d* mixing can occur to a greater extent and so the probability of '*d–d*' transitions is greater than in a centrosymmetric complex. This leads to tetrahedral complexes being more intensely coloured than octahedral complexes.

Worked example 20.3 Spin-allowed and spin-forbidden transitions



Explain why an electronic transition for high-spin $[Mn(OH_2)_6]^{2+}$ is spin-forbidden, but for $[Co(OH_2)_6]^{2+}$ is spin-allowed.

$[Mn(OH_2)_6]^{2+}$ is high-spin d^5 Mn(II):

A transition from a t_{2g} to e_g orbital is impossible without breaking the spin selection rule: $\Delta S = 0$.

$[Co(OH_2)_6]^{2+}$ is a high-spin d^7 Co(II) complex:

A transition from a t_{2g} to e_g orbital can occur without violating the spin selection rule.

NB: Transitions in both complexes are Laporte-forbidden.

Self-study exercises

1. Write down the spin selection rule.
[*Ans.* See text opposite]

2. What is the d^n configuration and the spin multiplicity of the ground state of (a) a Ti^{3+} and (b) a V^{3+} ion?
[*Ans.* (a) d^1; doublet; (b) d^2; triplet]

3. Why is a transition from a t_{2g} to an e_g orbital spin allowed in $[V(OH_2)_6]^{3+}$?
[*Ans.* Triplet to triplet; see question 1]

Electronic absorption spectra of octahedral and tetrahedral complexes

Electronic spectroscopy is a complicated topic and we shall restrict our discussion to high-spin complexes. This corresponds to the *weak field* limit. We begin with the electronic absorption spectrum of an octahedral d^1 ion, exemplified by $[Ti(OH_2)_6]^{3+}$. The spectrum of $[Ti(OH_2)_6]^{3+}$ (Fig. 20.4) exhibits one broad band. However, close inspection shows the presence of a shoulder indicating that the absorption is actually two closely spaced bands (see below). The term symbol for the ground state of Ti^{3+} (d^1, one electron with $L = 2$, $S = \frac{1}{2}$) is ^2D. In an octahedral field, this is split into $^2T_{2g}$ and ^2E_g terms separated by an energy Δ_{oct}. More generally, it can be shown from group theory that, in an octahedral or tetrahedral field, *D*, *F*, *G*, *H* and *I*, but not *S* and *P*, terms split. (Lanthanoid metal ions provide examples of ground state *H* and *I* terms: see Table 27.3.)

Term	Components in an octahedral field
S	A_{1g}
P	T_{1g}
D	$T_{2g} + E_g$
F	$A_{2g} + T_{2g} + T_{1g}$
G	$A_{1g} + E_g + T_{2g} + T_{1g}$
H	$E_g + T_{1g} + T_{1g} + T_{2g}$
I	$A_{1g} + A_{2g} + E_g + T_{1g} + T_{2g} + T_{2g}$

Similar splittings occur in a tetrahedral field, but the g labels are no longer applicable (see Box 20.1).

The splittings arise because the S, P, D, F and G terms refer to a degenerate set of d orbitals. In an octahedral field, this splits into the t_{2g} and e_g sets of orbitals (Fig. 20.2). For the d^1 ion (term symbol ^2D), there are therefore two possible configurations: $t_{2g}{}^1e_g{}^0$ or $t_{2g}{}^0e_g{}^1$, and these give rise to the $^2T_{2g}$ (ground state) and ^2E_g (excited state) terms. The energy separation between these states increases with increasing field strength (Fig. 20.18). The electronic absorption spectrum of Ti^{3+} arises from a transition from the T_{2g} to the E_g level. The energy of the transition depends on the field strength of the ligands in the octahedral Ti(III) complex. The observation that the absorption spectrum of $[Ti(OH_2)_6]^{3+}$ (Fig. 20.4) consists of two bands, rather than one, can be rationalized in terms of a Jahn–Teller effect in the excited state, $t_{2g}{}^0e_g{}^1$. Single occupancy of the e_g level results in a lowering of the degeneracy, although the resultant energy separation between the two orbitals is small. A corresponding effect in the t_{2g} set is even smaller and can be ignored. Hence, two transitions from ground to excited state are possible. These are close in energy and the spectrum exhibits two absorptions which are of similar wavelength.

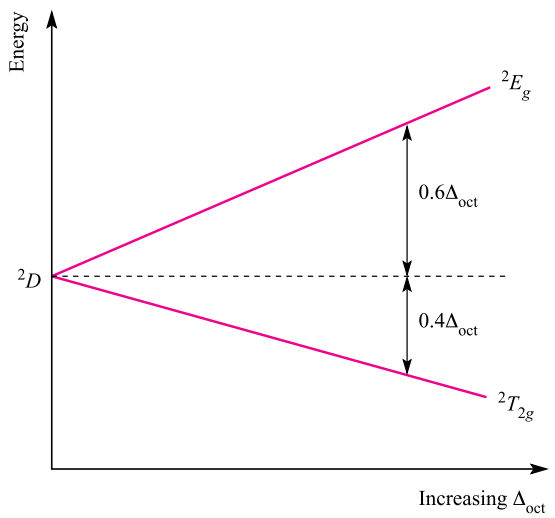


Fig. 20.18. Energy level diagram for a d^1 ion in an octahedral field.

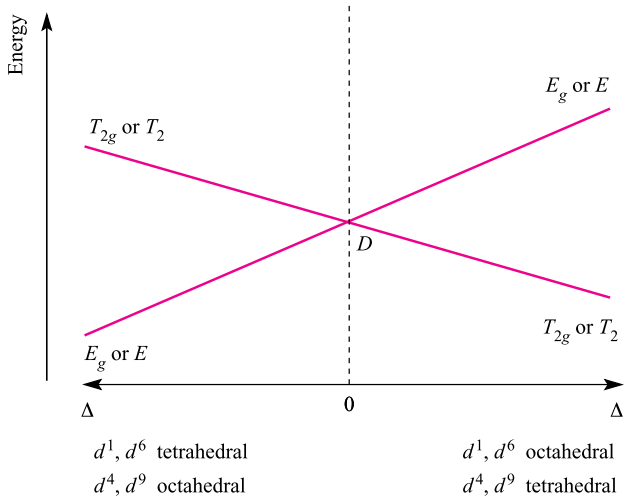

Fig. 20.19. Orgel diagram for d^1, d^4 (high-spin), d^6 (high-spin) and d^9 ions in octahedral (for which T_{2g} and E_g labels are relevant) and tetrahedral (E and T_2 labels) fields. In contrast to Fig. 20.18, multiplicities are not stated because they depend on the d^n configuration.

For the d^9 configuration (e.g. Cu^{2+}) in an octahedral field (actually, a rare occurrence because of Jahn–Teller effects which lower the symmetry), the ground state of the free ion (^2D) is again split into $^2T_{2g}$ and ^2E_g terms, but, in contrast to the d^1 ion (Fig. 20.18), the ^2E_g term is lower than the $^2T_{2g}$ term. The d^9 and d^1 configurations are related by a *positive hole* concept: d^9 is derived from a d^{10} configuration by replacing one electron by a positive hole. Thus, whereas the d^1 configuration contains one electron, d^9 contains one 'hole' (see Section 20.6). For a d^9 ion in an octahedral field, the splitting diagram is an inversion of that for the octahedral d^1 ion. This relationship is shown in Fig. 20.19 (an *Orgel diagram*) where the right-hand side describes the octahedral d^1 case and the left-hand side describes the octahedral d^9 ion.

Just as there is a relationship between the d^1 and d^9 configurations, there is a similar relationship between the d^4 and d^6 configurations. Further, we can relate the four configurations in an octahedral field as follows. In the weak-field limit, a d^5 ion is high-spin and spherically symmetric, and in this latter regard, d^0, d^5 and d^{10} configurations are analogous. Addition of one electron to the high-spin d^5 ion to give a d^6 configuration mimics going from a d^0 to d^1 configuration. Likewise, going from d^5 to d^4 by adding a positive hole mimics going from d^{10} to d^9. The result is that the Orgel diagrams for octahedral d^1 and d^6 ions are the same, as are the diagrams for octahedral d^4 and d^9 (Fig. 20.19).

Table 20.9 A shorthand table of microstates for a d^2 configuration; only a high-spin case (weak field limit) is considered, and each electron has $m_s = +\frac{1}{2}$. The microstates are grouped so as to show the derivation of the ^3F and ^3P terms. Table 20.7 provides the complete table of microstates for a d^2 ion.

$m_l = +2$	$m_l = +1$	$m_l = 0$	$m_l = -1$	$m_l = -2$	M_L	
↑	↑				+3	^3F (L = 3)
↑		↑			+2	
↑			↑		+1	
↑				↑	0	
	↑			↑	−1	
		↑		↑	−2	
			↑	↑	−3	
	↑	↑			+1	^3P (L = 1)
	↑		↑		0	
		↑	↑		−1	

Figure 20.19 also shows that the diagram for a d^1 or d^9 ion is inverted by going from an octahedral to tetrahedral field. Because the Orgel diagram uses a single representation for octahedral *and* tetrahedral fields, it is not possible to indicate that $\Delta_{tet} = \frac{4}{9}\Delta_{oct}$. Tetrahedral d^4 and d^6 ions can also be represented on the same Orgel diagram.

Finally, Fig. 20.19 shows that for each of the octahedral and tetrahedral d^1, d^4, d^6 and d^9 ions, only one electronic transition from a ground to excited state is possible:

- for octahedral d^1 and d^6, the transition is $E_g \leftarrow T_{2g}$
- for octahedral d^4 and d^9, the transition is $T_{2g} \leftarrow E_g$
- for tetrahedral d^1 and d^6, the transition is $T_2 \leftarrow E$
- for tetrahedral d^4 and d^9, the transition is $E \leftarrow T_2$

Each transition is *spin-allowed* (no change in total spin, S) and the electronic absorption spectrum of each ion exhibits one band. For the sake of completeness, the notation for the transitions given above should include spin multiplicities, $2S + 1$, e.g. for octahedral d^1, the notation is $^2E_g \leftarrow {}^2T_{2g}$, and for high-spin, octahedral d^4 it is $^5T_{2g} \leftarrow {}^5E_g$.

In an analogous manner to grouping d^1, d^4, d^6 and d^9 ions, we can consider together d^2, d^3, d^7 and d^8 ions in octahedral and tetrahedral fields. In order to discuss the electronic spectra of these ions, the terms that arise from the d^2 configuration must be known. In an absorption spectrum, we are concerned with electronic transitions from the ground state to one or more excited states. Transitions are possible from one excited state to another, but their probability is so low that they can be ignored. Two points are particularly important:

- selection rules restrict electronic transitions to those between terms with the *same* multiplicity;
- the ground state will be a term with the highest spin multiplicity (Hund's rules, see Section 20.6).

In order to work out the terms for the d^2 configuration, a table of microstates (Table 20.7) must be constructed. However, for interpreting electronic spectra, the table can be simplified because we need concern ourselves only with the terms of maximum spin multiplicity. This corresponds to a *weak field limit*. For the d^2 ion, we therefore focus on the ^3F and ^3P (triplet) terms. These are summarized in Table 20.9, with the corresponding microstates represented only in terms of electrons with $m_s = +\frac{1}{2}$. It follows from the rules given in Section 20.6 that the ^3F term is expected to be lower in energy than the ^3P term. In an octahedral field, the ^3P term does not split, and is labelled $^3T_{1g}$. The ^3F term splits into $^3T_{1g}$, $^3T_{2g}$ and $^3A_{2g}$ terms. The $^3T_{1g}(F)$ term corresponds to a $t_{2g}{}^2e_g{}^0$ arrangement and is triply degenerate because there are three ways of placing two electrons (with parallel spins) in any two of the d_{xy}, d_{yz} and d_{xz} orbitals. The $^3A_{2g}$ term corresponds to $t_{2g}{}^0e_g{}^2$ arrangement (singly degenerate). The $^3T_{2g}$ and $^3T_{1g}(P)$ terms equate with a $t_{2g}{}^1e_g{}^1$ configuration; the lower energy $^3T_{2g}$ term arises from placing two electrons in orbitals lying in mutually perpendicular planes, e.g. $(d_{xy})^1(d_{z^2})^1$, while the higher energy $^3T_{1g}(P)$ term arises from placing two electrons in orbitals lying in the same plane, e.g. $(d_{xy})^1(d_{x^2-y^2})^1$. The energies of the $^3T_{1g}(F)$, $^3T_{2g}$, $^3A_{2g}$ and $^3T_{1g}(P)$ terms are shown on the right-hand side of Fig. 20.20; note the effect of increasing field strength. Starting from this diagram and using the same arguments as for the d^1, d^4, d^6 and d^9 ions, we can derive the complete Orgel diagram shown in Fig. 20.20. At increased field strengths, the lines describing the $T_{1g}(F)$ and $T_{1g}(P)$ terms (or T_1, depending on whether we are dealing with octahedral or tetrahedral cases) curve away from one another; there is interaction between terms of the same symmetry and they are not allowed to cross (the *non-crossing rule*). From Fig. 20.20, we can see why three absorptions are observed in the electronic spectra of d^2, d^3, d^7 and d^8 octahedral and tetrahedral complexes. The transitions are from the ground to excited states, and are all spin-allowed, e.g. for an octahedral d^3 ion, the allowed

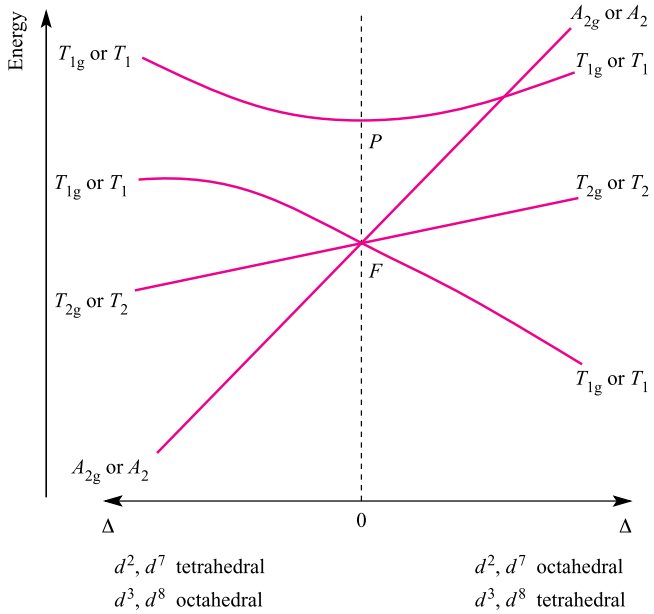

Fig. 20.20. Orgel diagram for d^2, d^3, d^7 and d^8 ions (high-spin) in octahedral (for which T_{1g}, T_{2g} and A_{2g} labels are relevant) and tetrahedral (T_1, T_2 and A_2 labels) fields. Multiplicities are not stated because they depend on the d^n configuration, e.g. for the octahedral d^2 ion, $^3T_{1g}$, $^3T_{2g}$ and $^3A_{2g}$ labels are appropriate.

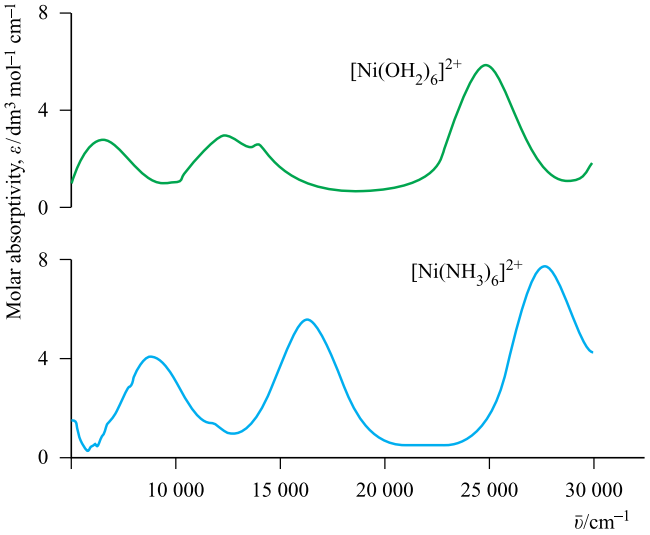

Fig. 20.21. Electronic spectra of $[Ni(OH_2)_6]^{2+}$ (0.101 mol dm^{-3}) and $[Ni(NH_3)_6]^{2+}$ (0.315 mol dm^{-3} in aqueous NH_3 solution) showing three absorption bands. Values of the molar absorptivity, ε, are related to absorbance by the Beer–Lambert law (eq. 20.12). [This figure is based on data provided by Christian Reber; see: M. Triest, G. Bussière, H. Bélisle and C. Reber (2000) *J. Chem. Educ.*, vol. 77, p. 670; pubs.acs.org/doi/suppl/10.1021/ed077p670.2/suppl_file/xjceni.html

transitions are $^4T_{2g} \leftarrow {}^4A_{2g}$, $^4T_{1g}(F) \leftarrow {}^4A_{2g}$ and $^4T_{1g}(P) \leftarrow {}^4A_{2g}$. Figure 20.21 illustrates spectra for octahedral nickel(II) (d^8) complexes.

For the high-spin d^5 configuration, all transitions are *spin-forbidden* and '*d–d*' transitions that are observed are between the ^6S ground state and quartet states (three unpaired electrons). Associated absorptions are extremely weak.

Worked example 20.4 Electronic absorption spectra

The electronic absorption spectrum of an aqueous solution of $[Ni(en)_3]^{2+}$ exhibits broad absorptions with $\lambda_{max} \approx$ 325, 550 and 900 nm. (a) Suggest assignments for the electronic transitions. (b) Which bands are in the visible region?

(a) $[Ni(en)_3]^{2+}$ is a Ni(II), d^8 complex. From the Orgel diagram in Fig. 20.20 the three transitions can be assigned; *lowest wavelength* corresponds to *highest energy* transition:

900 nm assigned to $^3T_{2g} \leftarrow {}^3A_{2g}$
550 nm assigned to $^3T_{1g}(F) \leftarrow {}^3A_{2g}$
325 nm assigned to $^3T_{1g}(P) \leftarrow {}^3A_{2g}$

(b) Visible region spans ≈400–750 nm, so only the 550 nm absorption falls in this range (see Table 19.2). The band at 325 nm may tail into the visible region.

Self-study exercises

1. Of the three absorptions in $[Ni(en)_3]^{2+}$, which is closest to the UV end of the spectrum? [*Ans.* Look at Appendix 4]
2. Does the notation $^3T_{2g} \leftarrow {}^3A_{2g}$ indicate an absorption or an emission band? [*Ans.* Look in Section 4.7]
3. Why are the three transitions for $[Ni(en)_3]^{2+}$ (a) spin-allowed, and (b) Laporte-forbidden?

Interpretation of electronic absorption spectra: use of Racah parameters

For a d^1 configuration, the energy of the absorption band in an electronic spectrum gives a direct measure of Δ_{oct}. Figure 20.22a shows the splitting of the ^2D term in an octahedral field into the T_{2g} and E_g levels, the difference in energy being Δ_{oct}. The dependence of this splitting on the ligand field strength is represented in the Orgel diagram in Fig. 20.18. For electron configurations other than d^1, the situation is more complicated. For example, from Fig. 20.20, we expect the electronic spectrum of an octahedral d^2, d^3, d^7 or d^8 ion to consist of three absorptions arising from *d–d* transitions. How do we determine a value of Δ_{oct} from such a spectrum? For a given electron configuration, the energies of the terms are given by equations involving *Racah parameters* (A, B and C)

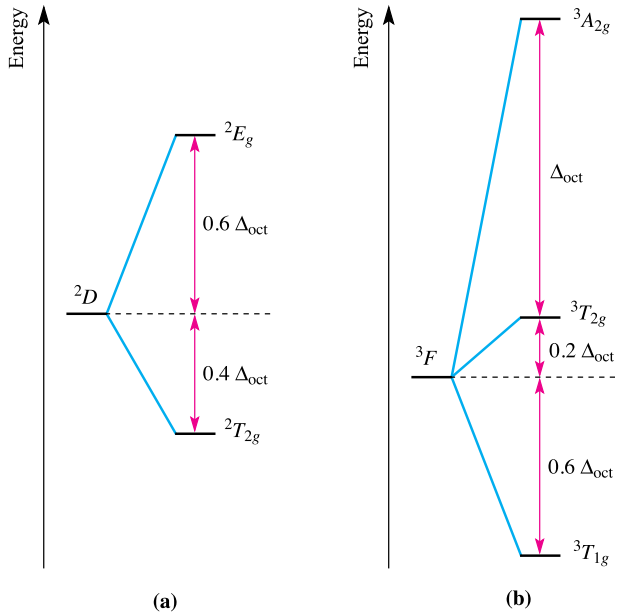

Fig. 20.22. (a) Splitting in an octahedral field of the (a) ^2D term arising from a d^1 configuration and (b) ^3F term arising from a d^2 configuration. The ^3P term for the d^2 configuration does not split. The diagram applies only to the weak field limit.

which allow for electron–electron repulsions. These parameters are used in addition to Δ_{oct} to quantify the description of the spectrum. For example, the ^3F, ^3P, ^1G, ^1D and ^1S terms arise from a d^2 configuration, and their energies are as follows:

Energy of $^1S = A + 14B + 7C$

Energy of $^1D = A - 3B + 2C$

Energy of $^1G = A + 4B + 2C$

Energy of $^3P = A + 7B$

Energy of $^3F = A - 8B$

The actual energies of the terms can be determined spectroscopically[†] and the ordering is found to be $^3F < {}^1D < {}^3P < {}^1G < {}^1S$. (Compare this with a predicted ordering from Hund's rules of $^3F < {}^3P < {}^1G < {}^1D < {}^1S$: see Section 20.6.) Racah parameters for a given system can be evaluated using the above equations. The values of the parameters depend on ion size (B and C become larger with decreasing ionic radius), and usually, the ratio $C/B \approx 4$. From the equations above, the energy difference between the terms of maximum spin multiplicity, ^3P and ^3F, requires the use only of the Racah parameter B. This is true for P and F terms of a common multiplicity arising from other d^n configurations (eq. 20.13).

$$\text{Energy difference between } P \text{ and } F \text{ terms} = (A + 7B) - (A - 8B) = 15B \qquad (20.13)$$

Now let us look in detail at the analysis of an electronic absorption spectrum for a d^2 ion in an octahedral field (*weak field ligands*). We have already seen that there are three possible transitions from the ground state: $^3T_{2g} \leftarrow {}^3T_{1g}(F)$, $^3T_{1g}(P) \leftarrow {}^3T_{1g}(F)$ and $^3A_{2g} \leftarrow {}^3T_{1g}(F)$ (Fig. 20.20). Figure 20.22b shows the splitting of the ^3F term, and how the energy separations of the T_{1g}, T_{2g} and A_{2g} levels are related to Δ_{oct}. There is, however, a complication. Figure 20.22b ignores the influence of the ^3P term which lies above the ^3F. As we have already noted, terms of the same symmetry (e.g. $T_{1g}(F)$ and $T_{1g}(P)$) interact, and this causes the 'bending' of the lines in the Orgel diagram in Fig. 20.20. Hence, a perturbation, x, has to be added to the energy level diagram in Fig. 20.22b, and this is represented in Fig. 20.23a. From eq. 20.13, the energy separation of the ^3P and ^3F terms is $15B$. The energies of the $^3T_{2g} \leftarrow {}^3T_{1g}(F)$, $^3T_{1g}(P) \leftarrow {}^3T_{1g}(F)$ and $^3A_{2g} \leftarrow {}^3T_{1g}(F)$ transitions can be written in terms of Δ_{oct}, B and x. Provided that all three absorptions are observed in the spectrum, Δ_{oct}, B and x can be determined. Unfortunately, one or more absorptions may be hidden under a charge transfer band, and in the next section, we describe an alternative strategy for obtaining values of Δ_{oct} and B.

Figure 20.23b shows the splitting of terms for a d^3 configuration (again, for a *limiting weak field* case). The initial splitting of the ^4F term is the inverse of that for the ^3F term in Fig. 20.23a (see Fig. 20.20 and related discussion). Mixing of the $^4T_{1g}(F)$ and $^4T_{1g}(P)$ terms results in the perturbation x shown in the figure. After taking this into account, the energies of the $^4T_{2g} \leftarrow {}^4A_{2g}$, $^4T_{1g}(F) \leftarrow {}^4A_{2g}$ and $^4T_{1g}(P) \leftarrow {}^4A_{2g}$ transitions are written in terms of Δ_{oct}, B and x. Once again, provided that all three bands are observed in the electron spectrum, these parameters can be determined.

The energy level diagram in Fig. 20.23a describes not only an octahedral d^2 configuration, but also an octahedral d^7, a tetrahedral d^3 and a tetrahedral d^8 (with appropriate changes to the multiplicities of the term symbols). Similarly, Fig. 20.23b describes octahedral d^3 and d^8, and tetrahedral d^2 and d^7 configurations.

It must be stressed that the above procedure works *only for the limiting case in which the field strength is very weak*. It cannot, therefore, be applied widely for the determination of Δ_{oct} and B for *d*-block metal complexes. Further development of this method is beyond the scope of this book,[‡] and a more general approach is the use of Tanabe–Sugano diagrams.

[†] Note that this involves the observation of transitions involving both triplet and singlet states.

[‡] For a full account of the treatment, see: A.B.P. Lever (1984) *Inorganic Electronic Spectroscopy*, Elsevier, Amsterdam.

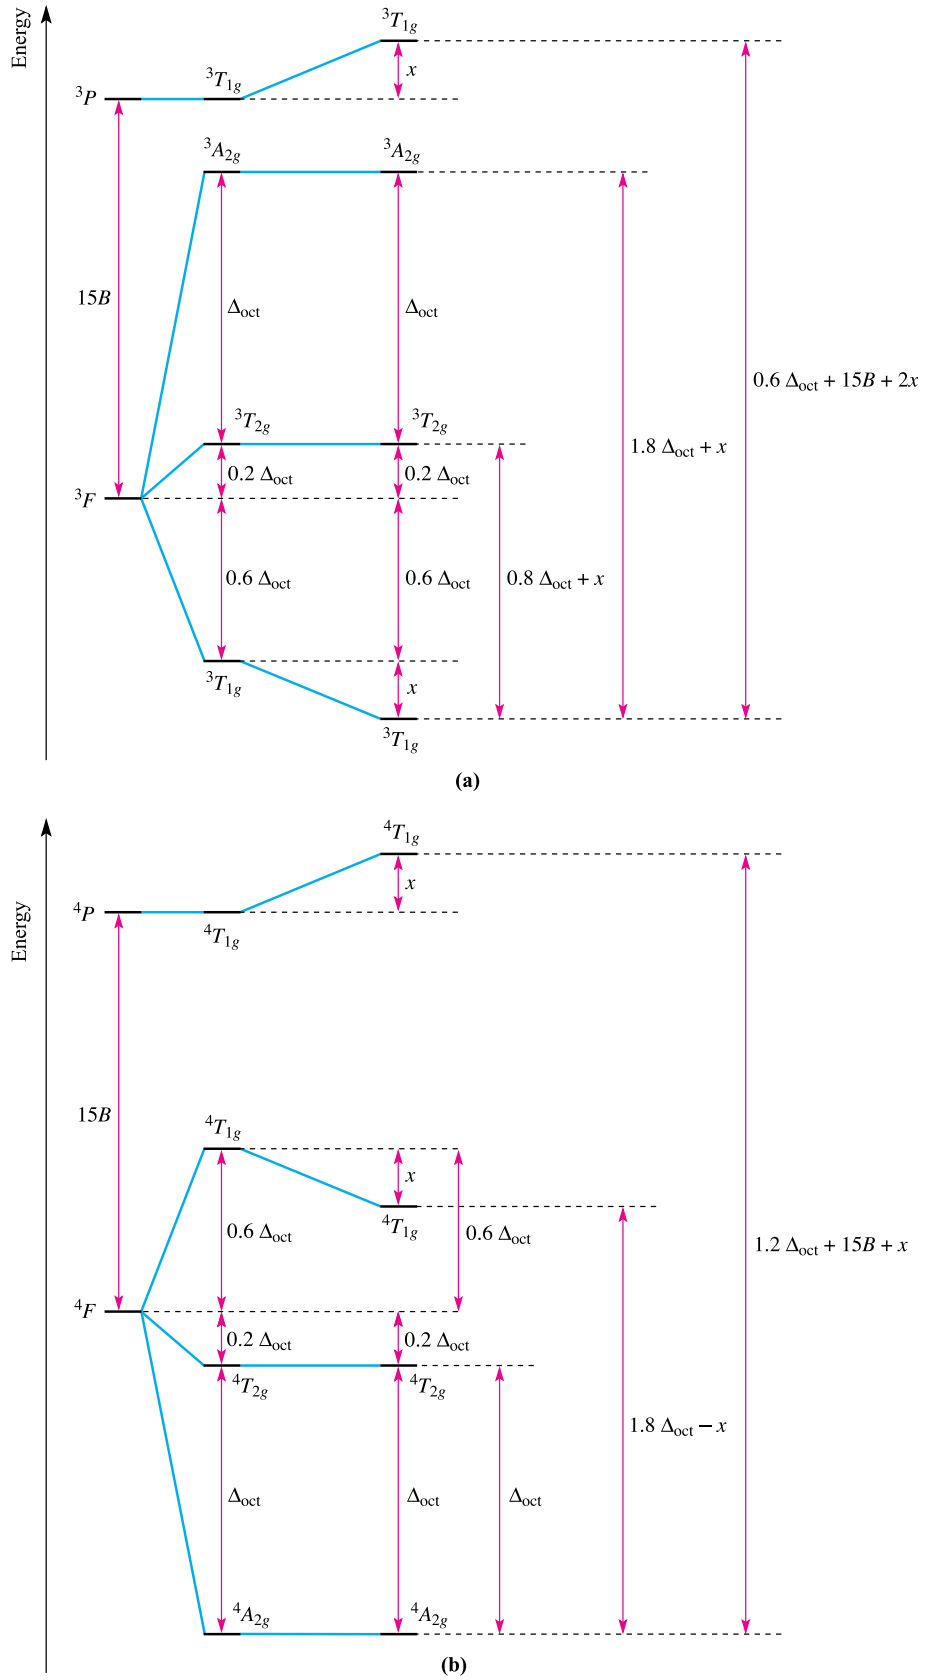

Fig. 20.23. Splitting in an octahedral field of (a) the ^3F and ^3P terms arising from a d^2 configuration, and (b) the ^4F and ^4P terms arising from a d^3 configuration. The initial splitting of the energy levels for the d^2 ion follows from Fig. 20.22b, and the splitting for the d^3 configuration is the inverse of this; x is the energy perturbation caused by mixing of the $T_{1g}(F)$ and $T_{1g}(P)$ terms. The three energy separations marked on the right-hand side of each diagram can be related to energies of transitions observed in electronic spectra of d^2 and d^3 ions. B is a Racah parameter (see eq. 20.13). The diagram applies only to the weak field limit.

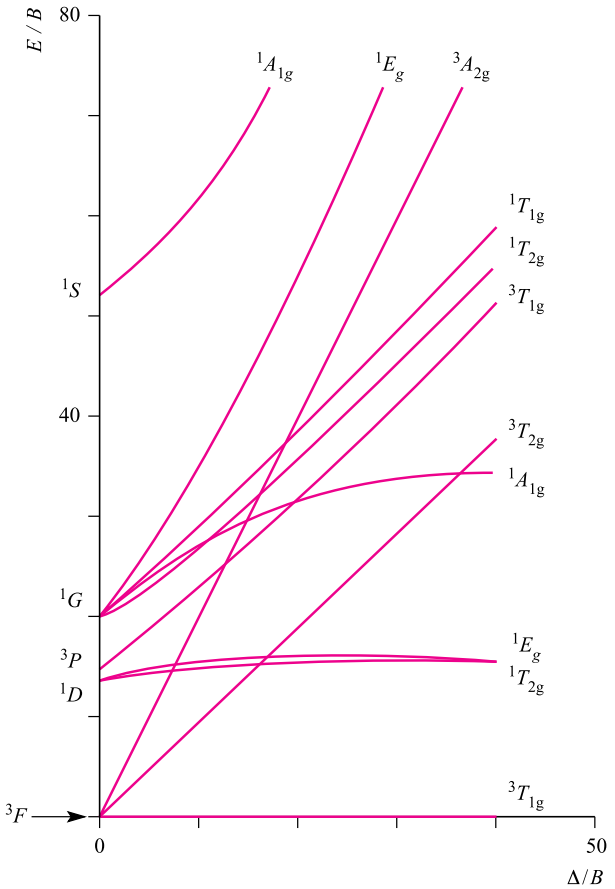

Fig. 20.24. Tanabe–Sugano diagram for the d^2 configuration in an octahedral field.

Interpretation of electronic absorption spectra: Tanabe–Sugano diagrams

A more advanced treatment of the energies of electronic states is found in *Tanabe–Sugano diagrams*. The energy of the ground state is taken to be zero for all field strengths, and the energies of all other terms and their components are plotted with respect to the ground term. If there is a change in ground term as the field strength increases, a discontinuity appears in the diagram. Figure 20.24 shows the Tanabe–Sugano diagram for the d^2 configuration in an octahedral field. Notice that the energy and field strength are both expressed in terms of the Racah parameter B. Application of Tanabe–Sugano diagrams is illustrated in worked example 20.5.

Worked example 20.5 Application of Tanabe–Sugano diagrams

Aqueous solutions of $[V(OH_2)_6]^{3+}$ show absorptions at 17 200 and 25 600 cm^{-1} assigned to the $^3T_{2g} \leftarrow {}^3T_{1g}(F)$ and $^3T_{1g}(P) \leftarrow {}^3T_{1g}(F)$ transitions. Estimate values of B and Δ_{oct} for $[V(OH_2)_6]^{3+}$.

$[V(OH_2)_6]^{3+}$ is a d^2 ion and the Tanabe–Sugano diagram in Fig. 20.24 is therefore appropriate. An important point to recognize is that with the diagram provided, only approximate values of B and Δ_{oct} can be obtained.

Let the transition energies be $E_2 = 25\,600\ cm^{-1}$ and $E_1 = 17\,200\ cm^{-1}$.

Values of transition energies cannot be read directly from the Tanabe–Sugano diagram, but ratios of energies can be obtained since:

$$\frac{\left(\frac{E_2}{B}\right)}{\left(\frac{E_1}{B}\right)} = \frac{E_2}{E_1}$$

From the observed absorption data:

$$\frac{E_2}{E_1} = \frac{25\,600}{17\,200} = 1.49$$

We now proceed by trial and error, looking for the value of $\frac{\Delta_{oct}}{B}$ which corresponds to a ratio:

$$\frac{\left(\frac{E_2}{B}\right)}{\left(\frac{E_1}{B}\right)} = 1.49$$

Trial points:

$$\text{when } \frac{\Delta_{oct}}{B} = 20, \quad \frac{\left(\frac{E_2}{B}\right)}{\left(\frac{E_1}{B}\right)} \approx \frac{32}{18} = 1.78$$

$$\text{when } \frac{\Delta_{oct}}{B} = 30, \quad \frac{\left(\frac{E_2}{B}\right)}{\left(\frac{E_1}{B}\right)} \approx \frac{41}{28} = 1.46$$

$$\text{when } \frac{\Delta_{oct}}{B} = 29, \quad \frac{\left(\frac{E_2}{B}\right)}{\left(\frac{E_1}{B}\right)} \approx \frac{40.0}{26.9} = 1.49$$

This is an *approximate* answer but we are now able to estimate B and Δ_{oct} as follows:

- when $\frac{\Delta_{oct}}{B} = 29$, we have $\frac{E_2}{B} \approx 40.0$, and since $E_2 = 25\,600\ cm^{-1}$, $B \approx 640\ cm^{-1}$;
- when $\frac{\Delta_{oct}}{B} = 29$, $\frac{E_1}{B} \approx 26.9$, and since $E_1 = 17\,200\ cm^{-1}$, $B \approx 640\ cm^{-1}$.

Substitution of the value of B into $\frac{\Delta_{oct}}{B} = 29$ gives an estimate of $\Delta_{oct} \approx 18\,600\ cm^{-1}$.

Accurate methods involving mathematical expressions can be used. These can be found in the advanced texts listed in the further reading at the end of the chapter.

Self-study exercises

1. Why are the two values of B obtained above self-consistent?
2. For $[Ti(OH_2)_6]^{3+}$, a value of Δ_{oct} can be determined directly from λ_{max} in the electronic spectrum. Why is this not possible for $[V(OH_2)_6]^{3+}$, and for most other octahedral ions?

20.8 Electronic spectra: emission

The energy of the absorbed radiation corresponds to the energy of a transition from ground to excited state. Selection rules for electronic spectroscopy only allow transitions between states of the same *multiplicity* (see Sections 20.6 and 20.7). Thus, excitation may occur from a singlet ground state (S_0 in photochemical notation) to the singlet first excited state (S_1). Decay of the excited state back to the ground state may take place by:

- radiative decay (i.e. the emission of electromagnetic radiation),
- non-radiative decay in which thermal energy is lost, or
- non-radiative intersystem crossing to a triplet state (T_1 in Fig. 20.25 represents the lowest energy triplet state).

These processes compete with each other. Emission without a change in multiplicity is called *fluorescence*, while *phosphorescence* refers to an emission in which there is a change in multiplicity. The excitation and decay processes are represented using a *Jablonski diagram* in which radiative transitions are represented by straight arrows and non-radiative transitions by wavy arrows (Fig. 20.25). It follows from the Jablonski diagram that the wavelength of light emitted in a phosphorescence will be to longer wavelength (red-shifted) than the absorbed radiation. In fluorescence, the emitted light is also red-shifted, but usually to a much smaller extent. This shift is called the Stokes shift. While the absorption (Fig. 20.25) involves the ground vibrational state of S_0 and an excited vibrational state of S_1, the emission is from the lowest vibrational state of S_1. Since phosphorescence involves a spin-forbidden transition, the lifetime of the excited state is often relatively long (nanoseconds to microseconds or longer). Fluorescence lifetimes (typically between singlet states) are shorter and usually lie in the picosecond to nanosecond range.

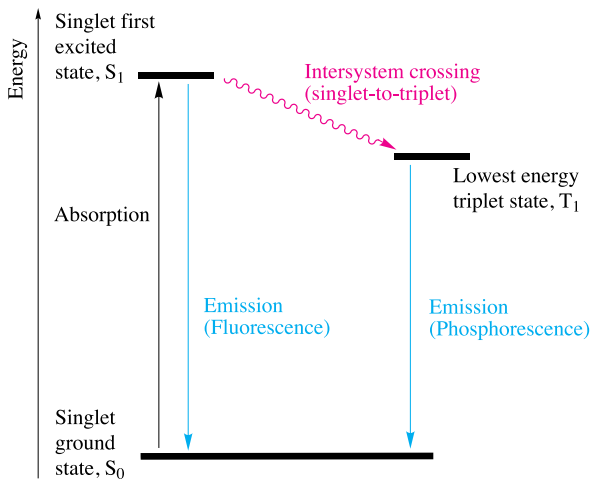

Fig. 20.25. Emission processes are represented using a Jablonski diagram. Radiative and non-radiative transitions are depicted by straight and wavy arrows, respectively.

Luminescence refers to the spontaneous emission of radiation from an electronically excited species and covers both ***fluorescence*** and ***phosphorescence***.

Emission without a change in multiplicity is called ***fluorescence***, and ***phosphorescence*** is emission in which the multiplicity changes.

Luminescence from *d*-block metal complexes was first observed for chromium(III) complexes. In a typical experiment, the absorption spectrum is first recorded. The sample is then irradiated with light corresponding to the absorption maximum (λ_{max}) and the emission spectrum is recorded. The ground and first excited states of Cr^{3+} ion (d^3) in O_h symmetry are the $^4A_{2g}$ and $^4T_{2g}$, respectively (see Fig. 20.20). Fluorescence arises from a $^4T_{2g} \longrightarrow {}^4A_{2g}$ transition. Intersystem crossing populates the ^2E_g excited state, and phosphorescence arises from a $^2E_g \longrightarrow {}^4A_{2g}$ transition. For octahedral complexes of Cr^{3+}, the nature of the observed emission spectrum is ligand-dependent because the energy of the $^4T_{2g}$ level varies with the ligand field strength. With weak-field ligands, both fluorescence and phosphorescence may be observed, while for strong-field ligands, intersystem-crossing dominates and emission typically consists only of phosphorescence. Figure 20.26 shows the absorption and emission spectra of $[Cr\{OC(NH_2)_2\}_6]^{3+}$ where $OC(NH_2)_2$ = urea; a broad fluorescence band and sharp phosphorescence band are observed. The relative energies of the fluorescence and phosphorescence emissions (phosphoresence at higher wavenumber, and therefore at higher energy, than fluorescence) show that in $[Cr\{OC(NH_2)_2\}_6]^{3+}$ (at 77 K), the ^2E_g excited state lies above the $^4A_{2g}$ excited state.[†] The red colour of rubies is due to the presence of trace amounts of Cr^{3+} ions in Al_2O_3, each Cr^{3+} ion residing in an octahedral CrO_6 environment. Synthetic ruby (Al_2O_3 doped with $\approx 0.05\%$ by weight of Cr^{3+}) rods are used in ruby lasers. The emission of a ruby laser at 694.3 nm corresponds to the $^2E_g \longrightarrow {}^4A_{2g}$ transition following excitation by a continuous or pulsed source of light.

20.9 Evidence for metal–ligand covalent bonding

The nephelauxetic effect

In metal complexes, there is evidence for sharing of electrons between metal and ligand. Pairing energies are lower in complexes than in gaseous M^{n+} ions, indicating that interelectronic repulsion is less in complexes and that the *effective* size of the metal orbitals has increased. This is the *nephelauxetic effect*.

Nephelauxetic means (electron) 'cloud expanding'.

For complexes with a common metal ion, it is found that the nephelauxetic effect of ligands varies according to a series independent of metal ion:

$$F^- < H_2O < NH_3 < en < [ox]^{2-} < [NCS]^- < Cl^- < [CN]^- < Br^- < I^-$$

increasing nephelauxetic effect

A nephelauxetic series for metal ions (independent of ligands) is as follows:

$$Mn(II) < Ni(II) \approx Co(II) < Mo(II) < Re(IV) < Fe(III) < Ir(III) < Co(III) < Mn(IV)$$

increasing nephelauxetic effect

The nephelauxetic effect can be parameterized and the values shown in Table 20.10 used to estimate the reduction in electron–electron repulsion upon complex formation. In eq. 20.14, the interelectronic repulsion in the complex is the Racah parameter B; B_0 is the interelectronic repulsion in the gaseous M^{n+} ion.

Table 20.10 Selected values of h and k which are used to parameterize the nephelauxetic series; worked example 20.6 shows their application.

Metal ion	k	Ligands	h
Co(III)	0.35	6 Br^-	2.3
Rh(III)	0.28	6 Cl^-	2.0
Co(II)	0.24	6 $[CN]^-$	2.0
Fe(III)	0.24	3 en	1.5
Cr(III)	0.21	6 NH_3	1.4
Ni(II)	0.12	6 H_2O	1.0
Mn(II)	0.07	6 F^-	0.8

$$\frac{B_0 - B}{B_0} \approx h_{\text{ligands}} \times k_{\text{metal ion}} \qquad (20.14)$$

The worked example and exercises below illustrate how to apply eq. 20.14.

Worked example 20.6 The nephelauxetic series

Use data in Table 20.10 to estimate the reduction in the interelectronic repulsion in going from the gaseous Fe^{3+} ion to $[FeF_6]^{3-}$.

The reduction in interelectronic repulsion is given by:

$$\frac{B_0 - B}{B_0} \approx h_{\text{ligands}} \times k_{\text{metal ion}}$$

In Table 20.10, values of h refer to an octahedral set of ligands.

For $[FeF_6]^{3-}$:

$$\frac{B_0 - B}{B_0} \approx 0.8 \times 0.24 = 0.192$$

Therefore, the reduction in interelectronic repulsion in going from the gaseous Fe^{3+} ion to $[FeF_6]^{3-}$ is ≈19%.

Self-study exercises

Refer to Table 20.10.

1. Show that the reduction in interelectronic repulsion in going from the gaseous Ni^{2+} ion to $[NiF_6]^{4-}$ is ≈10%.
2. Estimate the reduction in interelectronic repulsion on going from gaseous Rh^{3+} to $[Rh(NH_3)_6]^{3+}$.

[*Ans.* ≈39%]

THEORY

Box 20.4 Magnetic susceptibility

It is important to distinguish between the magnetic susceptibilities χ, χ_g and χ_m.

- Volume susceptibility is χ and is dimensionless.
- Gram susceptibility is $\chi_g = \frac{\chi}{\rho}$ where ρ is the density of the sample; the units of χ_g are $m^3\,kg^{-1}$.
- Molar susceptibility is $\chi_m = \chi_g M$ (where M is the molecular mass of the compound) and has SI units of $m^3\,mol^{-1}$.

EPR spectroscopy

Further proof of electron sharing comes from electron paramagnetic resonance (EPR) spectroscopy. As we described in Section 4.9, if a metal ion carrying an unpaired electron is linked to a ligand containing nuclei with nuclear spin quantum number $I \neq 0$, hyperfine splitting of the EPR signal is observed, showing that the orbital occupied by the electron has both metal and ligand character, i.e. there is metal–ligand covalent bonding. An example is the EPR spectrum of $Na_2[IrCl_6]$ (paramagnetic low-spin d^5) recorded for a solid solution in $Na_2[PtCl_6]$ (diamagnetic low-spin d^6); this was a classic EPR experiment, reported in 1953.[†] See Section 4.9 for details of EPR spectroscopy.

20.10 Magnetic properties

Magnetic susceptibility and the spin-only formula

We begin the discussion of magnetochemistry with the so-called *spin-only formula*, an *approximation* that has limited, but useful, applications.

Paramagnetism arises from unpaired electrons. Each electron has a magnetic moment with one component associated with the spin angular momentum of the electron and (except when the quantum number $l = 0$) a second component associated with the orbital angular momentum. For many complexes of first row *d*-block metal ions we can ignore the second component and the magnetic moment, μ, can be regarded as being determined by the number of unpaired electrons, n (eqs. 20.15 and 20.16). The two equations are related because the total spin quantum number $S = \frac{n}{2}$.

$$\mu(\text{spin-only}) = 2\sqrt{S(S+1)} \qquad (20.15)$$

$$\mu(\text{spin-only}) = \sqrt{n(n+2)} \qquad (20.16)$$

The *effective magnetic moment*, μ_{eff}, can be obtained from the experimentally measured *molar magnetic susceptibility*, χ_m (see Box 20.4), and is expressed in Bohr magnetons (μ_B) where $1\mu_B = eh/4\pi m_e = 9.27 \times 10^{-24}\,J\,T^{-1}$. Equation 20.17 gives the relationship between μ_{eff} and χ_m. Using SI units for the constants, this expression reduces to eq. 20.18 in which χ_m is in $cm^3\,mol^{-1}$. In the laboratory, the continued use of Gaussian units in magnetochemistry means that *irrational susceptibility* is the measured quantity and eq. 20.19 is therefore usually applied.[‡]

$$\mu_{eff} = \sqrt{\frac{3k\chi_m T}{L\mu_0\mu_B{}^2}} \qquad (20.17)$$

where k = Boltzmann constant; L = Avogadro number; μ_0 = vacuum permeability; T = temperature in kelvin

$$\mu_{eff} = 0.7977\sqrt{\chi_m T} \qquad (20.18)$$

$$\mu_{eff} = 2.828\sqrt{\chi_m T} \quad \text{(for use with Gaussian units)} \qquad (20.19)$$

Several methods can be used to measure χ_m, e.g. the *Gouy balance* (Fig. 20.27), the *Faraday balance* (which operates in a similar manner to the Gouy balance) and a more modern technique using a *SQUID* (see Section 28.4). The Gouy method makes use of the interaction between unpaired electrons and a magnetic field. A diamagnetic material is repelled by a magnetic field whereas a paramagnetic material is attracted into it. The compound for study is placed in a glass tube, suspended from a balance on which the weight of the sample is recorded. The tube is placed so that one end of the sample lies at the point of maximum magnetic flux in an electromagnetic field while the other end is at a point of low flux. Initially the magnet is switched off, but upon applying a magnetic field, paramagnetic compounds are drawn into it by an amount that depends on the number of unpaired electrons. The change in weight caused by the movement of the sample into the field is recorded, and from the associated

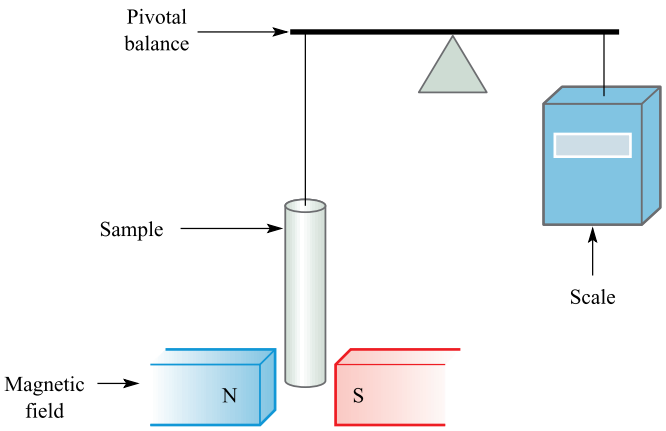

Fig. 20.27. Schematic representation of a Gouy balance.

force it is possible to calculate the magnetic susceptibility of the compound. The effective magnetic moment is then derived using eq. 20.19.

For metal complexes in which the spin quantum number S is the same as for the isolated gaseous metal ion, the spin-only formula (eq. 20.15 or 20.16) can be applied to find the number of unpaired electrons. Table 20.11 lists examples in which measured values of μ_{eff} correlate fairly well with those derived from the spin-only formula; note that all the metal ions are from the *first row* of the *d*-block. Use of the spin-only formula allows the number of unpaired electrons to be determined and gives information about oxidation state of the metal and whether the complex is low- or high-spin.

The use of magnetic data to assist in the assignments of coordination geometries is exemplified by the difference between tetrahedral and square planar d^8 species, e.g. Ni(II), Pd(II), Pt(II), Rh(I) and Ir(I). Whereas the greater crystal field splitting for the second and third row metal ions invariably leads to square planar complexes, nickel(II) is found in both tetrahedral and square planar environments. Square planar Ni(II) complexes are diamagnetic, whereas tetrahedral Ni(II) species are paramagnetic (see worked example 20.1).

Worked example 20.7 Magnetic moments: spin-only formula

At room temperature, the observed value of μ_{eff} for $[Cr(en)_3]Br_2$ is 4.75 μ_B. Is the complex high- or low-spin? (Ligand abbreviations: see Table 7.8.)

$[Cr(en)_3]Br_2$ contains the octahedral $[Cr(en)_3]^{2+}$ complex and a Cr^{2+} (d^4) ion. Low-spin will have two unpaired electrons ($n = 2$), and high-spin will have four ($n = 4$).

Assume that the spin-only formula is valid (first row metal, octahedral complex):

$$\mu(\text{spin-only}) = \sqrt{n(n+2)}$$

For low-spin: $\mu(\text{spin-only}) = \sqrt{8} = 2.83$

For high-spin: $\mu(\text{spin-only}) = \sqrt{24} = 4.90$

The latter is close to the observed value, and is consistent with a high-spin complex.

Self-study exercises

1. Given that (at 293 K) the observed value of μ_{eff} for $[VCl_4(MeCN)_2]$ is 1.77 μ_B, deduce the number of unpaired electrons and confirm that this is consistent with the oxidation state of the V atom.

Table 20.11 Spin-only values of μ_{eff} compared with approximate ranges of observed magnetic moments for high-spin complexes of first row *d*-block ions.

Metal ion	d^n configuration	S	μ_{eff}(spin-only)/μ_B	Observed values of μ_{eff}/μ_B
Sc^{3+}, Ti^{4+}	d^0	0	0	0
Ti^{3+}	d^1	$\frac{1}{2}$	1.73	1.7–1.8
V^{3+}	d^2	1	2.83	2.8–3.1
V^{2+}, Cr^{3+}	d^3	$\frac{3}{2}$	3.87	3.7–3.9
Cr^{2+}, Mn^{3+}	d^4	2	4.90	4.8–4.9
Mn^{2+}, Fe^{3+}	d^5	$\frac{5}{2}$	5.92	5.7–6.0
Fe^{2+}, Co^{3+}	d^6	2	4.90	5.0–5.6
Co^{2+}	d^7	$\frac{3}{2}$	3.87	4.3–5.2
Ni^{2+}	d^8	1	2.83	2.9–3.9
Cu^{2+}	d^9	$\frac{1}{2}$	1.73	1.9–2.1
Zn^{2+}	d^{10}	0	0	0

2. At 298 K, the observed value of μ_{eff} for $[Cr(NH_3)_6]Cl_2$ is 4.85 μ_B. Confirm that the complex is high-spin.

3. At 300 K, the observed value of μ_{eff} for $[V(NH_3)_6]Cl_2$ is 3.9 μ_B. Confirm that this corresponds to what is expected for an octahedral d^3 complex.

Spin and orbital contributions to the magnetic moment

By no means do all paramagnetic complexes obey the spin-only formula and caution must be exercised in its use. It is often the case that moments arising from *both* the spin and orbital angular momenta contribute to the observed magnetic moment. Details of the Russell–Saunders coupling scheme to obtain the total angular momentum quantum number, J, from quantum numbers L and S are given in Section 20.6, along with notation for term symbols $^{(2S+1)}L_J$. The energy difference between adjacent states with J values of J' and $(J'+1)$ is given by the expression $(J'+1)\lambda$ where λ is called the *spin–orbit coupling constant*. For the d^2 configuration, for example, the ^3F term in an octahedral field is split into $^3F_2$, $^3F_3$ and $^3F_4$, the energy differences between successive pairs being 3λ and 4λ respectively. In a magnetic field, each state with a different J value splits again to give $(2J+1)$ different levels separated by $g_J\mu_B B_0$ where g_J is a constant called the Landé splitting factor and B_0 is the magnetic field. It is the very small energy differences between these levels with which EPR spectroscopy is concerned and g-values are measured using this technique (see Section 4.9). The overall splitting pattern for a d^2 ion is shown in Fig. 20.28.

The value of λ varies from a fraction of a cm^{-1} for the very lightest atoms to a few thousand cm^{-1} for the heaviest ones. The extent to which states of different J values are populated at ambient temperature depends on how large their separation is compared with the thermal energy available, kT; at 300 K, $kT \approx 200\,cm^{-1}$ or $2.6\,kJ\,mol^{-1}$. It can be shown theoretically that if the separation of energy levels is large, the magnetic moment is given by eq. 20.20. Strictly, this applies only to free-ion energy levels, but it gives values for the magnetic moments of lanthanoid ions (for which λ is typically $1000\,cm^{-1}$) that are in good agreement with observed values (see Section 27.4).

$$\left.\begin{aligned} &\mu_{eff} = g_J\sqrt{J(J+1)} \\ \text{where}\quad &g_J = 1 + \left(\frac{S(S+1) - L(L+1) + J(J+1)}{2J(J+1)}\right) \end{aligned}\right\} \qquad (20.20)$$

For d-block metal ions, eq. 20.20 gives results that correlate poorly with experimental data (Tables 20.11 and 20.12). For many (but not all) first row metal ions, λ is very small and the spin and orbital angular momenta of the electrons operate independently. For this case, the van Vleck formula (eq. 20.21) was derived. Strictly, eq. 20.21 applies to free ions but, in a complex ion, the crystal field partly or fully *quenches* the orbital angular momentum. However, in practice, there is generally a poor fit between values of μ_{eff} calculated from eq. 20.21 and those observed (compare data in Tables 20.12 and 20.11).

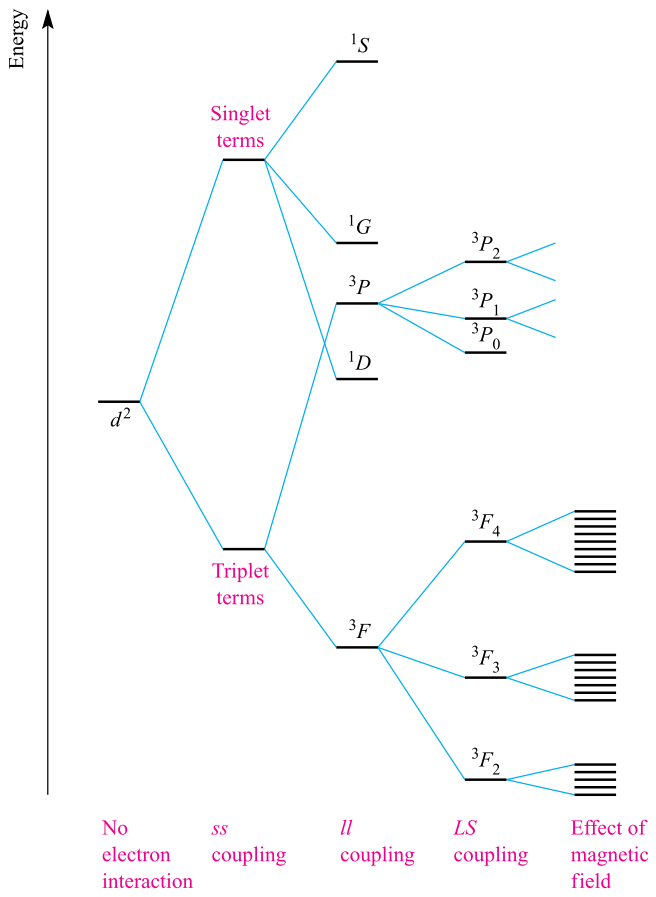

Fig. 20.28. Splitting of the terms of a d^2 ion (not to scale). See Section 20.6 for derivations of the term symbols. LS coupling is also called Russell–Saunders coupling.

$$\mu_{eff} = \sqrt{4S(S+1) + L(L+1)} \qquad (20.21)$$

If there is *no contribution* from orbital motion, then eq. 20.21 reduces to eq. 20.22 which is the spin-only formula we met earlier. Any ion for which $L = 0$ (e.g. high-spin d^5 Mn^{2+} or Fe^{3+} in which each orbital with $m_l = +2, +1, 0, -1, -2$ is singly occupied, giving $L = 0$) should, therefore, obey eq. 20.22.

$$\mu_{eff} = \sqrt{4S(S+1)} = 2\sqrt{S(S+1)} \qquad (20.22)$$

However, some other complex ions also obey the spin-only formula (Tables 20.11 and 20.12). In order for an electron to have orbital angular momentum, it must be possible to transform the orbital it occupies into an entirely equivalent

Table 20.12 Calculated magnetic moments for first row *d*-block metal ions in high-spin complexes at ambient temperatures. Compare these values with those observed (Table 20.11).

Metal ion	Ground term	μ_{eff}/μ_B calculated from eq. 20.20	μ_{eff}/μ_B calculated from eq. 20.21	μ_{eff}/μ_B calculated from eq. 20.22
Ti^{3+}	$^2D_{3/2}$	1.55	3.01	1.73
V^{3+}	$^3F_2$	1.63	4.49	2.83
V^{2+}, Cr^{3+}	$^4F_{3/2}$	0.70	5.21	3.87
Cr^{2+}, Mn^{3+}	$^5D_0$	0	5.50	4.90
Mn^{2+}, Fe^{3+}	$^6S_{5/2}$	5.92	5.92	5.92
Fe^{2+}, Co^{3+}	$^5D_4$	6.71	5.50	4.90
Co^{2+}	$^4F_{9/2}$	6.63	5.21	3.87
Ni^{2+}	$^3F_4$	5.59	4.49	2.83
Cu^{2+}	$^2D_{5/2}$	3.55	3.01	1.73

and degenerate orbital by rotation. The electron is then effectively rotating about the axis used for the rotation of the orbital. In an octahedral complex, for example, the three t_{2g} orbitals can be interconverted by rotations through 90°. Thus, an electron in a t_{2g} orbital has orbital angular momentum. The e_g orbitals, having different shapes, cannot be interconverted and so electrons in e_g orbitals never have angular momentum. There is, however, another factor that needs to be taken into account: if all the t_{2g} orbitals are singly occupied, an electron in, say, the d_{xz} orbital cannot be transferred into the d_{xy} or d_{yz} orbital because these already contain an electron having the same spin quantum number as the incoming electron. If all the t_{2g} orbitals are doubly occupied, electron transfer is also impossible. It follows that in high-spin octahedral complexes, orbital contributions to the magnetic moment are important only for the configurations t_{2g}^1, t_{2g}^2, $t_{2g}^4e_g^2$ and $t_{2g}^5e_g^2$. For tetrahedral complexes, it is similarly shown that the configurations that give rise to an orbital contribution are $e^2t_2^1$, $e^2t_2^2$, $e^4t_2^4$ and $e^4t_2^5$. These results lead us to the conclusion that an octahedral high-spin d^7 complex should have a magnetic moment greater than the spin-only value of 3.87 μ_B but a tetrahedral d^7 complex should not. However, the observed values of μ_{eff} for $[Co(OH_2)_6]^{2+}$ and $[CoCl_4]^{2-}$ are 5.0 and 4.4 μ_B respectively, i.e. *both* complexes have magnetic moments greater than μ(spin-only). The third factor involved is *spin–orbit coupling*.

Spin–orbit coupling is a complicated subject. We introduced *LS* (or Russell–Saunders) coupling in Section 20.6, and Fig. 20.28 shows the effects of *LS* coupling on the energy level diagram for a d^2 configuration. The extent of spin–orbit coupling is quantified by the constant λ, and for the d^2 configuration in Fig. 20.28, the energy differences between the $^3F_2$ and $^3F_3$ levels, and between the $^3F_3$ and $^3F_4$ levels, are 3λ and 4λ, respectively (see earlier). As a result of spin–orbit coupling, mixing of terms occurs. Thus, for example, the $^3A_{2g}$ ground term of an octahedral d^8 ion (Fig. 20.20) mixes with the higher $^3T_{2g}$ term. The extent of mixing is related to Δ_{oct} and to the spin–orbit coupling constant, λ. Equation 20.23 is a modification of the spin-only formula which takes into account spin–orbit coupling. Although the relationship depends on Δ_{oct}, it also applies to tetrahedral complexes. Equation 20.23 applies only to ions having *A* or *E* ground terms (Figs. 20.19 and 20.20). This simple approach is not applicable to ions with a *T* ground term.

$$\mu_{eff} = \mu(\text{spin-only})\left(1 - \frac{\alpha\lambda}{\Delta_{oct}}\right)$$

$$= \sqrt{n(n+2)}\left(1 - \frac{\alpha\lambda}{\Delta_{oct}}\right) \qquad (20.23)$$

where: λ = spin–orbit coupling constant

$\alpha = 4$ for an *A* ground term

$\alpha = 2$ for an *E* ground term

Some values of λ are given in Table 20.13. Note that λ is positive for less than half-filled shells and negative for

Table 20.13 Spin–orbit coupling coefficients, λ, for selected first row *d*-block metal ions.

Metal ion	Ti^{3+}	V^{3+}	Cr^{3+}	Mn^{3+}	Fe^{2+}	Co^{2+}	Ni^{2+}	Cu^{2+}
d^n configuration	d^1	d^2	d^3	d^4	d^6	d^7	d^8	d^9
λ / cm^{-1}	155	105	90	88	−102	−177	−315	−830

shells that are more than half-filled. Thus, spin–orbit coupling leads to:

- $\mu_{eff} > \mu$(spin-only) for d^6, d^7, d^8 and d^9 ions;
- $\mu_{eff} < \mu$(spin-only) for d^1, d^2, d^3 and d^4 ions.

Worked example 20.8 Magnetic moments: spin–orbit coupling

Calculate a value for μ_{eff} for $[Ni(en)_3]^{2+}$ taking into account spin–orbit coupling. Compare your answer with μ(spin-only) and the value of 3.16 μ_B observed experimentally for $[Ni(en)_3][SO_4]$. [Data: see Tables 20.2 and 20.13.]

Octahedral Ni(II) (d^8) has a $^3A_{2g}$ ground state. Equation needed:

$$\mu_{eff} = \mu(\text{spin-only})\left(1 - \frac{4\lambda}{\Delta_{oct}}\right)$$

$$\mu(\text{spin-only}) = \sqrt{n(n+2)} = \sqrt{8} = 2.83$$

From Table 20.2: $\Delta_{oct} = 11\,500\ cm^{-1}$
From Table 20.13: $\lambda = -315\ cm^{-1}$

$$\mu_{eff} = 2.83\left(1 + \frac{4 \times 315}{11\,500}\right) = 3.14\,\mu_B$$

The calculated value is significantly larger than μ(spin-only) as expected for a d^n configuration with a more than half-full shell. It agrees well with the experimental value.

Self-study exercises

Use data in Tables 20.2 and 20.13.

1. Calculate a value for μ_{eff} for $[Ni(NH_3)_6]^{2+}$ taking into account spin–orbit coupling. [*Ans.* 3.16μ_B]
2. Calculate a value for μ_{eff} for $[Ni(OH_2)_6]^{2+}$ taking into account spin–orbit coupling. [*Ans.* 3.25μ_B]

An important point is that spin–orbit coupling is generally large for second and third row *d*-block metal ions and this leads to large discrepancies between μ(spin-only) and observed values of μ_{eff}. The d^1 complexes *cis*-$[NbBr_4(NCMe)_2]$ and *cis*-$[TaCl_4(NCMe)_2]$ illustrate this clearly. Nb and Ta are second and third row group 5 metals, and the room temperature values of μ_{eff} for *cis*-$[NbBr_4(NCMe)_2]$ and *cis*-$[TaCl_4(NCMe)_2]$ are 1.27 and 0.45 μ_B, respectively. These data compare with a calculated μ(spin-only) of 1.73 μ_B.

The effects of temperature on μ_{eff}

So far, we have ignored the effects of temperature on μ_{eff}. If a complex obeys the Curie law (eq. 20.24), then μ_{eff} is independent of temperature. This follows from a combination of eqs. 20.18 and 20.24.

$$\chi = \frac{C}{T} \qquad (20.24)$$

where: C = Curie constant
T = temperature in K

However, the Curie law is rarely obeyed and so it is essential to state the temperature at which a value of μ_{eff} has been measured. For second and third row *d*-block metal ions in particular, quoting *only* a room temperature value of μ_{eff} is usually meaningless. When spin–orbit coupling is large, μ_{eff} is highly dependent on T. For a given electronic configuration, the influence of temperature on μ_{eff} can be seen from a *Kotani plot* of μ_{eff} against kT/λ where k is the Boltzmann constant, T is the temperature in K, and λ is the spin–orbit coupling constant. Remember that λ is small for first row metal ions, is large for a second row metal ion, and is even larger for a third row ion. Figure 20.29 shows a Kotani plot for a t_{2g}^4 configuration. Four points are indicated on the curve and correspond to typical values of μ_{eff}(298 K) for complexes of Cr(II) and Mn(III) from the first row, and Ru(IV) and Os(IV) from the second and third rows respectively. Points to note from these data are:

- the points corresponding to μ_{eff}(298 K) for the first row metal ions lie on the near-horizontal part of the curve, and so changing the temperature has little effect on μ_{eff};

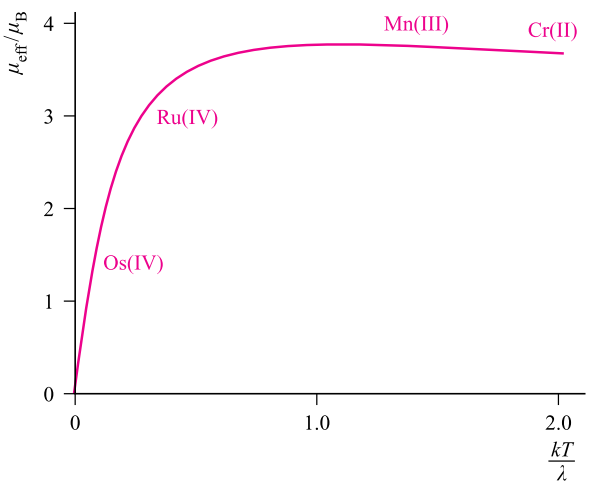

Fig. 20.29. Kotani plot for a t_{2g}^4 configuration; λ is the spin–orbit coupling constant. Typical values of μ_{eff}(298 K) for Cr(II), Mn(III), Ru(IV) and Os(IV) are indicated on the curve.

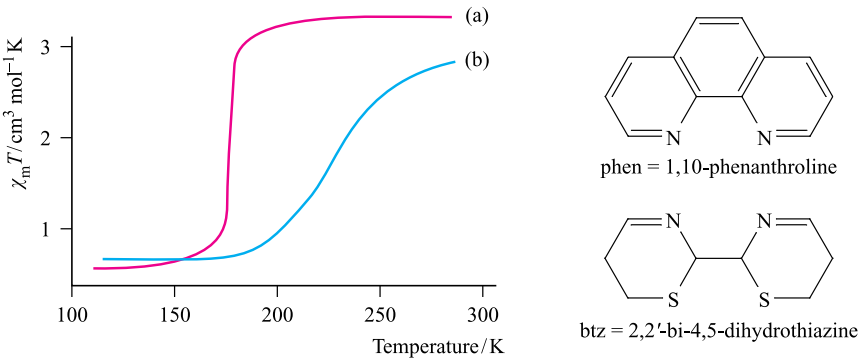

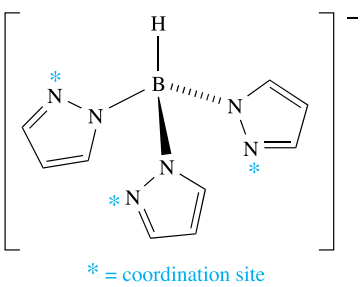

Fig. 20.30. The dependence of the observed values of μ_{eff} on temperature for (a) $[Fe(phen)_2(NCS\text{-}N)_2]$ where low- to high-spin crossover occurs abruptly at 175 K and (b) $[Fe(btz)_2(NCS\text{-}N)_2]$ where low- to high-spin crossover occurs more gradually. Ligand abbreviations are defined in the figure [data: J.-A. Real *et al.* (1992) *Inorg. Chem.*, vol. 31, p. 4972].

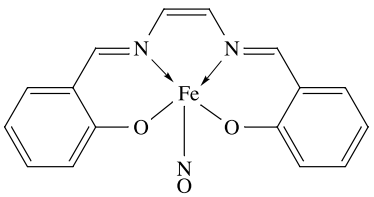
- the points relating to $\mu_{eff}(298\,K)$ for the heavier metal ions lie on parts of the curve with steep gradients, and so μ_{eff} is sensitive to changes in temperature; this is especially true for Os(IV) which lies on the steepest part of the curve.



Spin crossover

The choice between a low- and high-spin configuration for d^4, d^5, d^6 and d^7 complexes is not always unique and a *spin crossover* sometimes occurs. This may be initiated by a change in pressure (e.g. a low- to high-spin crossover for $[Fe(CN)_5(NH_3)]^{3-}$ at high pressure) or temperature (e.g. octahedral $[Fe(phen)_2(NCS\text{-}N)_2]$, octahedral $[Fe(\mathbf{20.9})_2]$ and the square-based pyramidal complex **20.10** undergo low- to high-spin crossovers at 175, 391 and 180 K respectively). The change in the value of μ_{eff} which accompanies the spin crossover may be gradual or abrupt (Fig. 20.30).†

(20.9)

Rev.*, vol. 313, p. 38; A. Bousseksou, G. Molnár, L. Salmon and W. Nicolazzi (2011) *Chem. Soc. Rev.*, vol. 40, p. 3313; M. Halcrow (2011) *Chem. Soc. Rev.*, vol. 40, p. 4119.

(20.10)

In addition to magnetic measurements, Mössbauer spectroscopy (see Section 4.10) can be used to study spin-crossover transitions. Isomer shifts of iron complexes are sensitive not only to oxidation state but also to spin state. Figure 20.31 shows the Mössbauer spectra of $[Fe\{HC(3,5\text{-}Me_2pz)_3\}_2]I_2$ over a temperature range from 295 to 4.2 K. Each spectrum is characterized by a 'split peak' which is described in terms of the isomer shift, δ, and the quadrupole splitting, ΔE_Q. At 295 K, the iron(II) centre is high-spin ($\delta = 0.969\,mm\,s^{-1}$, $\Delta E_Q = 3.86\,mm\,s^{-1}$). On cooling, the complex undergoes a change to a low-spin state, and at 4.2 K, the transition is complete. The lowest spectrum in Fig. 20.31 arises from low-spin $[Fe\{HC(3,5\text{-}Me_2pz)_3\}_2]I_2$ ($\delta = 0.463\,mm\,s^{-1}$, $\Delta E_Q = 0.21\,mm\,s^{-1}$). At intermediate temperatures, the Mössbauer spectroscopic data are fitted to a mixture of low- and high-spin complexes (exemplified in Fig. 20.31 by the spectrum at 166 K).

Ferromagnetism, antiferromagnetism and ferrimagnetism

Whenever we have mentioned magnetic properties so far, we have assumed that metal centres do not interact with one another (Fig. 20.32a). This is true for substances where the paramagnetic centres are well separated from each other by diamagnetic species. Such systems are said to be *magnetically dilute* (see Section 4.9). For a paramagnetic material, the magnetic susceptibility, χ, is inversely proportional to temperature. This is expressed by the Curie law

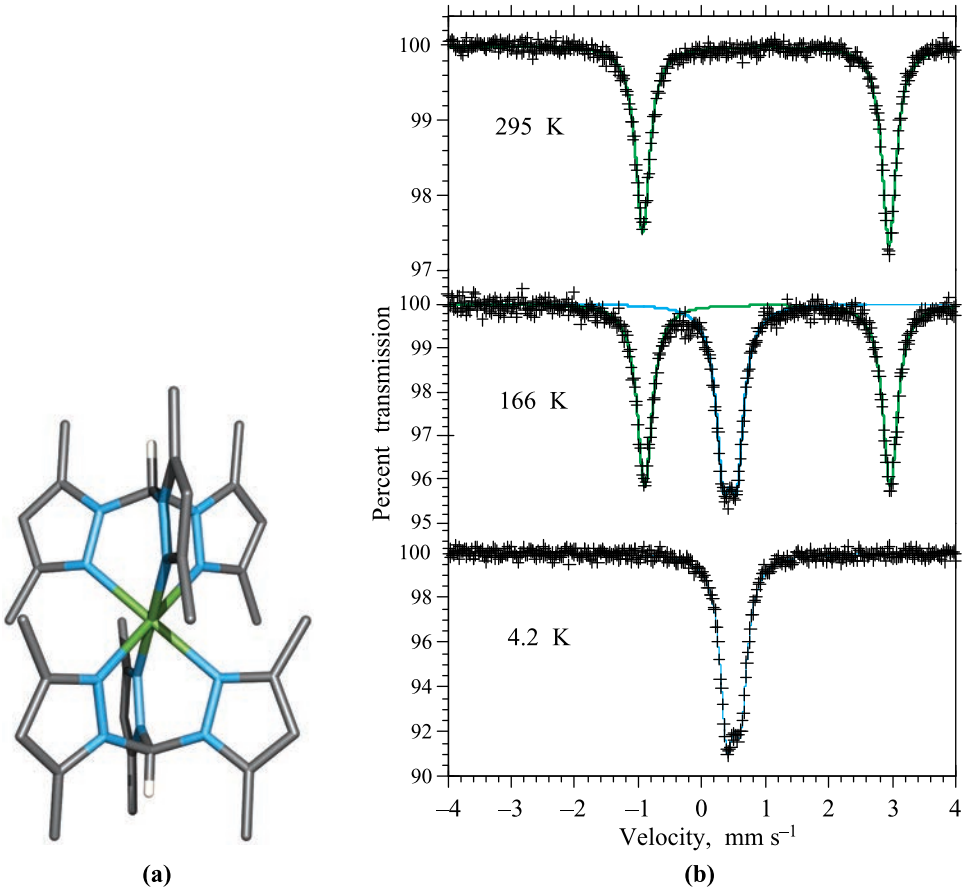


Fig. 20.31. (a) The structure (X-ray diffraction) of the $[Fe\{HC(3,5\text{-}Me_2pz)_3\}_2]^{2+}$ cation in which $HC(3,5\text{-}Me_2pz)_3$ is a tripodal ligand related to **20.9** (pz = pyrazoyl) [D.L. Reger *et al.* (2002) *Eur. J. Inorg. Chem.*, p. 1190]. (b) Mössbauer spectra of crystallized $[Fe\{HC(3,5\text{-}Me_2pz)_3\}_2]I_2$ at 295, 166 and 4.2 K obtained during cooling of the sample. The data points are shown by black crosses, and the data are fitted to the curves that are shown. [Prof. Gary J. Long is acknowledged for providing the spectra.]

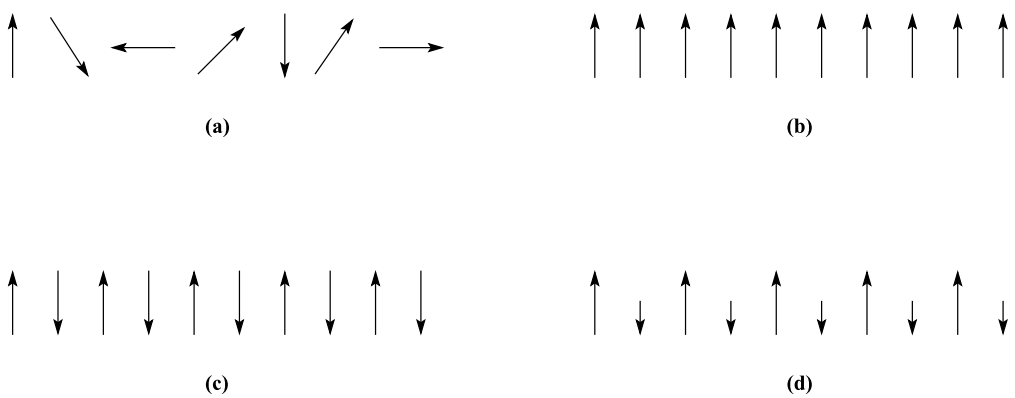

Fig. 20.32. Representations of (a) paramagnetism, (b) ferromagnetism, (c) antiferromagnetism and (d) ferrimagnetism.

(eq. 20.24 and Fig. 20.33a). When the paramagnetic species are very close together (as in the bulk metal) or are separated by a species that can transmit magnetic interactions (as in many *d*-block metal oxides, fluorides and chlorides), the metal centres may interact (*couple*) with one another. The interaction may give rise to *ferromagnetism* or *antiferromagnetism* (Figs. 20.32b and 20.32c).

In a ***ferromagnetic*** material, large domains of magnetic dipoles are aligned in the same direction. In an ***antiferromagnetic*** material, neighbouring magnetic dipoles are aligned in opposite directions.

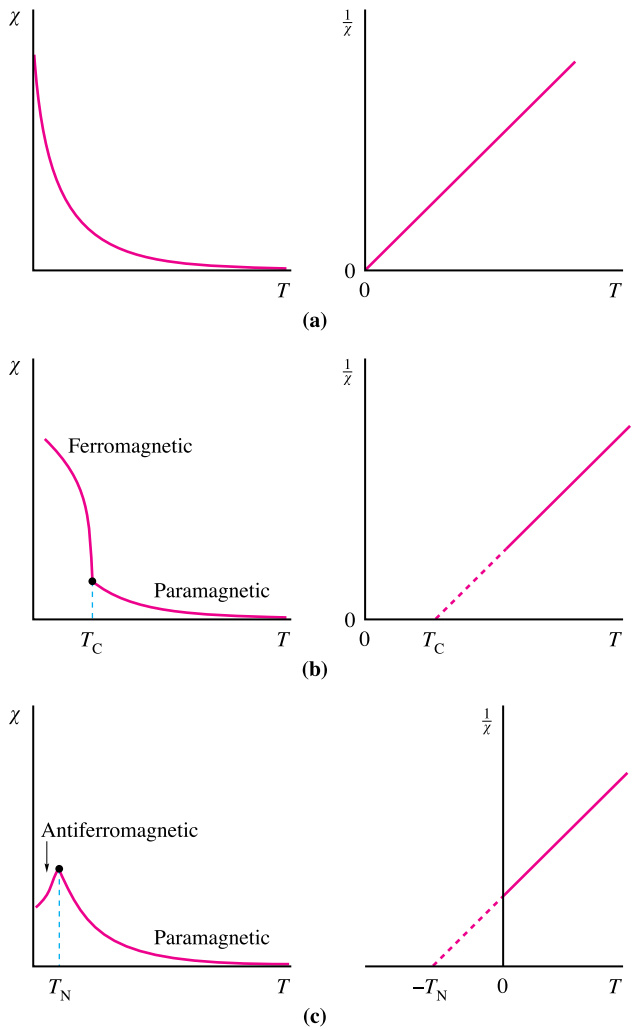
Ferromagnetism leads to greatly enhanced paramagnetism as in iron metal at temperatures of up to 1043 K

(the *Curie temperature*, T_C), above which thermal energy is sufficient to overcome the alignment and normal paramagnetic behaviour prevails. Above the Curie temperature, a ferromagnetic material obeys the Curie–Weiss law (eq. 20.25). This is represented graphically in Fig. 20.33b which illustrates that, on cooling a sample, ferromagnetic ordering (i.e. the change from paramagnetic to ferromagnetic domains, Fig. 20.32a to 20.32b) occurs at the Curie temperature, T_C. In many cases, the Weiss constant equals the Curie temperature, and the Curie–Weiss law can be written as in eq. 20.26.

$$\chi = \frac{C}{T - \theta} \qquad \text{Curie–Weiss law} \qquad (20.25)$$

where: θ = Weiss constant

C = Curie constant



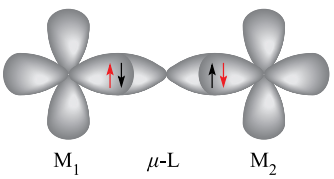


Fig. 20.33. The dependence of the magnetic susceptibility, χ, and of $^1/\chi$ on temperature for (a) a paramagnetic material, (b) a ferromagnetic material and (c) an antiferromagnetic material. The temperatures T_C and T_N are the Curie and Néel temperatures, respectively.

$$\chi = \frac{C}{T - T_C} \qquad (20.26)$$

where: T_C = Curie temperature

Antiferromagnetism occurs below the *Néel temperature*, T_N. As the temperature decreases, less thermal energy is available and the paramagnetic susceptibility falls rapidly. The dependence of magnetic susceptibility on temperature for an antiferromagnetic material is shown in Fig. 20.33c. The classic example of antiferromagnetism is MnO which has an NaCl-type structure and a Néel temperature of 118 K. Neutron diffraction is capable of distinguishing between sets of atoms having opposed magnetic moments and reveals that the unit cell of MnO at 80 K is double the one at 293 K. This indicates that in the conventional unit cell (Fig. 6.18), metal atoms at adjacent corners have opposed moments at 80 K and that the cells must be stacked to produce the 'true' unit cell. More complex behaviour may occur if some moments are systematically aligned so as to oppose others, but relative numbers or relative values of the moments are such as to lead to a finite resultant magnetic moment: this is *ferrimagnetism* and is represented schematically in Fig. 20.32d.

When a bridging ligand facilitates the coupling of electron spins on adjacent metal centres, the mechanism is one of *superexchange*. This is shown schematically in diagram **20.11**, in which the unpaired metal electrons are represented in red.

(20.11)

In a ***superexchange*** pathway, the unpaired electron on the first metal centre, M_1, interacts with a spin-paired pair of electrons on the bridging ligand with the result that the unpaired electron on M_2 is aligned in an antiparallel manner with respect to that on M_1.

20.11 Thermodynamic aspects: ligand field stabilization energies (LFSE)

Trends in LFSE

So far, we have considered Δ_{oct} (or Δ_{tet}) only as a quantity derived from electronic spectroscopy and representing the energy required to transfer an electron from a t_{2g} to an e_g level (or from an e to t_2 level). However, chemical significance can be attached to these values. Table 20.3 showed the variation in crystal field stabilization energies (CFSE)

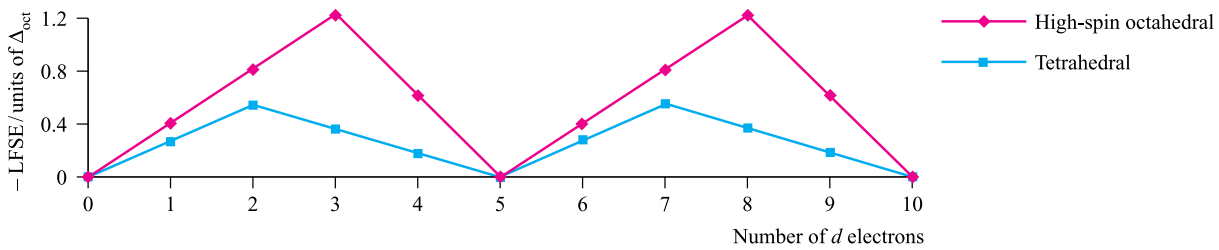

Fig. 20.34. Ligand field stabilization energies as a function of Δ_{oct} for high-spin octahedral systems and for tetrahedral systems; Jahn–Teller effects for d^4 and d^9 configurations have been ignored.

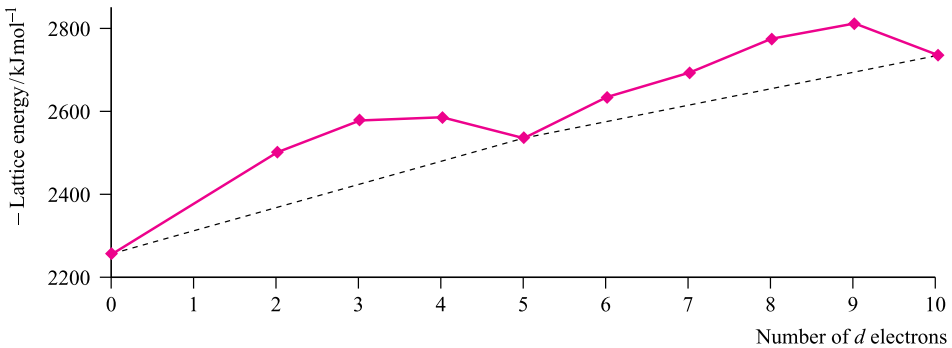

Fig. 20.35. Lattice energies (derived from Born–Haber cycle data) for MCl_2 where M is a first row *d*-block metal; the point for d^0 corresponds to $CaCl_2$. Data are not available for scandium where the stable oxidation state is +3.

for high- and low-spin octahedral systems. The trend for high-spin systems is shown in Fig. 20.34, where it is compared with that for a tetrahedral field, Δ_{tet} being expressed as a fraction of Δ_{oct} (see eq. 20.7). Note the change from CFSE to LFSE in moving from Table 20.3 to Fig. 20.34. This reflects the fact that we are now dealing with *ligand field theory* (see Section 20.5) and *ligand field stabilization energies*. In the discussion that follows, we consider relationships between observed trends in LFSE values and selected thermodynamic properties of high-spin compounds of the *d*-block metals.

Lattice energies and hydration energies of M^{n+} ions

Figure 20.35 shows a plot of experimental lattice energy data for metal(II) chlorides of first row *d*-block elements. In each salt, the metal ion is high-spin and lies in an octahedral environment in the solid state.[†] The 'double hump' in Fig. 20.35 is reminiscent of that in Fig. 20.34, albeit with respect to a reference line which shows a general increase in lattice energy as the period is crossed. Similar plots can be obtained for species such as MF_2, MF_3 and $[MF_6]^{3-}$, but for each series, only limited data are available and complete trends cannot be studied.

Water is a weak-field ligand and $[M(OH_2)_6]^{2+}$ ions of the first row metals are high-spin. The relationship between absolute enthalpies of hydration of M^{2+} ions (see Section 7.9) and d^n configuration is shown in Fig. 20.36, and again we see the same 'double-humped' appearance of Figs. 20.34 and 20.35.

For each plot in Figs. 20.35 and 20.36, deviations from the reference line joining the d^0, d^5 and d^{10} points may be taken as measures of 'thermochemical LFSE' values. In general, the agreement between these values and those calculated from the values of Δ_{oct} derived from electronic spectroscopic data are fairly close. For example, for $[Ni(OH_2)_6]^{2+}$, the values of LFSE(thermochemical) and LFSE(spectroscopic) are 120 and 126 kJ mol^{-1} respectively. The latter comes from an evaluation of $1.2\Delta_{oct}$ where Δ_{oct} is determined from the electronic spectrum of $[Ni(OH_2)_6]^{2+}$ to be 8500 cm^{-1}. We have to emphasize that this level of agreement is fortuitous. If we look more closely at the problem, we note that only *part* of the measured hydration enthalpy can be attributed to the first coordination sphere of six H_2O molecules, and, moreover, the definitions of LFSE(thermochemical) and LFSE(spectroscopic) are not strictly equivalent. In conclusion, interesting and useful though discussions of 'double-humped' graphs are in dealing with trends in the thermodynamics of high-spin complexes, it is important to note that they are

[†] Strictly, a purely electrostatic model does not hold for chlorides, but we include them because more data are available than for fluorides, for which the electrostatic model is more appropriate.

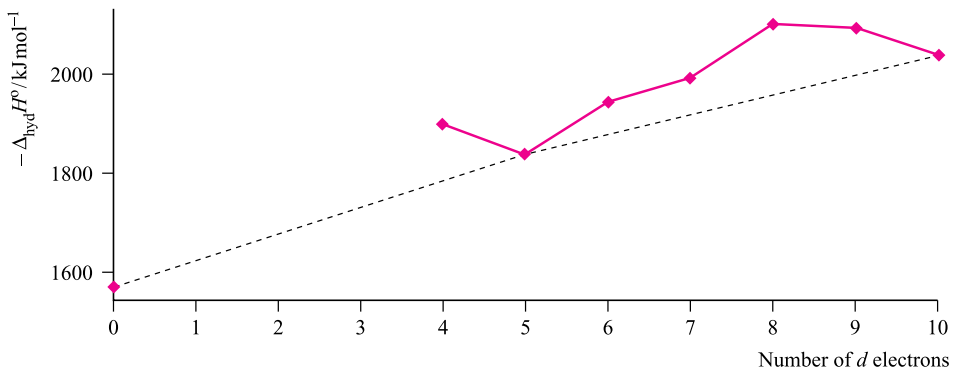

Fig. 20.36. Absolute enthalpies of hydration of the M^{2+} ions of the first row metals; the point for d^0 corresponds to Ca^{2+}. Data are not available for Sc^{2+}, Ti^{2+} and V^{2+}.

never more than *approximations*. It is crucial to remember that LFSE terms are only *small parts* of the total interaction energies (generally <10%).

Octahedral versus tetrahedral coordination: spinels

Figure 20.34 indicates that, if all other factors are equal, d^0, high-spin d^5 and d^{10} ions should have no electronically imposed preference between tetrahedral and octahedral coordination, and that the strongest preference for octahedral coordination should be found for d^3, d^8 and low-spin d^6 ions. Is there any unambiguous evidence for these preferences?

The distribution of metal ions between tetrahedral and octahedral sites in a spinel (see Box 13.7) can be rationalized in terms of LFSEs. In a normal spinel $A^{II}B^{III}_2O_4$ the tetrahedral sites are occupied by the A^{2+} ions and the octahedral sites by B^{3+} ions: $(A^{II})^{tet}(B^{III})^{oct}_2O_4$. In an inverse spinel, the distribution is $(B^{III})^{tet}(A^{II}B^{III})^{oct}O_4$. For spinel itself, A = Mg, B = Al. If at least one of the cations is from the *d*-block, the inverse structure is frequently (though by no means always) observed: $Zn^{II}Fe^{III}_2O_4$, $Fe^{II}Cr^{III}_2O_4$ and $Mn^{II}Mn^{III}_2O_4$ are normal spinels while $Ni^{II}Ga^{III}_2O_4$, $Co^{II}Fe^{III}_2O_4$ and $Fe^{II}Fe^{III}_2O_4$ are inverse spinels. To account for these observations we first note the following:

- the Madelung constants for the spinel and inverse spinel lattices are usually nearly equal;
- the charges on the metal ions are independent of environment (an assumption);
- Δ_{oct} values for complexes of M^{3+} ions are significantly greater than for corresponding complexes of M^{2+} ions.

Consider compounds with normal spinel structures: in $Zn^{II}Fe^{III}_2O_4$ (d^{10} and d^5), LFSE = 0 for each ion; in $Fe^{II}Cr^{III}_2O_4$ (d^6 and d^3), Cr^{3+} has a much greater LFSE in an octahedral site than does high-spin Fe^{2+}; in $Mn^{II}Mn^{III}_2O_4$ (d^5 and d^4), only Mn^{3+} has any LFSE and this is greater in an octahedral than a tetrahedral site. Now consider some inverse spinels: in $Ni^{II}Ga^{III}_2O_4$, only Ni^{2+} (d^8) has any LFSE and this is greater in an octahedral site; in each of $Co^{II}Fe^{III}_2O_4$ (d^7 and d^5) and $Fe^{II}Fe^{III}_2O_4$ (d^6 and d^5), LFSE = 0 for Fe^{3+} and so the preference is for Co^{2+} and Fe^{2+} respectively to occupy octahedral sites. While this argument is impressive, we must note that observed structures do not always agree with LFSE expectations, e.g. $Fe^{II}Al^{III}_2O_4$ is a normal spinel.

20.12 Thermodynamic aspects: the Irving–Williams series

In aqueous solution, water is replaced by other ligands (eq. 20.27, and see Table 7.8) and the position of equilibrium will be related to the difference between two LFSEs, since Δ_{oct} is ligand-dependent.

$$[Ni(OH_2)_6]^{2+} + [EDTA]^{4-} \rightleftharpoons [Ni(EDTA)]^{2-} + 6H_2O \quad (20.27)$$

Table 20.14 lists overall stability constants (see Section 7.12) for $[M(en)_3]^{2+}$ and $[M(EDTA)]^{2-}$ high-spin complexes for d^5 to d^{10} first row M^{2+} ions. For a given ligand and cation

Table 20.14 Overall stability constants for selected high-spin *d*-block metal complexes.

Metal ion	Mn^{2+}	Fe^{2+}	Co^{2+}	Ni^{2+}	Cu^{2+}	Zn^{2+}
log β_3 for $[M(en)_3]^{2+}$	5.7	9.5	13.8	18.6	18.7	12.1
log β for $[M(EDTA)]^{2-}$	13.8	14.3	16.3	18.6	18.7	16.1

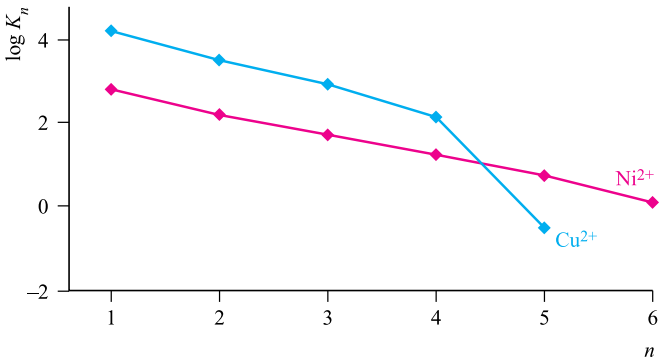

Fig. 20.37. Stepwise stability constants ($\log K_n$) for the displacement of H_2O by NH_3 from $[Ni(OH_2)_6]^{2+}$ (d^8) and $[Cu(OH_2)_6]^{2+}$ (d^9).

charge, ΔS^o should be nearly constant along the series and the variation in $\log \beta_n$ should approximately parallel the trend in values of $-\Delta H^o$. Table 20.14 shows that the trend from d^5 to d^{10} follows a 'single hump', with the ordering of $\log \beta_n$ for the high-spin ions being:

$$Mn^{2+} < Fe^{2+} < Co^{2+} < Ni^{2+} < Cu^{2+} > Zn^{2+}$$

This is called the *Irving–Williams series* and is observed for a wide range of ligands. The trend is a 'hump' that peaks at Cu^{2+} (d^9) and not at Ni^{2+} (d^8) as might be expected from a consideration of LFSEs (Fig. 20.34). While the variation in LFSE values is a contributing factor, it is not the sole arbiter. Trends in stability constants should bear a relationship to trends in ionic radii (see Appendix 6). The pattern in values of r_{ion} for 6-coordinate high-spin ions is:

$$Mn^{2+} > Fe^{2+} > Co^{2+} > Ni^{2+} < Cu^{2+} < Zn^{2+}$$

We might expect r_{ion} to decrease from Mn^{2+} to Zn^{2+} as Z_{eff} increases, but once again we see a dependence on the d^n configuration with Ni^{2+} being smallest. In turn, this predicts the highest value of $\log \beta_n$ for Ni^{2+}. Why, then, are copper(II) complexes so much more stable than might be expected? The answer lies in the Jahn–Teller distortion that a d^9 complex suffers. The six metal–ligand bonds are not of equal length and thus the concept of a 'fixed' ionic radius for Cu^{2+} is not valid. In an elongated complex (structure **20.5**) such as $[Cu(OH_2)_6]^{2+}$, there are four short and two long Cu−O bonds. Plots of stepwise stability constants for the displacement of H_2O by NH_3 ligands in $[Cu(OH_2)_6]^{2+}$ and $[Ni(OH_2)_6]^{2+}$ are shown in Fig. 20.37. For the first four substitution steps, complex stability is greater for Cu^{2+} than Ni^{2+}, reflecting the formation of four short (strong) Cu−N bonds. The value of $\log K_5$ for Cu^{2+} is consistent with the formation of a weak (axial) Cu−N bond; $\log K_6$ cannot be measured in aqueous solution. The magnitude of the overall stability constant for complexation of Cu^{2+} is dominated by values of K_n for the first four steps and the thermodynamic favourability of these displacement steps is responsible for the position of Cu^{2+} in the Irving–Williams series.

20.13 Thermodynamic aspects: oxidation states in aqueous solution

In the preceding sections, we have, with some degree of success, attempted to rationalize irregular trends in some thermodynamic properties of the first row *d*-block metals. Now we consider the variation in E^o values for equilibrium 20.28 (Table 19.1 and Fig. 20.38). The more negative the value of E^o, the less easily M^{2+} is reduced.

$$M^{2+}(aq) + 2e^- \rightleftharpoons M(s) \qquad (20.28)$$

This turns out to be a difficult problem. Water is relatively easily oxidized or reduced, and the range of oxidation states on which measurements can be made under aqueous conditions is therefore restricted, e.g. Sc(II) and Ti(II)

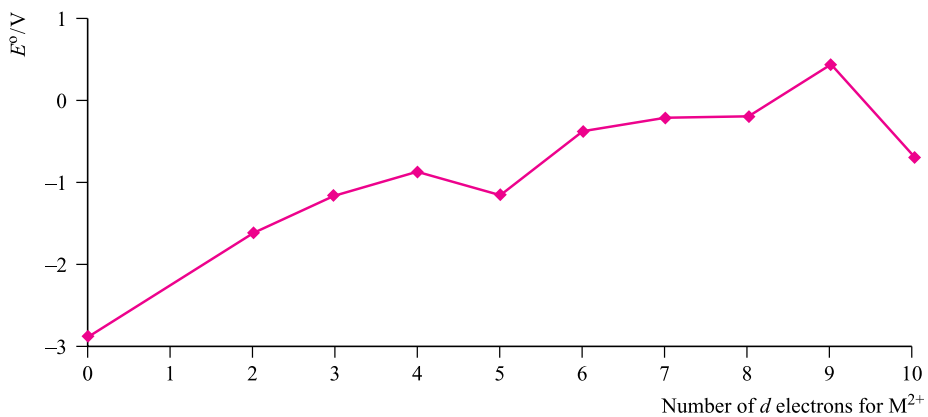

Fig. 20.38. The variation in values of $E^o(M^{2+}/M)$ as a function of d^n configuration for the first row metals; the point for d^0 corresponds to M = Ca.

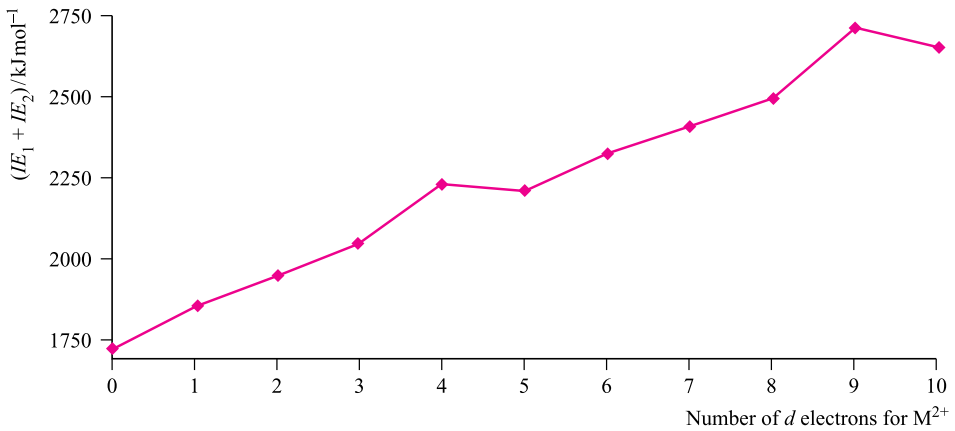

Fig. 20.39. The variation in the sum of the first and second ionization energies as a function of d^n configuration for the first row metals; the point for d^0 corresponds to M = Ca.

would liberate H_2. Values of $E^o(M^{2+}/M)$ are related (see Fig. 8.5) to energy changes accompanying the processes:

$M(s) \longrightarrow M(g)$ *atomization* ($\Delta_a H^o$)

$M(g) \longrightarrow M^{2+}(g)$ *ionization* ($IE_1 + IE_2$)

$M^{2+}(g) \longrightarrow M^{2+}(aq)$ *hydration* ($\Delta_{hyd}H^o$)

In crossing the first row of the *d*-block, the general trend is for $\Delta_{hyd}H^o$ to become more negative (Fig. 20.36). There is also a successive increase in the sum of the first two ionization energies albeit with discontinuities at Cr and Cu (Fig. 20.39). Values of $\Delta_a H^o$ vary erratically and over a wide range with a particularly low value for zinc (Table 6.2). The net effect of all these factors is an irregular variation in values of $E^o(M^{2+}/M)$ across the row, and it is clearly not worth discussing the relatively small variations in LFSEs.

Consider now the variations in $E^o(M^{3+}/M^{2+})$ across the row. The enthalpy of atomization is no longer relevant and we are concerned only with trends in the third ionization energy (Table 20.15) and the hydration energies of M^{2+} and M^{3+}. Experimental values for $E^o(M^{3+}/M^{2+})$ (Table 20.15) are restricted to the middle of the series; Sc(II) and Ti(II) would reduce water while Ni(III), Cu(III) and Zn(III) would oxidize it. In general, larger values of IE_3 correspond to more positive E^o values. This suggests that a steady increase in the difference between the hydration energies of M^{3+} and M^{2+} (which would become larger as the ions become smaller) is outweighed by the variation in IE_3. The only pair of metals for which the change in E^o appears out of step is vanadium and chromium. The value of IE_3 for Cr is 165 kJ mol^{-1} greater than for V and so it is harder to oxidize *gaseous* Cr^{2+} than V^{2+}. In aqueous solution however, Cr^{2+} is a more powerful reducing agent than V^{2+}. These oxidations correspond to changes in electronic configuration of $d^3 \longrightarrow d^2$ for V and $d^4 \longrightarrow d^3$ for Cr. The V^{2+}, V^{3+}, Cr^{2+} and Cr^{3+} hexaaqua ions are high-spin. Oxidation of V^{2+} is accompanied by a *loss* of LFSE (Table 20.3), while there is a *gain* in LFSE (i.e. more negative) upon oxidation of Cr^{2+} (minor consequences of the Jahn–Teller effect are ignored). Using values of Δ_{oct} from Table 20.2, these changes in LFSE are expressed as follows:

Change in LFSE on oxidation of V^{2+} is

$$-(1.2 \times 12\,400) \text{ to } -(0.8 \times 17\,850)$$
$$= -14\,880 \text{ to } -14\,280\,\text{cm}^{-1}$$
$$= +600\,\text{cm}^{-1}$$

Change in LFSE on oxidation of Cr^{2+} is

$$-(0.6 \times 14\,100) \text{ to } -(1.2 \times 17\,400)$$
$$= -8460 \text{ to } -20\,880\,\text{cm}^{-1}$$
$$= -12\,420\,\text{cm}^{-1}$$

The gain in LFSE upon formation of Cr^{3+} corresponds to $\approx$150 kJ mol^{-1} and largely cancels out the effect of the third ionization energy. Thus, the apparent anomaly of $E^o(Cr^{3+}/Cr^{2+})$ can be mostly accounted for in terms of LFSE effects – a considerable achievement in view of the simplicity of the theory.

Table 20.15 Standard reduction potentials for the equilibrium $M^{3+}(aq) + e^- \rightleftharpoons M^{2+}(aq)$ and values of the third ionization energies.

M	V	Cr	Mn	Fe	Co
E^o / V	−0.26	−0.41	+1.54	+0.77	+1.92
IE_3 / kJ mol^{-1}	2827	2992	3252	2962	3232

KEY TERMS

The following terms were introduced in this chapter. Do you know what they mean?

- ❑ high-spin
- ❑ low-spin
- ❑ crystal field theory
- ❑ Δ_{oct}, Δ_{tet} ...
- ❑ weak-field ligand
- ❑ strong-field ligand
- ❑ spectrochemical series
- ❑ crystal field stabilization energy (CFSE)
- ❑ pairing energy
- ❑ Jahn–Teller distortion
- ❑ π-donor ligand
- ❑ π-acceptor ligand
- ❑ 18-electron rule
- ❑ '*d–d*' transition
- ❑ quantum numbers for multi-electron species
- ❑ term symbol
- ❑ table of microstates
- ❑ Russell–Saunders coupling
- ❑ charge transfer absorption
- ❑ MLCT
- ❑ LMCT
- ❑ λ_{max} and ε_{max} for an absorption band
- ❑ selection rule: $\Delta S = 0$
- ❑ selection rule: $\Delta l = \pm 1$
- ❑ vibronic coupling
- ❑ Orgel diagram
- ❑ Racah parameter
- ❑ Tanabe–Sugano diagram
- ❑ nephelauxetic effect
- ❑ magnetic susceptibility
- ❑ effective magnetic moment
- ❑ spin-only formula
- ❑ Gouy balance
- ❑ spin–orbit coupling constant
- ❑ Curie law
- ❑ Kotani plot
- ❑ spin crossover
- ❑ ferromagnetism
- ❑ antiferromagnetism
- ❑ ferrimagnetism
- ❑ superexchange
- ❑ ligand field stabilization energy (LFSE)

PROBLEMS

20.1 Outline how you would apply crystal field theory to explain why the five *d*-orbitals in an octahedral complex are not degenerate. Include in your answer an explanation of the 'barycentre'.

20.2 The absorption spectrum of $[Ti(OH_2)_6]^{3+}$ exhibits a band with $\lambda_{max} = 510$ nm. What colour of light is absorbed and what colour will aqueous solutions of $[Ti(OH_2)_6]^{3+}$ appear?

20.3 Draw the structures of the following ligands, highlight the donor atoms and give the likely modes of bonding (e.g. monodentate): (a) en; (b) bpy; (c) $[CN]^-$; (d) $[N_3]^-$; (e) CO; (f) phen; (g) $[ox]^{2-}$; (h) $[NCS]^-$; (i) PMe_3.

20.4 Arrange the following ligands in order of increasing field strength: Br^-, F^-, $[CN]^-$, NH_3, $[OH]^-$, H_2O.

20.5 For which member of the following pairs of complexes would Δ_{oct} be the larger and why: (a) $[Cr(OH_2)_6]^{2+}$ and $[Cr(OH_2)_6]^{3+}$; (b) $[CrF_6]^{3-}$ and $[Cr(NH_3)_6]^{3+}$; (c) $[Fe(CN)_6]^{4-}$ and $[Fe(CN)_6]^{3-}$; (d) $[Ni(OH_2)_6]^{2+}$ and $[Ni(en)_3]^{2+}$; (e) $[MnF_6]^{2-}$ and $[ReF_6]^{2-}$; (f) $[Co(en)_3]^{3+}$ and $[Rh(en)_3]^{3+}$?

20.6 (a) Explain why there is no distinction between low- and high-spin arrangements for an octahedral d^8 metal ion. (b) Discuss the factors that contribute to the preference for forming either a high- or a low-spin d^4 complex. (c) How would you distinguish experimentally between the two configurations in (b)?

20.7 Verify the CFSE values in Table 20.3.

20.8 In each of the following complexes, rationalize the number of observed unpaired electrons (stated after the formula): (a) $[Mn(CN)_6]^{4-}$ (1); (b) $[Mn(CN)_6]^{2-}$ (3); (c) $[Cr(en)_3]^{2+}$ (4); (d) $[Fe(ox)_3]^{3-}$ (5); (e) $[Pd(CN)_4]^{2-}$ (0); (f) $[CoCl_4]^{2-}$ (3); (g) $[NiBr_4]^{2-}$ (2).

20.9 (a) Explain the forms of the *d* orbital splitting diagrams for trigonal bipyramidal and square pyramidal complexes of formula ML_5 shown in Fig. 20.11. (b) What would you expect concerning the magnetic properties of such complexes of Ni(II)?

20.10 (a) What do you understand by the *nephelauxetic effect*? (b) Place the following ligands in order of increasing nephelauxetic effect: H_2O, I^-, F^-, en, $[CN]^-$, NH_3.

20.11 Discuss each of the following observations:
(a) The $[CoCl_4]^{2-}$ ion is a regular tetrahedron but $[CuCl_4]^{2-}$ has a flattened tetrahedral structure.
(b) The electronic absorption spectrum of $[CoF_6]^{3-}$ contains two bands with maxima at 11 500 and 14 500 cm^{-1}.

20.12 The $3p^2$ configuration of an Si atom gives rise to the following terms: $^1S_0$, $^3P_2$, $^3P_1$, $^3P_0$ and $^1D_2$. Use Hund's rules to predict the relative energies of these terms, giving an explanation for your answer.

20.13 With reference to the ^3F, ^1D, ^3P, ^1G and ^1S terms of a d^2 configuration, explain how you can use term symbols to gain information about allowed electronic transitions.

20.14 What term or terms arise from a d^{10} configuration, and what is the ground state term? Give an example of a first row *d*-block metal ion with this configuration.

20.15 What are the limitations of the Russell–Saunders coupling scheme?

20.16 Deduce possible *J* values for a ^3F term. What is the degeneracy of each of these *J* levels, and what happens when a magnetic field is applied? Sketch an energy level diagram to illustrate your answer, and comment on its significance to EPR spectroscopy.

20.17 In an octahedral field, how will the following terms split, if at all: (a) ^2D, (b) ^3P and (c) ^3F?

20.18 (a) Set up a table of microstates to show that the ground term for the d^1 ion is the singlet ^2D. What are the components of this term in a tetrahedral field? (b) Repeat the process for a d^2 ion and show that the ground and excited terms are the ^3F and ^3P. What are the components of these terms in tetrahedral and octahedral fields?

20.19 (a) On Fig. 20.21, convert the wavenumber scale to nm. (b) Which part of the scale corresponds to the visible range? (c) What would you predict are the colours of $[Ni(OH_2)_6]^{2+}$ and $[Ni(NH_3)_6]^{2+}$. (d) Are the spectra in Fig. 20.21 consistent with the relative positions of H_2O and NH_3 in the spectrochemical series?

20.20 (a) How many '*d–d*' bands would you expect to find in the electronic absorption spectrum of an octahedral Cr(III) complex? (b) Account for the observation that the colour of *trans*-$[Co(en)_2F_2]^+$ is less intense than those of *cis*-$[Co(en)_2F_2]^+$ and *trans*-$[Co(en)_2Cl_2]^+$.

20.21 Comment on the following statements concerning electronic absorption spectra.
(a) $[OsCl_6]^{3-}$ and $[RuCl_6]^{3-}$ exhibit LMCT bands at 282 and 348 nm, respectively.
(b) $[Fe(bpy)_3]^{2+}$ is expected to exhibit an MLCT rather than an LMCT absorption.

20.22 Rationalize why the absorption spectrum of an aqueous solution of $[Ti(OH_2)_6]^{2+}$ (stable under acidic conditions) exhibits two well-separated bands (430 and 650 nm) assigned to '*d–d*' transitions, whereas that of an aqueous solution of $[Ti(OH_2)_6]^{3+}$ consists of one absorption ($\lambda_{max} = 490$ nm) with a shoulder (580 nm).

20.23 Describe how you could use Fig. 20.23 to determine Δ_{oct} and the Racah parameter *B* from the energies of absorptions observed in the spectrum of an octahedral d^3 ion. What are the significant limitations of this method?

20.24 The electronic absorption spectrum of $[Co(OH_2)_6]^{2+}$ exhibits bands at 8100, 16 000 and 19 400 cm^{-1}. (a) Assign these bands to electronic transitions. (b) The value of Δ_{oct} for $[Co(OH_2)_6]^{2+}$ listed in Table 20.2 is 9300 cm^{-1}. What value of Δ_{oct} would you obtain using the diagram in Fig. 20.23b? Why does the calculated value not match that in Table 20.2?

20.25 Values of the Racah parameter B for free gaseous Cr^{3+}, Mn^{2+} and Ni^{2+} ions are 918, 960 and 1041 cm^{-1}, respectively. For the corresponding hexaaqua ions, values of B are 725, 835 and 940 cm^{-1}. Suggest a reason for the reduction in B on forming each complex ion.

20.26 Find x in the formulae of the following complexes by determining the oxidation state of the metal from the experimental values of μ_{eff}: (a) $[VCl_x(bpy)]$, 1.77 μ_B; (b) $K_x[V(ox)_3]$, 2.80 μ_B; (c) $[Mn(CN)_6]^{x-}$, 3.94 μ_B. What assumption have you made and how valid is it?

20.27 Explain why in high-spin octahedral complexes, orbital contributions to the magnetic moment are only important for d^1, d^2, d^6 and d^7 configurations.

20.28 The observed magnetic moment for $K_3[TiF_6]$ is 1.70 μ_B. (a) Calculate μ(spin-only) for this complex. (b) Why is there a difference between calculated and observed values?

20.29 Comment on the observations that octahedral Ni(II) complexes have magnetic moments in the range 2.9–3.4 μ_B, tetrahedral Ni(II) complexes have moments up to $\approx 4.1\,\mu_B$, and square planar Ni(II) complexes are diamagnetic.

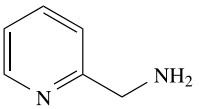
20.30 For which of the following ions would you expect the spin-only formula to give reasonable estimates of the magnetic moment: (a) $[Cr(NH_3)_6]^{3+}$, (b) $[V(OH_2)_6]^{3+}$, (c) $[CoF_6]^{3-}$? Rationalize your answer.

20.31 Which of the following ions are diamagnetic: (a) $[Co(OH_2)_6]^{3+}$, (b) $[CoF_6]^{3-}$, (c) $[NiF_6]^{2-}$, (d) $[Fe(CN)_6]^{3-}$, (e) $[Fe(CN)_6]^{4-}$, (f) $[Mn(OH_2)_6]^{2+}$? Rationalize your answer.

20.32 (a) Using data from Appendix 6, plot a graph to show how the ionic radii of high-spin, 6-coordinate M^{2+} ions of the first row of the d-block vary with the d^n configuration. Comment on factors that contribute to the observed trend. (b) Briefly discuss other properties of these metal ions that show related trends.

20.33 Values of Δ_{oct} for $[Ni(OH_2)_6]^{2+}$ and high-spin $[Mn(OH_2)_6]^{3+}$ have been evaluated spectroscopically as 8500 and 21 000 cm^{-1} respectively. Assuming that these values also hold for the corresponding oxide lattices, predict whether $Ni^{II}Mn^{III}_2O_4$ should have the normal or inverse spinel structure. What factors might make your prediction unreliable?

20.34 Discuss each of the following observations:
(a) Although $Co^{2+}(aq)$ forms the tetrahedral complex $[CoCl_4]^{2-}$ on treatment with concentrated HCl, $Ni^{2+}(aq)$ does not form a similar complex.
(b) E^o for the half-reaction:
$[Fe(CN)_6]^{3-} + e^- \rightleftharpoons [Fe(CN)_6]^{4-}$
depends on the pH of the solution, being most positive in strongly acidic medium.
(c) E^o for the Mn^{3+}/Mn^{2+} couple is much more positive than that for Cr^{3+}/Cr^{2+} or Fe^{3+}/Fe^{2+}.



OVERVIEW PROBLEMS

20.35 (a) Explain clearly why, under the influence of an octahedral crystal field, the energy of the d_{z^2} orbital is raised whereas that of the d_{xz} orbital is lowered. State how the energies of the other three d orbitals are affected. With respect to what are the orbital energies raised or lowered?
(b) What is the expected ordering of values of Δ_{oct} for $[Fe(OH_2)_6]^{2+}$, $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$? Rationalize your answer.
(c) Would you expect there to be an orbital contribution to the magnetic moment of a tetrahedral d^8 complex? Give an explanation for your answer.

20.36 (a) Which of the following complexes would you expect to suffer from a Jahn–Teller distortion: $[CrI_6]^{4-}$, $[Cr(CN)_6]^{4-}$, $[CoF_6]^{3-}$ and $[Mn(ox)_3]^{3-}$? Give reasons for your answers.
(b) $[Et_4N]_2[NiBr_4]$ is paramagnetic, but $K_2[PdBr_4]$ is diamagnetic. Rationalize these observations.
(c) Using a simple MO approach, explain what happens to the energies of the metal d orbitals on the formation of a σ-bonded complex such as $[Ni(NH_3)_6]^{2+}$.

20.37 Ligand **20.12** forms an octahedral complex, $[Fe(\mathbf{20.12})_3]^{2+}$. (a) Draw diagrams to show what

isomers are possible. (b) $[Fe(\mathbf{20.12})_3]Cl_2$ exhibits spin crossover at 120 K. Explain clearly what this statement means.

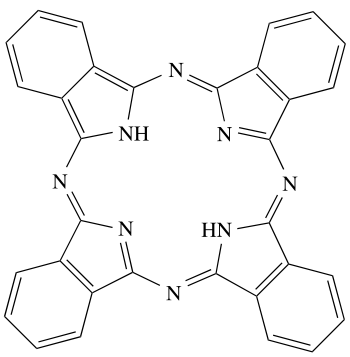
(20.12)

20.38 (a) The values of ε_{max} for the most intense absorptions in the electronic spectra of $[CoCl_4]^{2-}$ and $[Co(OH_2)_6]^{2+}$ differ by a factor of about 100. Comment on this observation and state which complex you expect to exhibit the larger value of ε_{max}.

(b) In the electronic absorption spectrum of a solution containing $[V(OH_2)_6]^{3+}$, two bands are observed at 17 200 and 25 600 cm^{-1}. No absorption for the $^3A_{2g} \leftarrow {}^3T_{1g}(F)$ transition is observed. Suggest a reason for this, and assign the two observed absorptions.

(c) Red crystalline $[NiCl_2(PPh_2CH_2Ph)_2]$ is diamagnetic. On heating to 387 K for 2 hours, a blue-green form of the complex is obtained, which has a magnetic moment of $3.18\mu_B$ at 295 K. Suggest an explanation for these observations and draw structures for the complexes, commenting on possible isomerism.

20.39 (a) A Kotani plot for the $t_{2g}^{\ 1}$ configuration consists of a curve similar to that in Fig. 20.29, but levelling off at $\mu_{eff} \approx 1.8\mu_B$ when $kT/\lambda \approx 1.0$. Suggest two metal ions that you might expect to possess room temperature values of μ_{eff} (i) on the near horizontal part of the curve and (ii) on the steepest part of the curve with $\mu_{eff} < 0.5$. For the four metal ions you have chosen, how do you expect μ_{eff} to be affected by an increase in temperature?



(b) Classify the following ligands as being σ-donor only, π-donor and π-acceptor: F^-, CO and NH_3. For each ligand, state what orbitals are involved in σ- or π-bond formation with the metal ion in an octahedral complex. Give diagrams to illustrate the overlap between appropriate metal orbitals and ligand group orbitals.

20.40 (a) Explain the origins of MLCT and LMCT absorptions in the electronic spectra of *d*-block metal complexes. Give examples to illustrate your answer.

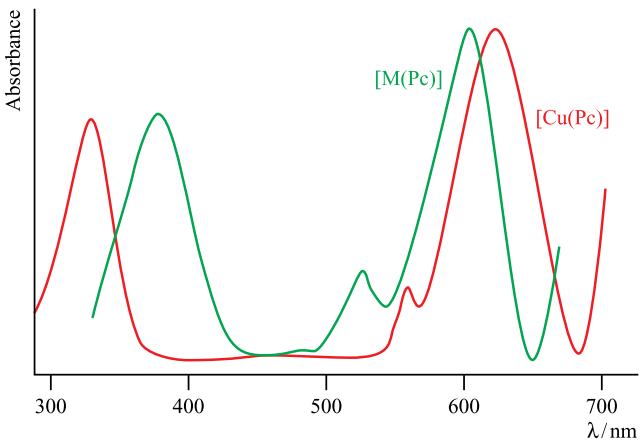
(b) Explain what information can be obtained from a Tanabe–Sugano diagram.

INORGANIC CHEMISTRY MATTERS

20.41 The structure of phthalocyanine is shown below:

H_2Pc

The complex [Cu(Pc)] is an important commercial pigment and its electronic absorption spectrum is shown in Fig. 20.40. The absorption spectrum represented by the green line in Fig. 20.40 arises from another metal(II) phthalocyanine complex, [M(Pc)]. (a) Suggest how the ligand H_2Pc binds Cu^{2+}, and draw the structure of [Cu(Pc)]. Comment on its formation in terms of the chelate effect. (b) What colour is the [Cu(Pc)] pigment? Rationalize your answer. (c) The absorptions around 600–650 nm in Fig. 20.40 arise from $\pi^* \leftarrow \pi$ transitions. Explain what this notation



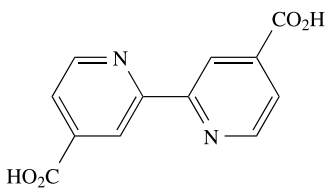


Fig. 20.40. The electronic absorption spectrum of copper(II) phthalocyanine, [Cu(Pc)], (red trace) and an absorption spectrum of a different metal(II) phthalocyanine, [M(Pc)] (green trace). [Based on Figure 4 in: P. Gregory in *Comprehensive Coordination Chemistry II*, 2004, Elsevier, Chapter 9.12, p. 549.]

means and the origins of the orbitals involved. (d) Explain how the absorption spectrum of [M(Pc)] gives rise to a green pigment. (e) When Cu^{2+} forms a complex with the perchlorinated analogue of H_2Pc, there is a red shift in the lowest energy absorption band compared to that in the spectrum of [Cu(Pc)]. How does this affect the colour of the pigment? (f) Inkjet printing dyes based on [Cu(Pc)] contain sulfonate substituents. Suggest a reason for this.

20.42 A crucial component of a dye-sensitized solar cell (DSC) is the sensitizer. The latter captures photons which are converted to electric current in the cell. A typical dye is *cis*-$[Ru(L)_2(NCS\text{–}N)_2]$ where L is the bpy derivative shown below:

(a) What conformational change does the bpy ligand undergo when it binds to Ru^{2+}? (b) An ideal dye should absorb light over the whole visible range, and the extinction coefficient should be high over the whole absorption range. Explain why this is. (c) The electronic transition associated with the absorption of *cis*-$[Ru(L)_2(NCS\text{-}N)_2]$ in the visible region involves an electron in the metal t_{2g} level and a low-lying π^* MO. What is the origin of the acceptor orbital, and what is the general name for this type of transition? Relate the type of transition to the redox properties of ruthenium(II).

21 d-Block metal chemistry: the first row metals

21.1 Introduction

The chemistry of the first row *d*-block metals is best considered separately from that of the second and third row metals for several reasons, including the following:

- the chemistry of the first member of a triad is distinct from that of the two heavier metals, e.g. Zr and Hf have similar chemistries but that of Ti differs;
- electronic absorption spectra and magnetic properties of many complexes of the first row metals can often be rationalized using crystal or ligand field theory, but effects of spin–orbit coupling are more important for the heavier metals (see Sections 20.9 and 20.10);
- complexes of the heavier metal ions show a wider range of coordination numbers than those of their first row congeners;
- trends in oxidation states (Table 19.3) are not consistent for all members of a triad, e.g. although the *maximum* oxidation state of Cr, Mo and W is +6, its stability is greater for Mo and W than for Cr;
- metal–metal bonding is more important for the heavier metals than for those in the first row.

The emphasis of this chapter is on inorganic and coordination chemistry; organometallic complexes are discussed in Chapter 24.

21.2 Occurrence, extraction and uses

Figure 21.1 shows the relative abundances of the first row *d*-block metals in the Earth's crust. ***Scandium*** occurs as a rare component in a range of minerals. Its main source is *thortveitite* $(Sc,Y)_2Si_2O_7$ (a rare mineral found in Scandinavia and Japan), and it can also be extracted from residues in uranium processing. Uses of scandium are limited; it is a component in high-intensity lights.

The main ore of ***titanium*** is ilmenite ($FeTiO_3$), and it also occurs as three forms of TiO_2 (*anatase*, *rutile* and *brookite*) and *perovskite* ($CaTiO_3$, Fig. 6.26). The structures of anatase, rutile and brookite differ as follows: whereas the structure of rutile (Fig. 6.24) is based on an hcp array of O^{2-} ions with half the octahedral holes occupied by Ti(IV) centres, those of anatase and brookite contain ccp arrays of O^{2-} ions. Titanium is present in meteorites, and rock samples from the *Apollo 17* lunar mission contain ≈12% of Ti. Production of Ti involves conversion of rutile or ilmenite to $TiCl_4$ (by heating in a stream of Cl_2 at 1200 K in the presence of coke) followed by reduction using Mg. Titanium(IV) oxide is also purified via $TiCl_4$ in the 'chloride process' (see Box 21.3). Titanium metal is resistant to corrosion at ambient temperatures, and is lightweight and strong, making it valuable as a component in alloys, e.g. in aircraft construction. Superconducting magnets (used, for example, in MRI equipment, see Box 4.3) contain NbTi multicore conductors.

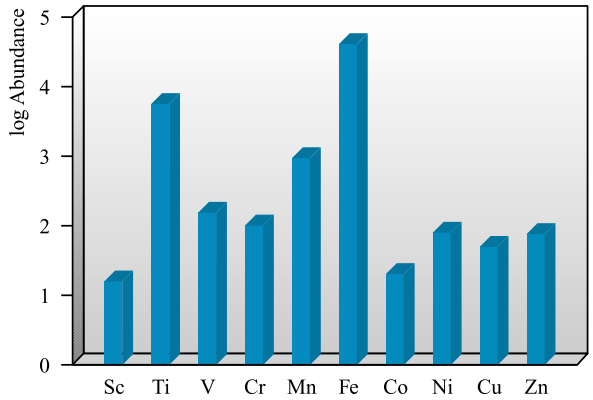

Fig. 21.1. Relative abundances of the first row *d*-block metals in the Earth's crust. The data are plotted on a logarithmic scale, and the units of abundance are parts per million (ppm).

Vanadium occurs in several minerals including *vanadinite* ($Pb_5(VO_4)_3Cl$), *carnotite* ($K_2(UO_2)_2(VO_4)_2{\cdot}3H_2O$), *roscoelite* (a vanadium-containing mica) and the polysulfide *patronite* (VS_4). It also occurs in phosphate rock (see Section 15.2) and in some crude oils. It is not mined directly and extraction of vanadium is associated with that of other metals. Roasting vanadium ores with Na_2CO_3 gives water-soluble $NaVO_3$ and from solutions of this salt, the sparingly soluble $[NH_4][VO_3]$ can be precipitated. This is heated to give V_2O_5, reduction of which with Ca yields V. The steel industry consumes about 85% of world supplies of V and *ferrovanadium* (used for toughening steels) is made by reducing a mixture of V_2O_5 and Fe_2O_3 with Al; steel–vanadium alloys are used for spring and high-speed cutting-tool steels. Vanadium(V) oxide is used as a catalyst in the oxidations of SO_2 to SO_3 (see Section 25.7) and of naphthalene to phthalic acid.

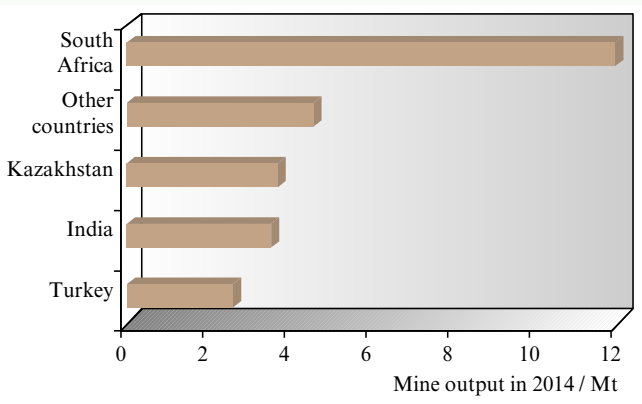
The major ore of ***chromium*** is *chromite* ($FeCr_2O_4$) which has a normal spinel structure (see Box 13.7 and Section 20.11). Chromite is reduced with carbon to produce *ferrochromium* for the steel industry; stainless steels contain Cr to increase their corrosion resistance (see Box 6.2). For the production of Cr metal, chromite is fused with Na_2CO_3 in the presence of air (eq. 21.1) to give water-soluble Na_2CrO_4 and insoluble Fe_2O_3. Extraction with water followed by acidification with H_2SO_4 gives a solution from which $Na_2Cr_2O_7$ can be crystallized. Equations 21.2 and 21.3 show the final two stages of production.

$$4FeCr_2O_4 + 8Na_2CO_3 + 7O_2 \longrightarrow 8Na_2CrO_4 + 2Fe_2O_3 + 8CO_2 \qquad (21.1)$$

$$Na_2Cr_2O_7 + 2C \xrightarrow{\Delta} Cr_2O_3 + Na_2CO_3 + CO \qquad (21.2)$$

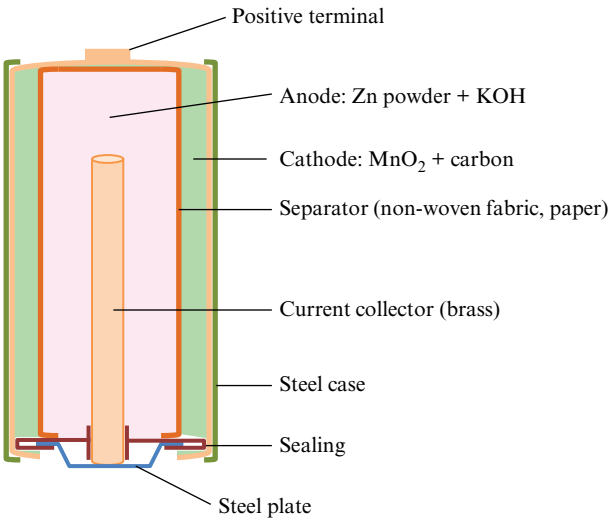
$$Cr_2O_3 + 2Al \xrightarrow{\Delta} Al_2O_3 + 2Cr \qquad (21.3)$$

The corrosion resistance of Cr leads to its widespread use as a protective coating (*chromium plating*). The metal is deposited by electrolysing aqueous $Cr_2(SO_4)_3$, produced by dissolving Cr_2O_3 in H_2SO_4. After the steel industry, the next major consumer of Cr (≈25%) is the chemical industry where applications include pigments (e.g. chrome yellow), tanning agents, mordants, catalysts and oxidizing agents. Chromite is used as a refractory material (see Section 12.6), e.g. in refractory bricks and furnace linings. Chromium compounds are toxic; chromates are corrosive to skin.



ENVIRONMENT

Box 21.1 Chromium: resources and recycling



About 95% of the world's reserve base of chromium ore lies in South Africa and Kazakhstan. The bar chart illustrates the dominance of South Africa in world chromite output.

Industrial nations in Europe and North America must rely on a supply of chromium ore from abroad, the US consuming ≈10% of world output. Because chromium is such a vital metal to the economy, government stockpiles in the US are considered an important strategy to ensure supplies during periods of military activity. Chromium ore is converted to chromium ferroalloys (for stainless steel and other alloys), chromite-containing refractory materials and chromium-based chemicals. The most important commercial applications of the latter are for pigments, leather tanning and wood preservation.

Recycling of stainless steel scrap as a source of Cr is an important secondary source. In 2015, 34% of the chromium consumed in the US orginated from recycled metal.

[Data: US Geological Survey.]

At anode: $Zn + 2OH^- \longrightarrow ZnO + H_2O + 2e^-$

At cathode: $2MnO_2 + H_2O + 2e^- \longrightarrow Mn_2O_3 + 2OH^-$

Overall cell reaction: $Zn + 2MnO_2 \longrightarrow ZnO + Mn_2O_3$

$E^o = 1.43$ V

Fig. 21.2. Schematic representation of a cutaway through an alkaline battery, and the cell reactions.

Several oxides of ***manganese*** occur naturally, the most important being *pyrolusite* (β-MnO_2). South Africa and Ukraine hold 80% and 10%, respectively, of the world's ore reserves. Little recycling of Mn currently takes place. Manganese nodules containing up to 24% of the metal have been discovered on the ocean bed. The main use of the element is in the steel industry. Pyrolusite is mixed with Fe_2O_3 and reduced with coke to give *ferromanganese* (≈80% Mn). Almost all steels contain some Mn; those with a high Mn content (up to 12%) possess very high resistance to shock and wear and are suitable for crushing, grinding and excavating machinery. Manganese metal is produced by the electrolysis of $MnSO_4$ solutions. Manganese(IV) oxide is used in alkaline batteries (Fig. 21.2) which are widely used in consumer goods. They were developed from the Leclanché cell (the dry battery or 'acid' cell) which differs from the alkaline battery in having KOH (Fig. 21.2) replaced by NH_4Cl. Alkaline batteries have greater energy density and longer lifetime than Leclanché cells. The development of rechargeable alkaline batteries (RAM = rechargeable alkaline manganese) adds lower environmental impact to their use. The strong oxidizing power of $KMnO_4$ makes this an important chemical (see Box 21.4). Manganese is an essential trace element for plants, and small amounts of $MnSO_4$ are added to fertilizers.

Iron is the most important of all metals and is the fourth most abundant element in the Earth's crust. The Earth's core is believed to consist mainly of iron and it is the main constituent of metallic meteorites. The chief ores are *haematite* (α-Fe_2O_3), *magnetite* (Fe_3O_4), *siderite* ($FeCO_3$), *goethite* (α-Fe(O)OH) and *lepidocrocite* (γ-Fe(O)OH). While *iron pyrites* (FeS_2) and *chalcopyrite* ($CuFeS_2$) are common, their high sulfur contents render them unsuitable for Fe production. Pure Fe (made by reduction of the oxides with H_2) is reactive and rapidly corrodes, and finely divided iron is pyrophoric. Although *pure* iron is not of commercial importance, steel production is carried out on a huge scale (see Section 6.7, Boxes 6.1, 6.2 and 8.4). α-Iron(III) oxide is used as a polishing and grinding agent and in the formation of ferrites (see Section 21.9). Iron oxides are important commercial pigments: α-Fe_2O_3 (red), γ-Fe_2O_3 (red-brown), Fe_3O_4 (black) and Fe(O)OH (yellow). Iron is of immense biological importance (see Chapter 29), and is present in, for example, haemoglobin and myoglobin (O_2 carriers), ferredoxins and cytochromes (redox processes), ferritin (iron storage), acid phosphatase (hydrolysis of phosphates), superoxide dismutases (O_2 dismutation) and nitrogenase (nitrogen fixation). A deficiency of iron in the body causes anaemia (see Box 21.5), while an excess causes haemochromatosis.

Cobalt occurs as a number of sulfide and arsenide ores including *cobaltite* (CoAsS) and *skutterudite* ($(Co,Ni)As_3$ which contains planar As_4-units). Production of the metal generally relies on the fact that it often occurs in ores of other metals (e.g. Ni, Cu and Ag) and the final processes involve reduction of Co_3O_4 with Al or C followed by electrolytic refining. Pure Co is brittle but it is commercially important in special steels, alloyed with Al, Fe and Ni (*Alnico* is a group of carbon-free alloys) in permanent magnets, and in the form of hard, strong, corrosion-resistant non-ferrous alloys (e.g. with Cr and W) which are important in the manufacture of jet engines and aerospace components. Cobalt compounds are widely used as pigments (blue hues in porcelain, enamels and glass, see Box 21.7), catalysts and as additives to animal feeds. Vitamin B_{12} is a cobalt complex, and a range of enzymes require B_{12} coenzymes.

Like cobalt, ***nickel*** occurs as sulfide and arsenide minerals, e.g. *pentlandite*, $(Ni,Fe)_9S_8$. Roasting such ores in air gives nickel oxide which is then reduced to the metal using carbon. The metal is refined electrolytically or by conversion to $Ni(CO)_4$ followed by thermal decomposition (eq. 21.4). This is the *Mond process*, which is based on the fact that Ni forms a carbonyl derivative more readily than any other metal.

$$Ni + 4CO \underset{423-573\ K}{\overset{323\ K}{\rightleftharpoons}} Ni(CO)_4 \qquad (21.4)$$

Nickel is used extensively in alloys, notably in stainless steel, other corrosion-resistant alloys such as *Monel metal*

(68% Ni and 32% Cu), and coinage metals. Electroplated Ni provides a protective coat for other metals. Nickel has widespread use in batteries; recently, this has included the production of 'environmentally friendly' nickel–metal hydride batteries (see Box 10.5) which are now superseding NiCd cells (eq. 21.5) as rechargeable sources of power in portable appliances.

$$\left.\begin{array}{ll} \textit{Anode:} & Cd + 2[OH]^- \longrightarrow Cd(OH)_2 + 2e^- \\ \textit{Cathode:} & NiO(OH) + H_2O + e^- \longrightarrow Ni(OH)_2 + [OH]^- \end{array}\right\} \quad (21.5)$$

Nickel is an important catalyst, e.g. for the hydrogenation of unsaturated organic compounds and in the water–gas shift reaction (see Section 10.4). *Raney nickel* is prepared by treating a NiAl alloy with NaOH and is a spongy material (pyrophoric when dry) which is a highly active catalyst. Recycling of nickel is becoming increasingly important with the major source being austenitic stainless steel (see Box 6.2). In the US, approximately 40% of nickel is recycled.

Copper is the least reactive of the first row metals and occurs native in small deposits in several countries. The chief ore is *chalcopyrite* ($CuFeS_2$). Other ores include *chalcanthite* ($CuSO_4{\cdot}5H_2O$), *atacamite* ($Cu_2(OH)_3Cl$), *malachite* ($Cu_2(OH)_2CO_3$) (Fig. 21.3), *azurite* ($Cu_3(OH)_2(CO_3)_2$) and *cuprite* (Cu_2O). Polished malachite is widely used for decorative purposes. Traditional Cu production involves roasting chalcopyrite in a limited air supply to give Cu_2S and FeO. The latter is removed by combination with silica to form a slag, and Cu_2S is converted to Cu by reaction 21.6. However, since the 1980s, methods which avoid SO_2 emissions have been introduced (Box 21.2).

$$Cu_2S + O_2 \longrightarrow 2Cu + SO_2 \quad (21.6)$$

Fig. 21.3. A piece of unpolished malachite, $Cu_2(OH)_2CO_3$.

Electrolytic purification of Cu is carried out by constructing a cell with impure Cu as the anode, clean Cu as the cathode and $CuSO_4$ as electrolyte. During electrolysis, Cu is transferred from anode to cathode, yielding high-purity metal (e.g. suitable for electrical wiring, a major use) and a deposit under the anode from which metallic Ag and Au can be extracted. Recycling of copper is important (Box 21.2). Being corrosion-resistant, Cu is in demand for water and steam piping and is used on the exterior of buildings, e.g. roofing and flashing, where long-term exposure results in a green patina of basic copper sulfate or carbonate. Alloys of Cu such as brass (Cu/Zn) (see Section 6.7), bronze (Cu/Sn), nickel silver (Cu/Zn/Ni) and coinage metal (Cu/Ni) are commercially important. Copper(II) sulfate is used extensively as a fungicide. Copper has a vital biochemical role (see Section 29.4), e.g. in cytochrome oxidase (involved in reduction of O_2 to H_2O) and haemocyanin (an O_2-carrying copper protein in arthropods). Copper compounds have numerous catalytic uses, and analytical applications include the biuret test and use of Fehling's solution (see Section 21.12).

The principal ores of ***zinc*** are *sphalerite* (*zinc blende*, ZnS, see Fig. 6.21), *calamine* (*hemimorphite*, $Zn_4Si_2O_7(OH)_2{\cdot}H_2O$) and *smithsonite* ($ZnCO_3$). Extraction from ZnS involves roasting in air to give ZnO followed by reduction with carbon. Zinc is more volatile (bp 1180 K) than most metals and can be separated by rapid chilling (to prevent reversing the reaction) and purified by distillation or electrolysis. Recycling of Zn has grown in importance, providing a secondary source of the metal. Figure 21.4 summarizes major uses of Zn. It is used to galvanize steel (see Section 6.7 and Box 8.4), and Zn alloys are commercially important, e.g. brass (Cu/Zn) and nickel silver (Cu/Zn/Ni). Alkaline batteries use zinc as the anode (Fig. 21.2). Zinc–air batteries have an advantage of being made from cheap materials. The overall cell reaction is the oxidation of Zn by O_2 which diffuses from the air into the cell. The cell reactions are shown in scheme 21.7, and spent batteries can be regenerated at specialized recycling centres, or *in situ* in specially designed regenerative zinc–air fuel cells. During regeneration, the cell reactions in scheme 21.7 are reversed.[†] Zinc–air batteries or rechargeable zinc–air fuel cells are used in hearing-aids and as back-up emergency power supplies, and show potential for use in electrically powered vehicles.

Zhang (2007) *J. Power Sources*, vol. 165, p. 897 – 'A regenerative zinc–air fuel cell'; Y. Li and H. Dai (2014) *Chem. Soc. Rev.*, vol. 43, p. 5257 – 'Recent advances in zinc–air batteries'.

ENVIRONMENT

Box 21.2 Copper: resources and recycling

The resources of copper on the Earth's surface have recently been re-estimated. About 550 million tonnes of copper are thought to be present in bedrock minerals and deep-sea nodules. The main copper ore for traditional mining is chalcopyrite ($CuFeS_2$). The conventional extraction process involves smelting and produces large quantities of SO_2 (see Box 16.5). Reactions that occur during smelting include:

$$2CuFeS_2 + O_2 \xrightarrow{\Delta} Cu_2S + 2FeS + SO_2$$

$$2CuFeS_2 + 4O_2 \xrightarrow{\Delta} Cu_2S + 2FeO + 3SO_2$$

$$2Cu_2S + 3O_2 \xrightarrow{\Delta} 2Cu_2O + 2SO_2$$

$$2Cu_2O + Cu_2S \xrightarrow{\Delta} 6Cu + SO_2$$

$$Cu_2O + FeS \xrightarrow{\Delta} Cu_2S + FeO$$

$$10Cu_2O + 3FeS \xrightarrow{\Delta} 20Cu + Fe_3O_4 + 3SO_2$$

$$3Fe_3O_4 + FeS \xrightarrow{\Delta} 10FeO + SO_2$$

FeO is converted to $FeSiO_3$ (called *slag*) by reaction with SiO_2. In the 1980s, a new copper extraction method was introduced that uses H_2SO_4 from the smelting process to extract Cu from copper ores other than those used in traditional mining, e.g. azurite ($Cu_3(OH)_2(CO_3)_2$) and malachite ($Cu_2(OH)_2CO_3$). Copper is extracted in the form of aqueous $CuSO_4$. This is mixed with an organic solvent, chosen so that it can extract Cu^{2+} ions by exchanging H^+ for Cu^{2+}, thus producing H_2SO_4 which is recycled back into the leaching stage of the operation. The aqueous-to-organic phase change separates Cu^{2+} ions from impurities. Acid is again added, releasing Cu^{2+} into an aqueous phase which is electrolysed to produce copper metal. The overall process is known as leach–solvent extraction–electrowinnning (SX/EW) and operates at ambient temperatures. It is an environmentally friendly, hydrometallurgical process, but because it relies on H_2SO_4, it is currently coupled to conventional smelting of sulfide ores. In South America, >40% of Cu is currently (in 2016) extracted by the SX/EW process. Worldwide, the SX/EW process is becoming increasingly important and, in 2017, accounted for ≈21% of world copper production.

In regions where sulfide ores predominate, copper is leached using bacteria. Naturally occurring bacteria called *Acidithiobacillus thiooxidans* oxidize sulfide to sulfate ion, and this bioleaching process now works in parallel with SX/EW as a substitute for a significant fraction of conventional smelting operations.

Among metals, consumption of Cu is exceeded only by steel and Al. The recovery of Cu from scrap metal is an essential part of copper-based industries, e.g. in 2015 in the US, recycled metal constituted ≈32% of the Cu supply. Worldwide mine production in 2015 was 18.7 Mt, with 30% originating from Chile, 9% from China, 9% from Peru and 7% from the US (the world's leading producers). Recycling of the metal is important for environmental reasons: dumping of waste leads to pollution, e.g. of water supplies. In the electronics industry, solutions of NH_3-NH_4Cl in the presence of O_2 are used to etch Cu in printed circuit boards. The resulting Cu(II) waste is subjected to a process analogous to SX/EW described above. The waste is first treated with an organic solvent XH which is a compound of the type RR'C(OH)C(NOH)R", the conjugate base of which can function as a ligand:

$$[Cu(NH_3)_4]^{2+}(aq) + 2XH(org) \longrightarrow CuX_2(org) + 2NH_3(aq) + 2NH_4{}^+(aq)$$

where aq and org represent the aqueous and organic phases respectively. Treatment with H_2SO_4 follows:

$$CuX_2 + H_2SO_4 \longrightarrow CuSO_4 + 2XH$$

and then Cu is reclaimed by electrolytic methods:

At the cathode: $Cu^{2+}(aq) + 2e^- \longrightarrow Cu(s)$

Bioleaching of copper from copper sulfide ores at the Skouriotissa copper mine in Cyprus.

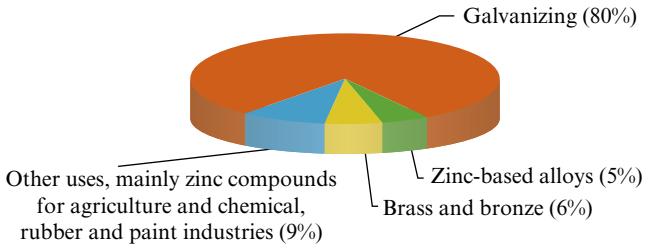

Fig. 21.4. Uses of zinc in the US in 2015. [Data: US Geological Survey.]

$$\left.\begin{aligned} &\textit{At the anode:} && Zn + 4[OH]^- \longrightarrow [Zn(OH)_4]^{2-} + 2e^- \\ & && [Zn(OH)_4]^{2-} \longrightarrow ZnO + 2[OH]^- + H_2O \\ &\textit{At the cathode:} && O_2 + 2H_2O + 4e^- \longrightarrow 4[OH]^- \\ &\textit{Overall:} && 2Zn + O_2 \longrightarrow 2ZnO \end{aligned}\right\} \quad (21.7)$$

Zinc oxide is widely used in skin creams and talcum powders, and is an ingredient in sunscreen lotions for protection against UV radiation. One of its major applications is in the rubber industry, where it lowers the vulcanization temperature and facilitates faster vulcanization (see Section 16.4). Both ZnO and ZnS are used as white pigments, although for most purposes TiO_2 is superior (see Box 21.3 and Section 28.5).

21.3 Physical properties: an overview

Physical data for the first row metals were discussed earlier in the book, but Table 21.1 summarizes selected physical properties. Additional data are tabulated as follows:

- metal structure types (Table 6.2);
- values of ionic radii, r_{ion}, which depend on charge, geometry and whether the ion is high- or low-spin (Appendix 6);
- standard reduction potentials, $E^o(M^{2+}/M)$ and $E^o(M^{3+}/M^{2+})$ (see Tables 19.1 and 20.15 and Appendix 11).

For electronic absorption spectroscopic data (e.g. Δ_{oct} and spin–orbit coupling constants) and magnetic moments, you should refer to the relevant sections in Chapter 20.

21.4 Group 3: scandium

The metal

In its chemistry, Sc shows a greater similarity to Al than to the heavier group 3 metals; E^o values are given for comparison in eq. 21.8.

$$M^{3+}(aq) + 3e^- \rightleftharpoons M(s) \quad \begin{cases} M = Al, & E^o = -1.66\,V \\ M = Sc, & E^o = -2.08\,V \end{cases} \quad (21.8)$$

Scandium metal dissolves in both acids and alkalis, and combines with halogens. It reacts with N_2 at high temperatures to give ScN which is hydrolysed by water. Scandium normally shows one stable oxidation state in its compounds, Sc(III). However, reactions of $ScCl_3$ and Sc at high temperatures lead to a number of subhalides (e.g. Sc_7Cl_{10} and Sc_7Cl_{12}).

Scandium(III)

Direct combination of Sc and a halogen gives anhydrous ScF_3 (water-insoluble white solid), $ScCl_3$ and $ScBr_3$ (soluble white solids) and ScI_3 (moisture-sensitive yellow solid). The fluoride crystallizes with the ReO_3 structure (Fig. 21.5) in which each Sc centre is octahedrally sited. In each of $ScCl_3$, $ScBr_3$ and ScI_3, the Sc atoms occupy two-thirds of the octahedral sites in an hcp array of halogen atoms (i.e. a BiI_3-type structure, Fig. 21.6). On reaction with MF (M = Na, K, Rb, NH_4), ScF_3 forms water-soluble complexes $M_3[ScF_6]$ containing octahedral $[ScF_6]^{3-}$.

Addition of aqueous alkali to solutions of Sc(III) salts precipitates ScO(OH) which is isostructural with AlO(OH). In the presence of excess $[OH]^-$, ScO(OH) redissolves as $[Sc(OH)_6]^{3-}$. Dehydration of ScO(OH) yields Sc_2O_3.

The coordination chemistry of Sc(III) is far more limited than that of the other first row *d*-block metal ions and is generally restricted to hard donors such as N and O. Coordination numbers of 6 are favoured, e.g. $[ScF_6]^{3-}$, $[Sc(bpy)_3]^{3+}$, *mer*-$[ScCl_3(OH_2)_3]$, *mer*-$[ScCl_3(THF)_3]$ and $[Sc(acac)_3]$. Among complexes with higher coordination numbers are $[ScF_7]^{4-}$ (pentagonal bipyramid), $[ScCl_2(15\text{-crown-}5)]^+$ (Fig. 19.8d), $[Sc(NO_3)_5]^{2-}$ (see end of Section 9.11) and $[Sc(OH_2)_9]^{3+}$ (tricapped trigonal prism). Bulky amido ligands stabilize low coordination numbers, e.g. $[Sc\{N(SiMe_3)_2\}_3]$.

Self-study exercise

Refer to Fig. 21.6.

1. In solid BiI_3, what is the relationship between the stoichiometry of the compound and the coordination numbers of Bi and I?

2. What type of forces operate between the layers in BiI_3?
[*Ans.* See the discussion of CdI_2, Fig. 6.25]

3. Relate the diagram in Fig. 21.6a to a description that 'the Bi atoms occupy two-thirds of the octahedral sites in an hcp array of iodine atoms', i.e. the description given for ScX_3 in the text.

21.5 Group 4: titanium

The metal

Titanium does not react with alkalis (cold or hot) and does not dissolve in mineral acids at room temperature. It is attacked by hot HCl, forming Ti(III) and H_2, and hot HNO_3 oxidizes the metal to hydrous TiO_2. Titanium wire dissolves in aqueous HF with vigorous liberation of H_2 and the formation of green-yellow solutions containing Ti(IV) and Ti(II) (eq. 21.9).

$$2Ti + 6HF \longrightarrow [TiF_6]^{2-} + Ti^{2+} + 3H_2 \quad (21.9)$$

Titanium reacts with most non-metals at high temperatures. With C, O_2, N_2 and halogens X_2, it forms TiC, TiO_2 (see Fig. 6.24), TiN (see Section 15.6) and TiX_4 respectively. With H_2, it forms 'TiH_2' but this has a wide non-stoichiometric range, e.g. $TiH_{1.7}$. The binary hydrides, carbide (see Section 14.7), nitride and borides (see Section 13.10) are all inert, high-melting, refractory materials.

In its compounds, Ti exhibits oxidation states of +4 (by far the most stable), +3, +2 and, rarely, 0.

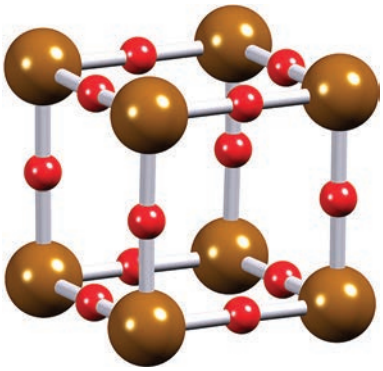

Fig. 21.5. Unit cell of ReO_3, a prototype structure; Re atoms are shown in brown and O atoms in red. This structure type is adopted by ScF_3 and FeF_3.

Titanium(IV)

Titanium(IV) halides can be formed from the elements. Industrially, $TiCl_4$ is prepared by reacting TiO_2 with Cl_2 in the presence of carbon and this reaction is also used in the purification of TiO_2 in the 'chloride process' (see Box 21.3). Titanium(IV) fluoride is a hygroscopic white solid which forms HF on hydrolysis. The vapour contains tetrahedral TiF_4 molecules. Solid TiF_4 consists of Ti_3F_{15}-units in which the Ti atoms are octahedrally sited; the corner-sharing octahedra (Fig. 21.7) are linked through the F_a atoms (shown in Fig. 21.7a) to generate isolated columns in an infinite array. $TiCl_4$ and $TiBr_4$ hydrolyse more readily than TiF_4. At 298 K, $TiCl_4$ is a colourless liquid (mp 249 K, bp 409 K) and $TiBr_4$ a yellow solid. The tetraiodide is a red-brown hygroscopic solid which sublimes *in vacuo* at 473 K to a red vapour. Tetrahedral molecules are present in the solid and vapour phases of $TiCl_4$, $TiBr_4$ and TiI_4. Each tetrahalide acts as a Lewis acid. $TiCl_4$ is the most important, being used with $AlCl_3$ in

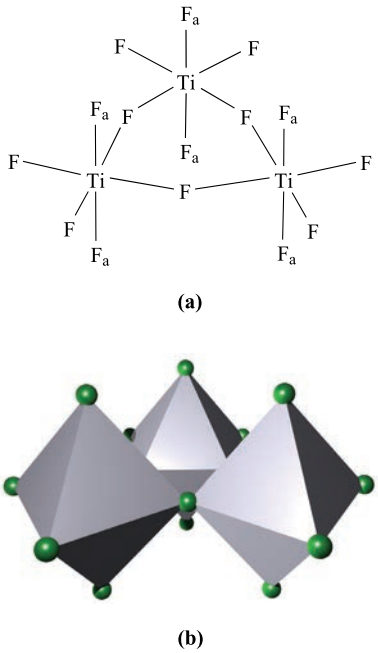

Fig. 21.7. The solid state structure of TiF_4 consists of columnar stacks of corner-sharing octahedra. The building blocks are Ti_3F_{15}-units shown here in (a) schematic representation and (b) polyhedral representation; F atoms are shown in green. [Data: H. Bialowons *et al.* (1995) *Z. Anorg. Allg. Chem.*, vol. 621, p. 1227.]

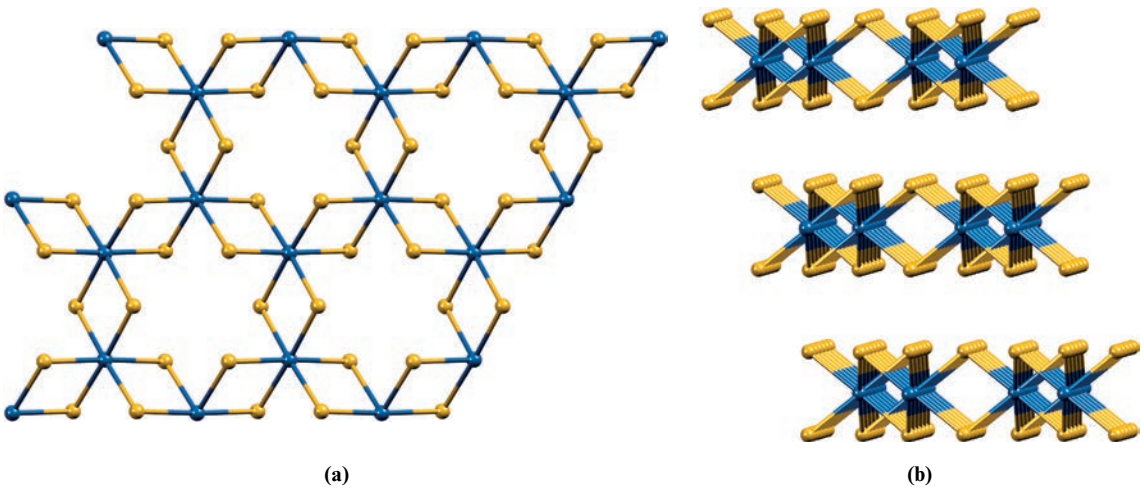
Ziegler–Natta catalysts for alkene polymerization (see Section 25.8) and as a catalyst in a variety of other organic reactions. The Lewis acidity of $TiCl_4$ is seen in complex formation. It combines with tertiary amines and phosphanes to give octahedral complexes such as $[TiCl_4(NMe_3)_2]$ and $[TiCl_4(PEt_3)_2]$. Salts containing $[TiCl_6]^{2-}$ are made in thionyl chloride solution since they are hydrolysed by water. In contrast, salts of $[TiF_6]^{2-}$ can be prepared in aqueous media. With the diarsane **21.1** (see scheme 23.89),



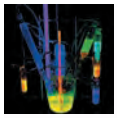


Fig. 21.6. The prototype BiI_3-structure consists of layers. (a) Looking down on part of one layer; each Bi atom is octahedrally sited and each I atom bridges two Bi atoms. (b) Parts of three adjacent layers. Colour code: Bi, blue; I, gold.

APPLICATIONS

Box 21.3 Commercial demand for TiO_2

Titanium dioxide has wide industrial applications as a brilliant white pigment and its applications as a pigment in the US in 2015 are shown in the chart opposite. This commercial application arises from the fact that fine particles scatter incident light extremely strongly; even crystals of TiO_2 possess a very high refractive index ($\mu = 2.70$ for rutile, 2.55 for anatase). Historically, Pb(II) compounds were used as pigments in paints but the associated health hazards make lead undesirable; TiO_2 has negligible health risks. Two manufacturing methods are used:

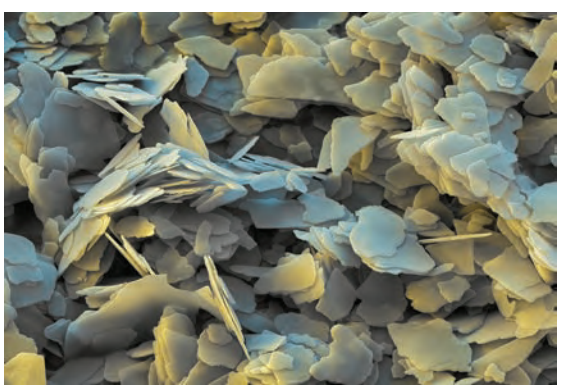
- the *sulfate process* produces TiO_2 in the form of rutile and anatase;
- the *chloride process* produces rutile.

The raw material for the sulfate process is ilmenite, $FeTiO_3$; treatment with H_2SO_4 at 420–470 K yields $Fe_2(SO_4)_3$, $TiOSO_4$ and some $FeSO_4$. The $Fe_2(SO_4)_3$ is reduced and separated as $FeSO_4{\cdot}7H_2O$ by a crystallization process. Hydrolysis of $TiOSO_4$ yields hydrated TiO_2 which is subsequently dehydrated to give TiO_2:

$$TiOSO_4 + (n+1)H_2O \xrightarrow{\text{aqu. alkali}} TiO_2{\cdot}nH_2O + H_2SO_4$$

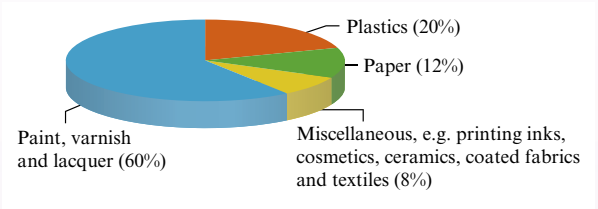
$$TiO_2{\cdot}nH_2O \xrightarrow{\Delta} TiO_2 + nH_2O$$

Sulfuric acid is removed by neutralization with $CaCO_3$ to produce gypsum as a by-product:



$$CaCO_3 + H_2SO_4 + H_2O \longrightarrow CaSO_4{\cdot}2H_2O + CO_2$$

Gypsum is recycled into the building trade (see Boxes 12.6 and 14.8). TiO_2 produced by the sulfate process is in the form of *anatase* unless seed crystals of *rutile* are introduced in the final stages of production. Rutile ore occurs naturally in, for example, apatite veins in Norway, and is the raw material for the chloride process. Initially, TiO_2 ore is converted to $TiCl_4$ by treatment with Cl_2 and C at 1200 K. Oxidation by O_2 at ≈1500 K yields pure rutile:



$$\underset{\text{crude}}{TiO_2} + 2Cl_2 + C \longrightarrow TiCl_4 + CO_2$$

$$TiCl_4 + O_2 \longrightarrow \underset{\text{pure}}{TiO_2} + 2Cl_2$$

The Cl_2 from the second step is recycled for use in the initial chlorination step.

Scanning electron microscopy (SEM) image of TiO_2 flakes. Magnification ×900.

Uses of TiO_2 pigment in the US in 2015. [Data: US Geological Survey.]

Originally, the sulfate process was the more industrially important process, but since the early 1990s, the chloride process has been favoured on both financial and environmental grounds. Both processes are in current use.

Titanium dioxide is a wide band-gap semiconductor and is an excellent photocatalyst for the photomineralization of water, i.e. the degradation of pollutants in water is catalysed by TiO_2 in the presence of UV radiation. Pollutants which can be successfully destroyed include a wide range of hydrocarbons and halogenated organic compounds as well as some herbicides, pesticides and dyes. The semiconducting properties of TiO_2 have also led to its being used as a gas sensor for detection of Me_3N emitted from decaying fish. Other uses of TiO_2 include applications in cosmetics and ceramics, and in anodes for various electrochemical processes. TiO_2 is used as a UV filter in suncreams and for this application, control over particle size is important since the optimum light scattering occurs when the TiO_2 particle diameter is 180–220 nm.

While only a fraction of a percent of the world's demand for TiO_2, the application of nanocrystalline TiO_2 (anatase) in Grätzel's dye-sensitized solar cells is becoming increasingly important. A film of the TiO_2 wide band-gap semiconductor is coated onto a transparent fluorine-doped tin oxide conducting glass. A redox active dye (which absorbs light over as wide a range of the visible spectrum as possible) is then adsorbed onto the TiO_2 surface. Excitation of the dye as a photon is absorbed is accompanied by injection of an electron into the conduction band of the semiconductor (see Section 28.3).

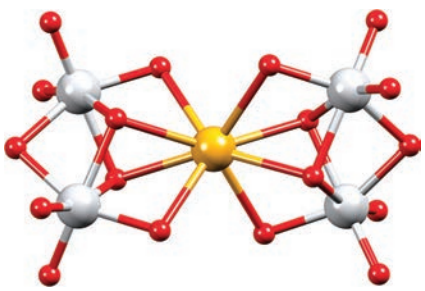
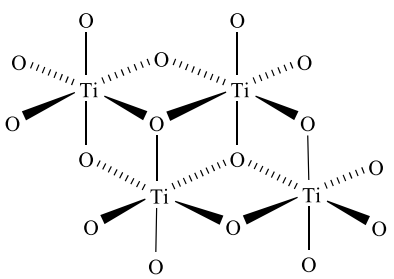
the dodecahedral complex $[TiCl_4(\mathbf{21.1})_2]$ is formed. Reaction of N_2O_5 with $TiCl_4$ yields anhydrous $[Ti(NO_3)_4]$ in which the Ti(IV) centre is in a dodecahedral environment (Fig. 21.8a).



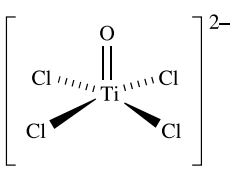
(21.1)



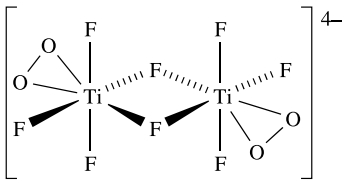
The commercial importance of TiO_2 is described in Box 21.3, and the structure of its rutile form was shown in Fig. 6.24. Although it may be formulated as $Ti^{4+}(O^{2-})_2$, the very high value of the sum of the first four ionization energies of the metal (8797 kJ mol^{-1}) makes the validity of the ionic model doubtful. Dry TiO_2 is difficult to dissolve in acids, but the hydrous form (precipitated by adding base to solutions of Ti(IV) salts) dissolves in HF, HCl and H_2SO_4 giving fluorido, chlorido and sulfato complexes respectively. There is no simple aqua ion of Ti^{4+}. The reaction of TiO_2 with CaO at 1620 K gives the *titanate* $CaTiO_3$. Other members of this group include $BaTiO_3$ and $FeTiO_3$ (*ilmenite*). The $M^{II}TiO_3$ titanates are *mixed oxides* and do *not* contain $[TiO_3]^{2-}$ ions. The structure type depends on the size of M^{2+}: if it is large (e.g. M = Ca), a perovskite lattice is favoured (Fig. 6.26) but if M^{2+} is similar in size to Ti(IV), a corundum structure (see Section 13.7), in which M(II) and Ti(IV) replace two Al(III) centres, is preferred, e.g. ilmenite. Above 393 K, $BaTiO_3$ has the perovskite structure, but at lower temperatures it transforms successively into three phases, each of which is a *ferroelectric*, i.e. the phase has an electric dipole moment even in the absence of an external magnetic field. This arises because the small Ti(IV) centre tends to lie off-centre in the octahedral O_6-hole (Fig. 6.26). Application of an electric field causes all such ions to be drawn to the same side of the holes and leads to a great increase in specific permittivity; thus, barium titanates are used in capacitors. Application of pressure to one side of a $BaTiO_3$ crystal causes the Ti^{4+} ions to migrate, generating an electric current (the piezoelectric effect, see Section 14.9), and this property makes $BaTiO_3$ suitable for use in electronic devices such as microphones. Interest in perovskite-phases such as $BaTiO_3$ and $CaTiO_3$ has led to investigations of solid state materials such as $[M\{Ti_2(OEt)_9\}_2]$ (M = Ba or Ca) (Fig. 21.8b) derived from reactions of alkoxides of Ti(IV) and Ba or Ca.

(a)

(b)



(c)



(d)

Fig. 21.8. (a) The structure of $Ti(NO_3)_4$ (X-ray diffraction) showing the dodecahedral environment of the Ti atom; compare with Fig. 19.10 [C.D. Garner *et al.* (1966) *J. Chem. Soc.*, *A*, p. 1496]; (b) the structure of $[Ca\{Ti_2(OEt)_9\}_2]$ (X-ray diffraction); Et groups are omitted [E.P. Turevskaya *et al.* (1994) *J. Chem. Soc.*, *Chem. Commun.*, p. 2303]; (c) the tetrameric structure of $[Ti(OEt)_4]$ i.e. $[Ti_4(OEt)_{16}]$ with ethyl groups omitted for clarity; (d) the structure of $[Ti_7(\mu_4\text{-}O)_2(\mu_3\text{-}O)_2(OEt)_{20}]$ (X-ray diffraction); Et groups are omitted [R. Schmid *et al.* (1991) *J. Chem. Soc.*, *Dalton Trans.*, p. 1999]. Colour code: Ti, pale grey; O, red; N, blue; Ca, yellow.

Titanium alkoxides are widely used in waterproofing fabrics and in heat-resistant paints. Thin films of TiO_2 are used in capacitors and can be deposited using Ti(IV) alkoxides such as $[Ti(OEt)_4]$. The ethoxide is prepared from $TiCl_4$ and Na[OEt] (or from $TiCl_4$, dry NH_3 and EtOH) and has a tetrameric structure (Fig. 21.8c) in which each Ti is octahedrally sited. Larger structures which retain TiO_6 'building-blocks' can be assembled. For example, reaction of $[Ti(OEt)_4]$ with anhydrous EtOH at 373 K gives $[Ti_{16}O_{16}(OEt)_{32}]$, while $[Ti_7O_4(OEt)_{20}]$ (Fig. 21.8d) is the product if basic $CuCO_3$ is present. Similar structures are observed for vanadates (Section 21.6), molybdates and tungstates (Section 22.7).

(21.2)

(21.3)

The reaction of TiO_2 and $TiCl_4$ at 1320 K in a fluidized bed produces $[Cl_3Ti(\mu\text{-}O)TiCl_3]$ which reacts with $[Et_4N]Cl$ to give $[Et_4N]_2[TiOCl_4]$. The $[TiOCl_4]^{2-}$ ion (**21.2**) has a square-based pyramidal structure with the oxido ligand in the apical position. A number of peroxido complexes of Ti(IV) are known and include products of reactions between TiO_2 in 40% HF and 30% H_2O_2; at pH 9 the product is $[TiF_2(\eta^2\text{-}O_2)_2]^{2-}$ while at pH 6, $[TiF_5(\eta^2\text{-}O_2)]^{3-}$ is formed. The dinuclear species $[Ti_2F_6(\mu\text{-}F)_2(\eta^2\text{-}O_2)_2]^{4-}$ (**21.3**) is made by treating $[TiF_6]^{2-}$ with 6% H_2O_2 at pH 5.

Titanium(III)

Titanium(III) fluoride is prepared by passing H_2 and HF over Ti or its hydride at 970 K. TiF_3 is a blue solid (mp 1473 K) with a structure related to ReO_3 (Fig. 21.5). $TiCl_3$ exists in four forms (α, β, γ and δ). The α-form (a violet solid) is prepared by reducing $TiCl_4$ with H_2 above 770 K and has a layer structure with Ti atoms in octahedral sites. The brown β-form is prepared by heating $TiCl_4$ with trialkyl aluminium compounds; it is fibrous and contains face-sharing $TiCl_6$ octahedra. $TiCl_3$ is commercially available. It is used as a catalyst in alkene polymerization (see Section 25.8) and is a powerful reducing agent. In air, $TiCl_3$ is readily oxidized, and disproportionates above 750 K (eq. 21.10).

$$2TiCl_3 \longrightarrow TiCl_4 + TiCl_2 \qquad (21.10)$$

$TiBr_3$ is made by heating $TiBr_4$ with Al, or by reaction of BBr_3 with $TiCl_3$; it is a grey solid with a layer structure analogous to α-$TiCl_3$. Reduction of TiI_4 with Al gives violet TiI_3. Both $TiBr_3$ and TiI_3 disproportionate when heated >600 K. The magnetic moment of TiF_3 (1.75 μ_B at 300 K) is consistent with one unpaired electron per metal centre. However, magnetic data for $TiCl_3$, $TiBr_3$ and TiI_3 indicate significant Ti−Ti interactions in the solid state. For $TiCl_3$, the magnetic moment at 300 K is 1.31 μ_B and $TiBr_3$ is only weakly paramagnetic.

When aqueous solutions of Ti(IV) are reduced by Zn, the purple aqua ion $[Ti(OH_2)_6]^{3+}$ is obtained (see eq. 7.35 and Fig. 20.4). This is a powerful reductant (eq. 21.11) and aqueous solutions of Ti(III) must be protected from aerial oxidation.

$$[TiO]^{2+}(aq) + 2H^+(aq) + e^- \rightleftharpoons Ti^{3+}(aq) + H_2O(l) \qquad E^\circ = +0.1\,V \qquad (21.11)$$

In alkaline solution (partly because of the involvement of H^+ in redox equilibrium 21.11, and partly because of the low solubility of the product), Ti(III) compounds liberate H_2 from H_2O and are oxidized to TiO_2. In the absence of air, alkali precipitates hydrous Ti_2O_3 from solutions of $TiCl_3$. Dissolution of this oxide in acids gives salts containing $[Ti(OH_2)_6]^{3+}$, e.g. $[Ti(OH_2)_6]Cl_3$ and $CsTi(SO_4)_2{\cdot}12H_2O$, the latter being isomorphous with other alums (see Section 13.9).

Titanium(III) oxide is made by reducing TiO_2 with Ti at high temperatures. It is a purple-black, insoluble solid with the corundum structure (see Section 13.7) and exhibits a transition from semiconductor to metallic character on heating above 470 K or doping with, for example, V(III). Uses of Ti_2O_3 include those in thin film capacitors.

Complexes of Ti(III) usually have octahedral structures, e.g. $[TiF_6]^{3-}$, $[TiCl_6]^{3-}$, $[Ti(CN)_6]^{3-}$, *trans*-$[TiCl_4(THF)_2]^-$, *trans*-$[TiCl_4(py)_2]^-$, *mer*-$[TiCl_3(THF)_3]$, *mer*-$[TiCl_3(py)_3]$ and $[Ti\{(H_2N)_2CO\text{-}O\}_6]^{3+}$, and magnetic moments close to the spin-only (d^1) value. Examples of 7-coordinate complexes include $[Ti(EDTA)(OH_2)]^-$ and $[Ti(OH_2)_3(ox)_2]^-$.

Low oxidation states

Titanium(II) chloride, bromide and iodide can be prepared by thermal disproportionation of TiX_3 (eq. 21.10) or by reaction 21.12. They are red or black solids which adopt the CdI_2 structure (Fig. 6.25).

$$TiX_4 + Ti \xrightarrow{\Delta} 2TiX_2 \qquad (21.12)$$

With water, $TiCl_2$, $TiBr_2$ and TiI_2 react violently, liberating H_2 as Ti(II) is oxidized. Equation 21.9, however, shows that the Ti^{2+} ion can be formed in aqueous solution under appropriate conditions. Either Ti or $TiCl_3$ dissolved in aqueous HF gives a mixture of $[TiF_6]^{2-}$ and $[Ti(OH_2)_6]^{2+}$. The former can be precipitated as $Ba[TiF_6]$ or $Ca[TiF_6]$, and the remaining $[Ti(OH_2)_6]^{2+}$ ion (d^2) exhibits an electronic absorption spectrum with two bands at 430 and 650 nm, which is similar to that of the isoelectronic $[V(OH_2)_6]^{3+}$ ion.

Titanium(II) oxide is manufactured by heating TiO_2 and Ti *in vacuo*. It is a black solid and a metallic conductor which adopts a defect NaCl-type structure: at room temperature one-sixth of both anion and cation sites are unoccupied, i.e. a Schottky defect. The oxide also exists as a non-stoichiometric compound with compositions in the range $TiO_{0.82}$–$TiO_{1.23}$. Conducting properties of the first row metal(II) oxides are compared in Section 28.2.

Reduction of $TiCl_3$ with Na/Hg, or of $TiCl_4$ with Li in THF and 2,2'-bipyridine leads to violet $[Ti(bpy)_3]$. Formally this contains Ti(0), but results of MO calculations and spectroscopic studies indicate that electron delocalization occurs such that the complex should be considered as $[Ti^{3+}(bpy^-)_3]$; see also the end of Section 19.5 and discussion of complexes containing ligand **19.11** in Section 19.7.

Self-study exercises

1. The structure of TiO_2 (rutile) is a 'prototype structure'. What does this mean? What are the coordination environments of the Ti and O centres? Give two other examples of compounds that adopt the same structure as TiO_2.
[*Ans.* See Fig. 6.24 and discussion]

2. The pK_a value for $[Ti(OH_2)_6]^{3+}$ is 3.9. To what equilibrium does this value relate? How does the strength of aqueous $[Ti(OH_2)_6]^{3+}$ as an acid compare with those of $MeCO_2H$, $[Al(OH_2)_6]^{3+}$, HNO_2 and HNO_3?
[*Ans.* See eqs. 7.35, and 7.9, 7.14, 7.13 and 7.34]

3. What is the electronic configuration of the Ti^{3+} ion? Explain why the electronic absorption spectrum of $[Ti(OH_2)_6]^{3+}$ consists of an absorption with a shoulder rather than a single absorption.
[*Ans.* See Section 20.7, after worked example 20.3]

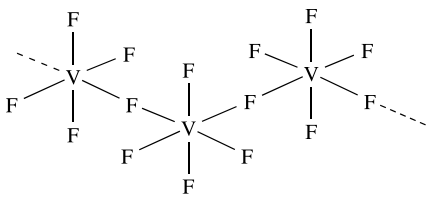
4. The electronic absorption spectrum of $[Ti(OH_2)_6]^{2+}$ consists of two bands assigned to '*d*–*d*' transitions. Is this consistent with what is predicted from the Orgel diagram shown in Fig. 20.20? Comment on your answer.

21.6 Group 5: vanadium

The metal

In many ways, V metal is similar to Ti. Vanadium is a powerful reducing agent (eq. 21.13) but is passivated by an oxide film.

$$V^{2+} + 2e^- \rightleftharpoons V \qquad E^o = -1.18\,V \qquad (21.13)$$



The metal is insoluble in non-oxidizing acids (except HF) and alkalis, but is attacked by HNO_3, *aqua regia* and solutions of $[S_2O_8]^{2-}$. On heating, V reacts with halogens (eq. 21.14) and combines with O_2 to give V_2O_5, and with B, C and N_2 to yield solid state materials (see Sections 13.10, 14.7 and 15.6).

$$V \begin{cases} \xrightarrow{F_2} VF_5 \\ \xrightarrow{Cl_2} VCl_4 \\ \xrightarrow{X_2} VX_3 \quad (X = Br \text{ or } I) \end{cases} \qquad (21.14)$$

The normal oxidation states of vanadium are +5, +4, +3 and +2. Oxidation state 0 occurs in a few compounds with π-acceptor ligands, e.g. $V(CO)_6$ (see Chapter 24).

Vanadium(V)

The only binary halide of vanadium(V) is VF_5 (eq. 21.14). It is a volatile white solid which is readily hydrolysed and is a powerful fluorinating agent. In the gas phase, VF_5 exists as trigonal bipyramidal molecules but the solid has a polymeric structure (**21.4**). The salts $K[VF_6]$ and $[Xe_2F_{11}][VF_6]$ are made by reacting VF_5 with KF or XeF_6 (at 250 K) respectively.

(21.4)

The halidooxidovanadium(V) compounds VOX_3 (X = F or Cl) are made by halogenation of V_2O_5. Reaction of VOF_3 with $(Me_3Si)_2O$ yields VO_2F, and treatment of $VOCl_3$ with Cl_2O gives VO_2Cl. Halidooxidovanadium(V) compounds are hygroscopic and hydrolyse readily. Both VO_2F and VO_2Cl decompose on heating (eq. 21.15).

$$3VO_2X \xrightarrow{\Delta} VOX_3 + V_2O_5 \qquad (X = F \text{ or } Cl) \qquad (21.15)$$

Pure V_2O_5 is an orange or red powder depending on its state of division, and is manufactured by heating $[NH_4][VO_3]$ (eq. 21.16).

$$2[NH_4][VO_3] \xrightarrow{\Delta} V_2O_5 + H_2O + 2NH_3 \qquad (21.16)$$

Vanadium(V) oxide is amphoteric, being sparingly soluble in water but dissolving in alkalis to give a wide range of vanadates, and in strong acids to form complexes of

$[VO_2]^+$. The species present in vanadium(V)-containing solutions depend on the pH:

pH 14 — $[VO_4]^{3-}$

$[VO_3(OH)]^{2-}$ in equilibrium with $[V_2O_7]^{4-}$

$[V_4O_{12}]^{4-}$

pH 6 — $[H_nV_{10}O_{28}]^{(6-n)-}$

V_2O_5

pH 0 — $[VO_2]^+$

This dependence can be expressed in terms of a series of equilibria such as eqs. 21.17–21.23.

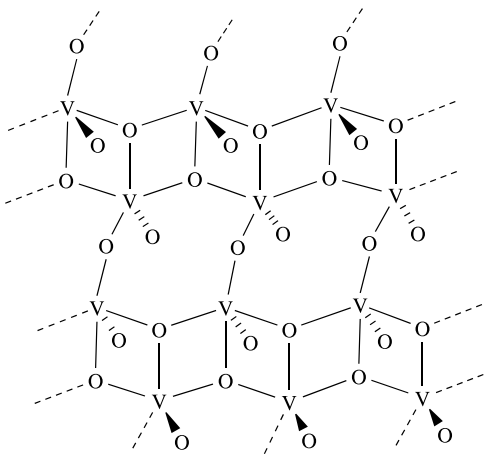
$$[VO_4]^{3-} + H^+ \rightleftharpoons [VO_3(OH)]^{2-} \quad (21.17)$$

$$2[VO_3(OH)]^{2-} \rightleftharpoons [V_2O_7]^{4-} + H_2O \quad (21.18)$$

$$[VO_3(OH)]^{2-} + H^+ \rightleftharpoons [VO_2(OH)_2]^- \quad (21.19)$$

$$4[VO_2(OH)_2]^- \rightleftharpoons [V_4O_{12}]^{4-} + 4H_2O \quad (21.20)$$

$$10[V_3O_9]^{3-} + 15H^+ \rightleftharpoons 3[HV_{10}O_{28}]^{5-} + 6H_2O \quad (21.21)$$

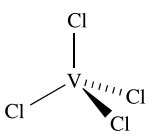


$$[HV_{10}O_{28}]^{5-} + H^+ \rightleftharpoons [H_2V_{10}O_{28}]^{4-} \quad (21.22)$$

$$[H_2V_{10}O_{28}]^{4-} + 14H^+ \rightleftharpoons 10[VO_2]^+ + 8H_2O \quad (21.23)$$

Isopolyanions (***homopolyanions***) are complex metal oxoanions (polyoxometallates) of type $[M_xO_y]^{n-}$, e.g. $[V_{10}O_{28}]^{6-}$ and $[Mo_6O_{19}]^{2-}$. A ***heteropolyanion*** contains a hetero atom, e.g. $[PW_{12}O_{40}]^{3-}$.

The formation of polyoxometallates is a characteristic of V, Mo, W (see Section 22.7) and, to a lesser extent, Nb, Ta and Cr. Characterization of solution species is aided by ^{17}O and ^{51}V NMR spectroscopies, and solid state structures for a range of salts are known. The structural chemistry of V_2O_5 and vanadates is complicated and only a brief survey is given here. The structure of V_2O_5 consists of layers of edge-sharing, approximately square-based pyramids (**21.5**). Each V centre is bonded to one O at 159 pm (apical site and not shared), one O at 178 pm (shared with one other V) and two O at 188 pm and one at 202 pm (shared with two other V atoms). Salts of $[VO_4]^{3-}$ (*orthovanadates*) contain discrete tetrahedral ions, and those of $[V_2O_7]^{4-}$ (*pyrovanadates*) also contain discrete anions (Fig. 21.9a); $[V_2O_7]^{4-}$ is isoelectronic and isostructural with $[Cr_2O_7]^{2-}$. The ion $[V_4O_{12}]^{4-}$ has a cyclic structure (Fig. 21.9b). Anhydrous salts of $[VO_3]^-$ (*metavanadates*) contain infinite chains of vertex-sharing VO_4 units (Figs. 21.9c and d). However, this structure type is not common to all metavanadates, e.g. in $KVO_3{\cdot}H_2O$ and $Sr(VO_3)_2{\cdot}4H_2O$ each V is bonded to five O atoms in a double-chain structure. The $[V_{10}O_{28}]^{6-}$ anion exists in solution (at appropriate pH) and has been characterized in the solid state in, for example, $[H_3NCH_2CH_2NH_3]_3[V_{10}O_{28}]{\cdot}6H_2O$ and $[^iPrNH_3]_6[V_{10}O_{28}]{\cdot}4H_2O$ (Fig. 21.9e). It consists of 10 VO_6 octahedral units with two μ_6-O, four μ_3-O, 14 μ-O and eight terminal O atoms. Crystalline salts of $[HV_{10}O_{28}]^{5-}$, $[H_2V_{10}O_{28}]^{4-}$ and $[H_3V_{10}O_{28}]^{3-}$ have also been isolated and the anions retain the framework shown in Fig. 21.9e. Examples of isopolyanions of vanadium with open ('bowl-shaped') structures are known, e.g. $[V_{12}O_{32}]^{4-}$, and these may act as 'hosts' to small molecules. In $[Ph_4P]_4[V_{12}O_{32}]{\cdot}4MeCN{\cdot}4H_2O$, one MeCN molecule resides partially within the cavity of the anion, while an $[NO]^-$ ion is encapsulated in $[Et_4N]_5[NO][V_{12}O_{32}]$.



Reduction of yellow $[VO_2]^+$ in acidic solution yields successively blue $[VO]^{2+}$, green V^{3+} and violet V^{2+}. The potential and Frost–Ebsworth diagrams in Fig. 21.10 show that all oxidation states of vanadium in aqueous solution are stable with respect to disproportionation.

(21.5)

Vanadium(IV)

The highest chloride of vanadium is VCl_4 (eq. 21.14). It is a toxic, red-brown liquid (mp 247 K, bp 421 K) and the liquid and vapour phases contain tetrahedral molecules (**21.6**). It readily hydrolyses to $VOCl_2$ (see below), and at 298 K, slowly decomposes (eq. 21.24). The reaction of VCl_4 with anhydrous HF gives lime-green VF_4 (solid at 298 K) which is also formed with VF_5 when V reacts with F_2. On heating, VF_4 disproportionates (eq. 21.25) in contrast to the behaviour of VCl_4 (eq. 21.24).

(21.6)

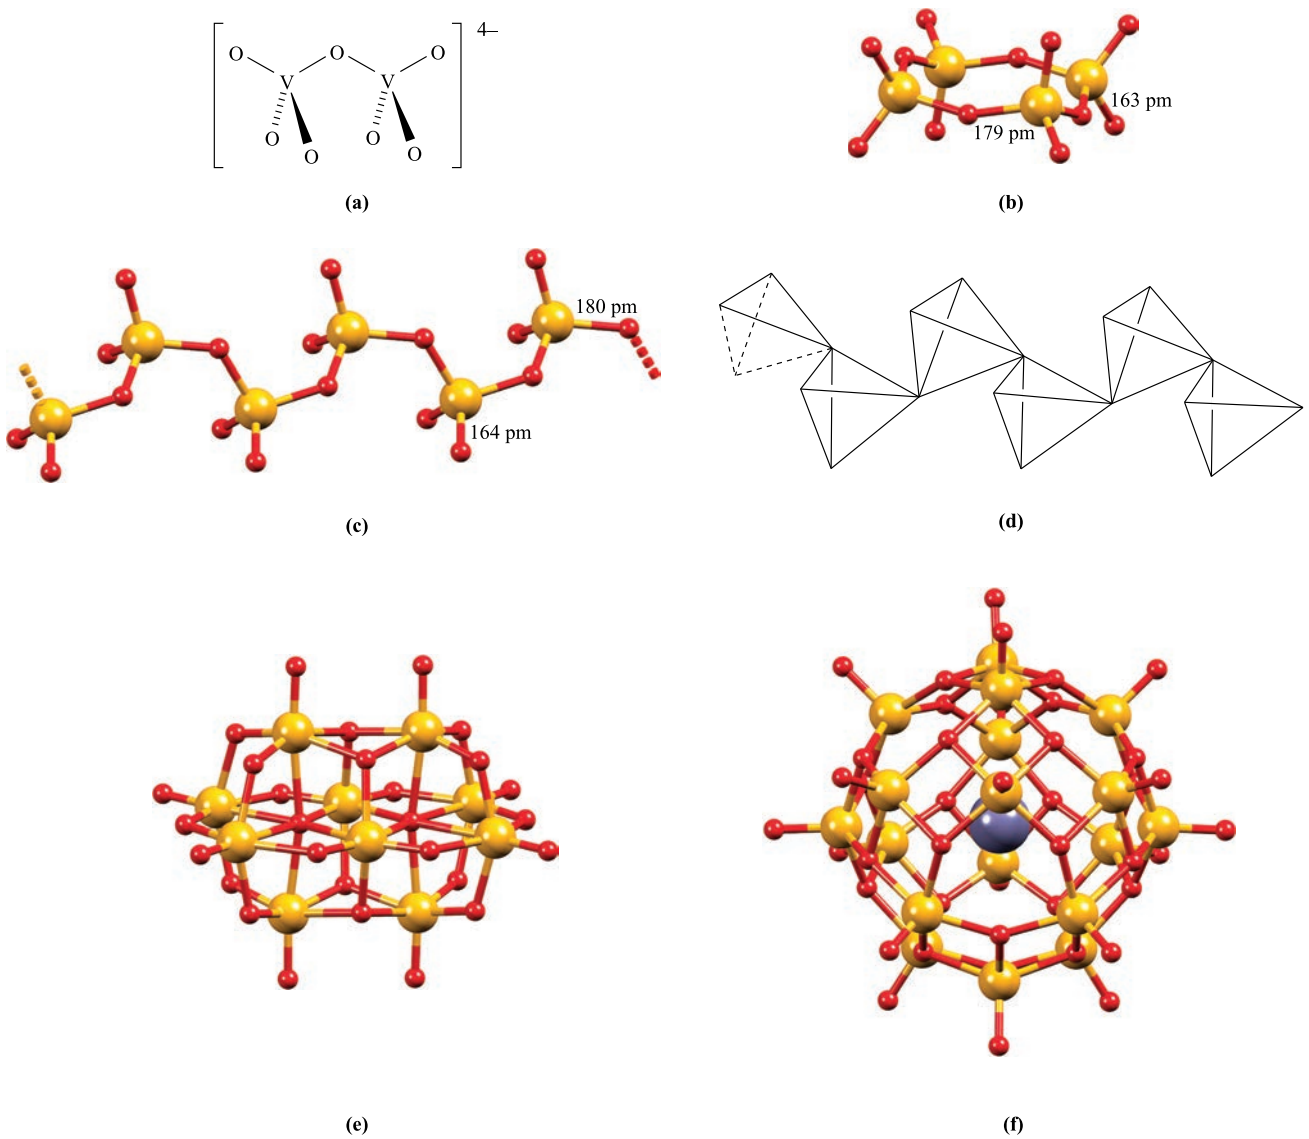


Fig. 21.9. (a) The structure of the $[V_2O_7]^{4-}$ anion consists of two tetrahedral units sharing a common oxygen atom; (b) the structure of $[V_4O_{12}]^{4-}$ in the salt $[Ni(bpy)_3]_2[V_4O_{12}]\cdot 11H_2O$ (X-ray diffraction) [G.-Y. Yang *et al.* (1998) *Acta Crystallogr., Sect. C*, vol. 54, p. 616]; (c) infinite chains of corner-sharing tetrahedral VO_4 units are present in anhydrous metavanadates; this shows part of one chain in $[n\text{-}C_6H_{13}NH_3][VO_3]$ (an X-ray diffraction determination) [P. Roman *et al.* (1991) *Mater. Res. Bull.*, vol. 26, p. 19]; (d) the structure of the metavanadate shown in (c) can be represented as a chain of corner-sharing tetrahedra, each tetrahedron representing a VO_4 unit; (e) the structure of $[V_{10}O_{28}]^{6-}$ in the salt $[^iPrNH_3]_6[V_{10}O_{28}]\cdot 4H_2O$ (X-ray diffraction) [M.-T. Averbuch-Pouchot *et al.* (1994) *Eur. J. Solid State Inorg. Chem.*, vol. 31, p. 351]; (f) in $[Et_4N]_5[V_{18}O_{42}I]$ (X-ray diffraction), the $[V_{18}O_{42}]^{4-}$ ion contains square-based pyramidal VO_5 units and the cage encapsulates I^- [A. Müller *et al.* (1997) *Inorg. Chem.*, vol. 36, p. 5239]. Colour code: V, yellow; O, red; I, purple.

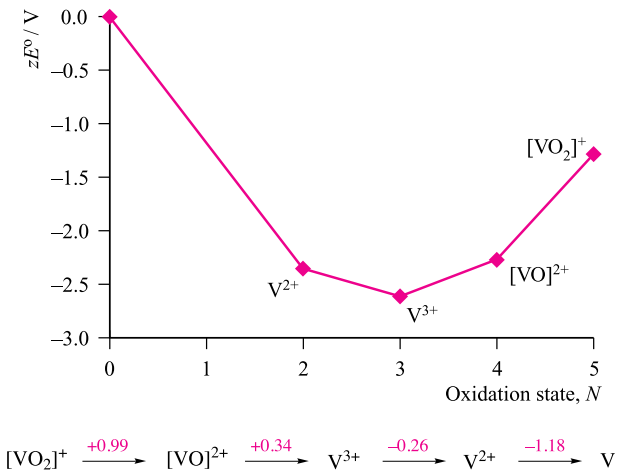
$$2VCl_4 \longrightarrow 2VCl_3 + Cl_2 \qquad (21.24)$$

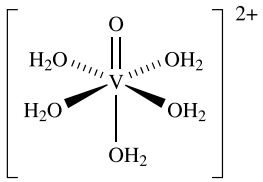
$$2VF_4 \xrightarrow{\geq 298\,K} VF_5 + VF_3 \qquad (21.25)$$

The structure of solid VF_4 consists of fluorine bridged VF_6-units. Four VF_6-units are linked by V–F–V bridges to give tetrameric rings (as in CrF_4, structure **21.14**) and these motifs are connected through additional fluorine bridges to form layers. Reaction between VF_4 and KF in anhydrous HF gives $K_2[VF_6]$ containing octahedral $[VF_6]^{2-}$. Vanadium(IV) bromide is known but decomposes at 250 K to VBr_3 and Br_2.

Green $VOCl_2$ (prepared from V_2O_5 and VCl_3) is polymeric and has a temperature-dependent magnetic moment (1.40 μ_B at 296 K, 0.95 μ_B at 113 K); it decomposes on heating (eq. 21.26).

$$2VOCl_2 \xrightarrow{650\,K} VOCl_3 + VOCl \qquad (21.26)$$





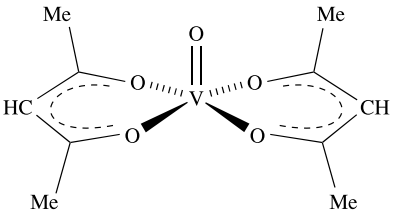


Fig. 21.10. Potential (lower) and Frost–Ebsworth diagrams for vanadium at pH 0.

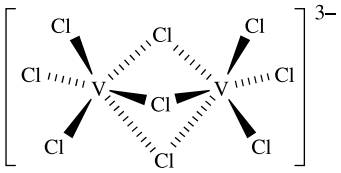
(21.7)

Figure 21.10 shows that vanadium(V) is quite a powerful oxidant, and only mild reducing agents (e.g. SO_2) are needed to convert V(V) to V(IV). In aqueous solution, V(IV) is present as the hydrated vanadyl ion $[VO]^{2+}$ (**21.7**) of which many salts are known. Anhydrous $V(O)SO_4$ is manufactured by reducing a solution of V_2O_5 in H_2SO_4 with $H_2C_2O_4$. Blue solid $V(O)SO_4$ has a polymeric structure with vertex-sharing VO_6 octahedra linked by sulfate groups. The hydrate $V(O)SO_4{\cdot}5H_2O$ contains octahedrally sited V(IV) involving one oxido ligand (V–O = 159 pm) and five other O atoms (from sulfate and four H_2O) at 198–222 pm. The reaction of V_2O_5 and Hacac (see Table 7.8) gives blue $[VO(acac)_2]$ which has a square-based pyramidal structure (**21.8**). This readily forms complexes with *N*-donor ligands which occupy the site *trans* to the oxido ligand. The salt $[NH_4]_2[VOCl_4]$ can be obtained by crystallization of a solution of $VOCl_3$ and $[NH_4]Cl$ in hydrochloric acid. The $[VOCl_4]^{2-}$ ion has a square-based pyramidal structure with the oxido ligand in the apical site. This preference is seen throughout related derivatives containing the $[VO]^{2+}$ unit. Its presence is detected by a characteristic IR spectroscopic absorption around 980 cm^{-1} (the corresponding value for a V–O single bond is ≈480 cm^{-1}).

(21.8)



Vanadium(IV) oxide, VO_2, is prepared by heating V_2O_5 with $H_2C_2O_4$. It crystallizes with a rutile-type structure (Fig. 6.24) which is distorted at 298 K so that pairs of V(IV) centres are alternately 262 and 317 pm apart. The shorter distance is consistent with metal–metal bonding. This polymorph is an insulator, but above 343 K, the electrical conductivity and magnetic susceptibility of VO_2 increase as the regular rutile structure is adopted. Vanadium(IV) oxide is blue but shows thermochromic behaviour.

The colour of a ***thermochromic*** compound is temperature dependent. The phenomenon is called ***thermochromism***.

Vanadium(IV) oxide is amphoteric, dissolving in non-oxidizing acids to give $[VO]^{2+}$ and in alkalis to form homopolyanions such as $[V_{18}O_{42}]^{12-}$, the Na^+ and K^+ salts of which can be isolated by heating $V(O)SO_4$ and MOH (M = Na or K) in water at pH 14 in an inert atmosphere. The structure of $[V_{18}O_{42}]^{12-}$ consists of square-based pyramidal VO_5-units, the apical O atoms of which are terminal (i.e. V=O units) while basal O atoms are involved in V–O–V bridges to build an almost spherical cage. Related anions such as $[V_{18}O_{42}]^{4-}$, $[V_{18}O_{42}]^{5-}$ and $[V_{18}O_{42}]^{6-}$ formally contain V(IV) and V(V) centres. The cavity in $[V_{18}O_{42}]^{n-}$ is able to accommodate an *anionic* guest as in $[V_{18}O_{42}I]^{5-}$ (Fig. 21.9f) or $[H_4V_{18}O_{42}X]^{9-}$ (X = Cl, Br, I).

Vanadium(III)

The trihalides VF_3, VCl_3, VBr_3 and VI_3 are all known. The yellow-green, insoluble trifluoride is made from V and HF at 500 K. Vanadium(III) chloride is a violet, hygroscopic solid which dissolves in water without decomposition to give $[V(OH_2)_6]Cl_3$. Anhydrous VCl_3 is made by decomposition of VCl_4 at 420 K (eq. 21.24), but above 670 K, it disproportionates to VCl_4 and VCl_2. Reaction of VCl_3 with BBr_3, or V with Br_2, yields VBr_3, a green-black, water-soluble solid which disproportionates to VBr_2 and VBr_4. The brown, hygroscopic VI_3 is made from V with I_2, and decomposes above 570 K to VI_2 and I_2. Each of the solid trihalides adopts a structure in which the V(III) centres occupy two thirds of the octahedral sites in an hcp array of halogen atoms (i.e. a BiI_3 prototype structure).

(21.9)

Vanadium(III) forms a variety of octahedral complexes, e.g. *mer*-$[VCl_3(THF)_3]$ and *mer*-$[VCl_3(^tBuNC\text{-}C)_3]$, which have magnetic moments close to the spin-only value for a d^2 ion. The $[VF_6]^{3-}$ ion is present in simple salts such as K_3VF_6, but various extended structures are observed in other salts. The reaction of CsCl with VCl_3 at 1000 K produces $Cs_3[V_2Cl_9]$. $[V_2Cl_9]^{3-}$ (**21.9**) is isomorphous with $[Cr_2Cl_9]^{3-}$ and consists of two face-sharing octahedra with *no* metal–metal interaction. Examples of complexes with higher coordination numbers are known, e.g. $[V(CN)_7]^{4-}$ (pentagonal bipyramidal) made from VCl_3 and KCN in aqueous solution and isolated as the K^+ salt.

The oxide V_2O_3 (which, like Ti_2O_3, adopts the corundum structure, see Section 13.7) is made by partial reduction of V_2O_5 using H_2, or by heating (1300 K) V_2O_5 with vanadium. It is a black solid which, on cooling, exhibits a metal–insulator transition at 155 K. The oxide is basic, dissolving in acids to give $[V(OH_2)_6]^{3+}$. The hydrated oxide may be precipitated by adding alkali to green solutions of vanadium(III) salts. The $[V(OH_2)_6]^{3+}$ ion is present in alums such as $[NH_4]V(SO_4)_2{\cdot}12H_2O$ formed by electrolytic reduction of $[NH_4][VO_3]$ in sulfuric acid.

Self-study exercises

1. VCl_3 and VI_3 are *hygroscopic*. What does this mean?
[*Ans.* See p. 374]

2. $[V_2Cl_9]^{3-}$ has a structure described as 'face-sharing octahedra'. What does this tell you about the role of the chlorido ligands?

3. Describe the BiI_3 prototype structure.
[*Ans.* See Fig. 21.6]

Vanadium(II)

Green VCl_2 is made from VCl_3 and H_2 at 770 K and is converted to blue VF_2 by reaction with HF and H_2. VCl_2 can also be obtained from VCl_3 as described above, and similarly brown-red VBr_2 and violet VI_2 can be produced from VBr_3 and VI_3, respectively. Vanadium(II) fluoride crystallizes with a rutile-type structure (Fig. 6.24) and becomes antiferromagnetic below 40 K. VCl_2, VBr_2 and VI_2 (all paramagnetic) possess CdI_2 layer structures (Fig. 6.25). The dihalides are water-soluble.

Vanadium(II) is present in aqueous solution as the violet, octahedral $[V(OH_2)_6]^{2+}$ ion. It can be prepared by reduction of vanadium in higher oxidation states electrolytically or using zinc amalgam. It is strongly reducing, being rapidly oxidized on exposure to air. Compounds such as Tutton salts contain $[V(OH_2)_6]^{2+}$; e.g. $K_2V(SO_4)_2{\cdot}6H_2O$ is made by adding K_2SO_4 to an aqueous solution of VSO_4 and forms violet crystals.

A ***Tutton salt*** has the general formula $[M^I]_2M^{II}(SO_4)_2{\cdot}6H_2O$ (compare with an ***alum***, Section 13.9).

Vanadium(II) oxide is a grey, metallic solid and is obtained by reduction of higher oxides at high temperatures. It is non-stoichiometric, varying in composition from $VO_{0.8}$ to $VO_{1.3}$, and possesses an NaCl (Fig. 6.18) or defect NaCl structure (see Section 6.18). Conducting properties of the first row metal(II) oxides are compared in Section 28.2.

Simple vanadium(II) complexes include $[V(CN)_6]^{4-}$, the K^+ salt of which is made by reducing $K_4[V(CN)_7]$ with K metal in liquid NH_3. The magnetic moment of 3.5 μ_B for $[V(CN)_6]^{4-}$ is close to the spin-only value of 3.87 μ_B. Octahedral $[V(NCMe)_6]^{2+}$ has been isolated in the $[ZnCl_4]^{2-}$ salt from the reaction of VCl_3 with Et_2Zn in MeCN. Treatment of $VCl_2{\cdot}4H_2O$ with phen gives $[V(phen)_3]Cl_2$, for which $\mu_{eff} = 3.82\,\mu_B$ (300 K), consistent with octahedral d^3.

Self-study exercises

1. The magnetic moment of a green salt $K_n[VF_6]$ is 2.79 μ_B at 300 K. With what value of n is this consistent?
[*Ans.* $n = 3$]

2. The octahedral complex $[VL_3]$ where HL = $CF_3COCH_2COCH_3$ (related to Hacac) exists as *fac* and *mer* isomers in solution. Draw the structures of these isomers, and comment on further isomerism exhibited by this complex.
[*Ans.* See structures 2.36 and 2.37, Fig. 3.20b, Section 19.8]

3. The electronic absorption spectrum of $[VCl_4(bpy)]$ shows an asymmetric band: $\lambda_{max} = 21\,300\,cm^{-1}$ with a shoulder at $17\,400\,cm^{-1}$. Suggest an explanation for this observation.
[*Ans.* d^1, see Fig. 20.4 and discussion]

4. The vanadate $[V_{14}O_{36}Cl]^{5-}$ is an open cluster with a guest Cl^- ion. (a) What are the formal oxidation states

of the V centres? (b) The electronic absorption spectrum exhibits intense charge transfer bands. Explain why these are likely to arise from LMCT rather than MLCT transitions.

[*Ans.* (a) 2 V(IV) and 12 V(V)]

21.7 Group 6: chromium

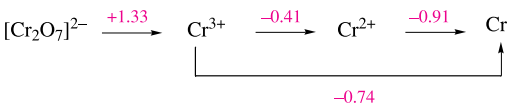
The metal

At ordinary temperatures, Cr metal is resistant to chemical attack (although it dissolves in dilute HCl and H_2SO_4). This inertness is kinetic rather than thermodynamic in origin as the Cr^{2+}/Cr and Cr^{3+}/Cr couples in Fig. 21.11 show. Nitric acid renders Cr passive, and Cr is resistant to alkalis. At higher temperatures the metal is reactive: it decomposes steam and combines with O_2, halogens, and most other non-metals. Borides, carbides and nitrides (see Sections 13.10, 14.7 and 15.6) exist in various phases (e.g. CrN, Cr_2N, Cr_3N, Cr_3N_2) and are inert materials (e.g. CrN is used in wear-resistant coatings). The black sulfide Cr_2S_3 is formed by direct combination of the elements on heating. Other sulfides are formed by reactions other than direct combination of Cr and S_8, e.g. CrS is formed by thermal decomposition of Cr_2S_3.

The main oxidation states of chromium are +6, +3 and +2. A few compounds of Cr(V) and Cr(IV) are known, but are unstable with respect to disproportionation. Chromium(0) is stabilized by π-acceptor ligands (see Chapter 24).

Chromium(VI)

No halides of chromium(VI) have been isolated. Early reports of CrF_6 have since been shown to be incorrect, the vibrational spectrum being due not to CrF_6, but to CrF_5. However, the halidooxidochromium(VI) compounds CrO_2F_2 and CrO_2Cl_2 are known. Fluorination of CrO_3 with SeF_4, SF_4 or HF yields CrO_2F_2 (violet crystals, mp 305 K), while CrO_2Cl_2 (red liquid, mp 176 K, bp 390 K) is prepared by heating a mixture of $K_2Cr_2O_7$, KCl and concentrated H_2SO_4. CrO_2Cl_2 is an oxidant and chlorinating agent. It has a molecular structure (**21.10**) and is light-sensitive and readily hydrolysed (eq. 21.27). If CrO_2Cl_2 is added to a concentrated KCl solution, $K[CrO_3Cl]$ precipitates. Structure **21.11** shows the $[CrO_3Cl]^-$ ion.



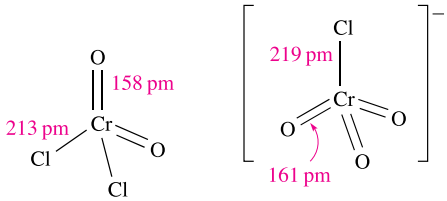


Fig. 21.11. Potential diagram for chromium at pH 0. A Frost–Ebsworth diagram for Cr is shown in Fig. 8.4a.

(21.10) **(21.11)**

$$2CrO_2Cl_2 + 3H_2O \longrightarrow [Cr_2O_7]^{2-} + 4Cl^- + 6H^+ \qquad (21.27)$$

Chromium(VI) oxide ('chromic acid'), CrO_3, separates as a purple-red solid when concentrated H_2SO_4 is added to a solution of a dichromate(VI) salt. It is a powerful oxidant with uses in organic synthesis. It melts at 471 K and at slightly higher temperatures decomposes to Cr_2O_3 and O_2 with CrO_2 formed as an intermediate. The solid state structure of CrO_3 consists of chains of corner-sharing tetrahedral CrO_4 units (as in Fig. 21.9d).

Chromium(VI) oxide dissolves in base to give yellow solutions of $[CrO_4]^{2-}$. This is a weak base and forms $[HCrO_4]^-$ and then H_2CrO_4 as the pH is lowered (H_2CrO_4: $pK_a(1) = 0.74$; $pK_a(2) = 6.49$). In solution, these equilibria are complicated by the formation of orange dichromate(VI), $[Cr_2O_7]^{2-}$ (eq. 21.28).

$$2[HCrO_4]^- \rightleftharpoons [Cr_2O_7]^{2-} + H_2O \qquad (21.28)$$

Further condensation occurs at high $[H^+]$ to give $[Cr_3O_{10}]^{2-}$ and $[Cr_4O_{13}]^{2-}$. The structures (determined for solid state salts) of $[Cr_2O_7]^{2-}$ and $[Cr_3O_{10}]^{2-}$ are shown in Fig. 21.12, although the conformation of $[Cr_2O_7]^{2-}$ is variable depending upon the cation.[†] Like $[CrO_4]^{2-}$, they contain tetrahedral CrO_4 units and the chains in the di- and trinuclear species contain corner-sharing tetrahedra (i.e. as in CrO_3). The $[Cr_4O_{13}]^{2-}$ ion has a related structure. Higher species are not observed and thus chromates do not mimic vanadates in their structural complexity.

Complex formation by Cr(VI) requires strong π-donor ligands such as O^{2-} or $[O_2]^{2-}$. When H_2O_2 is added to an acidified solution of a chromate(VI) salt, the product (formed as a solution species) is a deep violet-blue complex which contains both oxido and peroxido ligands (eq. 21.29).

$$[CrO_4]^{2-} + 2H^+ + 2H_2O_2 \longrightarrow [Cr(O)(O_2)_2] + 3H_2O \qquad (21.29)$$

[†] M.R. Sundberg, J. Valo, R. Uggla and M. Melnik (2012) *Inorg. Chim. Acta*, vol. 383, p. 164 – 'Conformational diversity of dichromate dianion'.

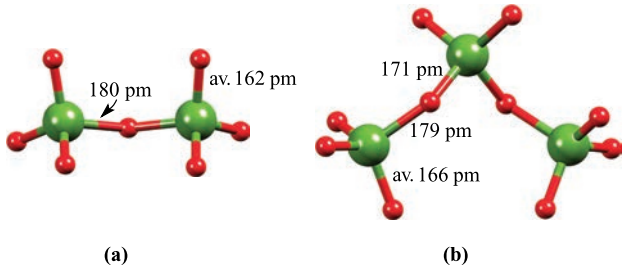

Fig. 21.12. Structures (X-ray diffraction) of (a) $[Cr_2O_7]^{2-}$ in the 2-amino-5-nitropyridinium salt [J. Pecaut *et al.* (1993) *Acta Crystallogr., Sect. B*, vol. 49, p. 277], and (b) $[Cr_3O_{10}]^{2-}$ in the guanidinium salt [A. Stepien *et al.* (1977) *Acta Crystallogr., Sect. B*, vol. 33, p. 2924]. Colour code: Cr, green; O, red.

In aqueous solution, $[Cr(O)(O_2)_2]$ rapidly decomposes to Cr(III) and O_2. A solution in diethyl ether is more stable and, from it, after addition of pyridine, the adduct $[Cr(O)(O_2)_2(py)]$ may be isolated. In the solid state, $[Cr(O)(O_2)_2(py)]$ contains an approximate pentagonal pyramidal arrangement of donor atoms with the oxido ligand in the apical site (Figs. 21.13a and b). If each peroxido ligand is considered to occupy one rather than two coordination sites, then the coordination environment is tetrahedral (Fig. 21.13c). This and related compounds (which are explosive when dry) have uses as oxidants in organic syntheses. Like other Cr(VI) compounds, $[Cr(O)(O_2)_2(py)]$ has a very small paramagnetic susceptibility (arising from coupling of the diamagnetic ground state with excited states). The action of H_2O_2 on neutral or slightly acidic solutions of $[Cr_2O_7]^{2-}$ (or reaction between $[Cr(O)(O_2)_2]$ and alkalis) yields diamagnetic, dangerously explosive, red-violet salts of $[Cr(O)(O_2)_2(OH)]^-$. Imido ligands $[RN]^{2-}$ may formally replace oxido groups in Cr(VI) species, e.g. $[Cr(N^tBu)_2Cl_2]$ is structurally related to CrO_2Cl_2.

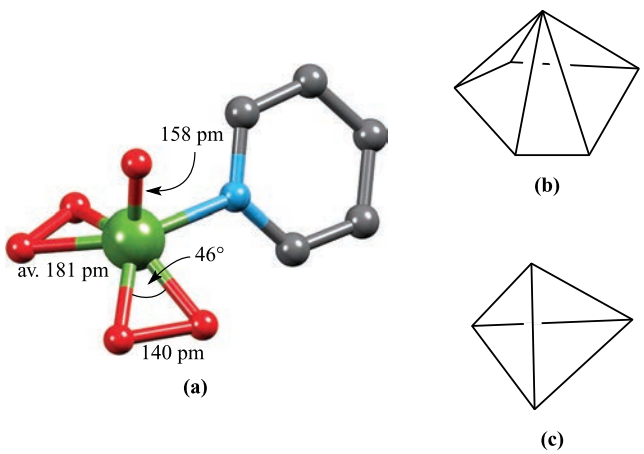

Fig. 21.13. (a) The structure of $[Cr(O)(O_2)_2(py)]$ determined by X-ray diffraction [R. Stomberg (1964) *Ark. Kemi*, vol. 22, p. 29]; colour code: Cr, green; O, red; N, blue; C, grey. The coordination environment can be described as (b) pentagonal pyramidal or (c) tetrahedral (see text).

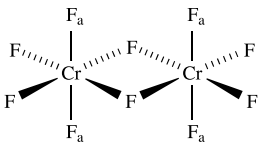
Chromium(VI) in acidic solution is a powerful oxidizing agent (eq. 21.30), but reactions are often slow. Both $Na_2Cr_2O_7$ and $K_2Cr_2O_7$ are manufactured on a large scale; $K_2Cr_2O_7$ is less soluble in water than $Na_2Cr_2O_7$. Both are widely used as oxidants in organic syntheses. Commercial applications include those in tanning, corrosion inhibitors and insecticides. The use of 'chromated copper arsenate' in wood preservatives is being discontinued on environmental grounds (see Box 15.1). Potassium dichromate(VI) is used in titrimetric analysis (e.g. reaction 21.31) and the colour change accompanying reduction of $[Cr_2O_7]^{2-}$ to Cr^{3+} is the basis for some types of breathalyser units in which ethanol is oxidized to acetaldehyde. Sodium chromate(VI), also an important oxidant, is manufactured by reaction 21.32.

$$\underset{\text{orange}}{[Cr_2O_7]^{2-}} + 14H^+ + 6e^- \rightleftharpoons \underset{\text{green}^\dagger}{2Cr^{3+}} + 7H_2O \qquad E^\circ = +1.33\,V \qquad (21.30)$$

$$[Cr_2O_7]^{2-} + 14H^+ + 6Fe^{2+} \longrightarrow 2Cr^{3+} + 7H_2O + 6Fe^{3+} \qquad (21.31)$$

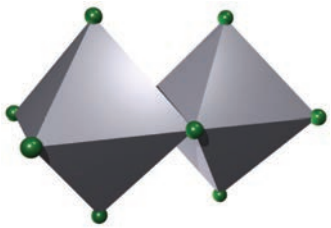
$$Na_2Cr_2O_7 + 2NaOH \longrightarrow 2Na_2CrO_4 + H_2O \qquad (21.32)$$

Chromium(VI) compounds are highly toxic (suspected carcinogens) and must be stored away from combustible materials; violent reactions occur with some organic compounds.



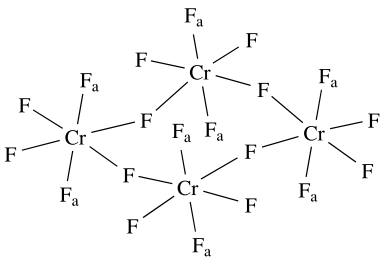
Self-study exercises

1. Consider the structure of $[Cr_2O_7]^{2-}$ in Fig. 21.12a. Explain how the anion can show conformational flexibility.
   [*Ans.* See: M.R. Sundberg *et al.* (2012) *Inorg. Chim. Acta*, vol. 383, p. 164]
2. Comment on how the following ligands bind to Cr(VI): (a) oxido, (b) peroxido, (c) imido. How would you classify these ligands (σ-donor, π-donor or π-acceptor)?
3. Aqueous solutions of $[CrO_4]^{2-}$ are yellow (λ_{max} = 373 nm). Explain the origins of the transitions that lead to this absorption band, and state why the transitions are fully allowed.
   [*Ans.* See Table 20.8 and associated text in Ch. 20]



† The green colour is due to a sulfato complex, H^+ being supplied as sulfuric acid; $[Cr(OH_2)_6]^{3+}$ is violet, see later.

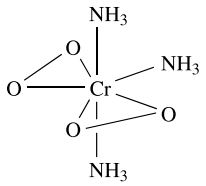
Chromium(V) and chromium(IV)



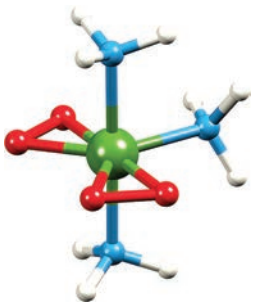
Unlike CrF_6, CrF_5 is well established. It is a red, volatile solid (mp 303 K), formed by direct combination of the elements at ≈570 K. The vapour is yellow and contains distorted trigonal bipyramidal CrF_5 molecules. It is a strong oxidizing and fluorinating agent. For Cr(V), the fluoride is the only halide known. Pure CrF_4 can be made by fluorination of Cr using HF/F_2 under solvothermal conditions. The pure material is violet, but the colour of samples prepared by different routes varies (green, green-black, brown) with descriptions being affected by the presence of impurities. In the vapour, CrF_4 exists as a tetrahedral molecule. Solid CrF_4 is dimorphic. In α-CrF_4, pairs of edge-sharing CrF_6-octahedra (**21.12** and **21.13**) assemble into columns through Cr–F–Cr bridges involving the atoms marked F_a in structure **21.12**. In β-CrF_4, Cr_4F_{20}-rings (**21.14**) are connected through the apical F_a atoms to generate columns. Compare the structures of α- and β-CrF_4 with that of solid TiF_4 (Fig. 21.7).

(21.12)

(21.13)



(21.14)



Chromium(IV) chloride and bromide have been prepared but are unstable.

Chromium(IV) oxide, CrO_2, is usually made by controlled decomposition of CrO_3. It is a brown-black solid which has the rutile structure and is a metallic conductor (compare with VO_2). It is ferromagnetic and is widely used in magnetic recording tapes. Magnetic tape is used for the storage of digital data and, in 2014, the application of nano-grained magnetic particles resulted in Sony attaining a record storage capacity of 23 Gbit cm^{-2} of tape.

When an acidic solution in which $[Cr_2O_7]^{2-}$ is oxidizing propan-2-ol is added to aqueous $MnSO_4$, MnO_2 is precipitated, although acidified $[Cr_2O_7]^{2-}$ alone does not effect this oxidation. This observation is evidence for the participation of Cr(V) or Cr(IV) in dichromate(VI) oxidations. Under suitable conditions, it is possible to isolate salts of $[CrO_4]^{3-}$ and $[CrO_4]^{4-}$. For example, dark blue Sr_2CrO_4 is produced by heating $SrCrO_4$, Cr_2O_3 and $Sr(OH)_2$ at 1270 K, and dark green Na_3CrO_4 results from reaction of Na_2O, Cr_2O_3 and Na_2CrO_4 at 770 K.

Complexes of chromium(V) may be stabilized by π-donor ligands, e.g. $[CrF_6]^-$, $[CrOF_4]^-$, $[CrOF_5]^{2-}$, $[CrNCl_4]^{2-}$ and $[Cr(N^tBu)Cl_3]$. Peroxido complexes containing $[Cr(O_2)_4]^{3-}$ are obtained by reaction of chromate(V) with H_2O_2 in alkaline solution; $[Cr(O_2)_4]^{3-}$ has a dodecahedral structure. These salts are explosive but are less dangerous than the Cr(VI) peroxido complexes. The explosive Cr(IV) peroxido complex $[Cr(O_2)_2(NH_3)_3]$ (**21.15**) is formed when $[Cr_2O_7]^{2-}$ reacts with aqueous NH_3 and H_2O_2. A related complex is $[Cr(O_2)_2(CN)_3]^{3-}$.

(21.15)

Self-study exercises

1. The solid state structure of $[XeF_5]^+[CrF_5]^-$ contains infinite chains of distorted CrF_6 octahedra connected through *cis*-vertices. Draw part of the chain, ensuring that the 1:5 Cr:F stoichiometry is maintained.

2. Assuming that the cations in $[XeF_5]^+[CrF_5]^-$ are discrete, what geometry for each cation would be consistent with the VSEPR model?

[For the answers to both exercises, see: K. Lutar *et al.* (1998) *Inorg. Chem.*, vol. 37, p. 3002]

Chromium(III)

The +3 oxidation state is the most stable for chromium in its compounds and octahedral coordination dominates for Cr(III) centres. Table 20.3 shows the large LFSE associated with the octahedral d^3 configuration, and Cr(III) complexes are generally kinetically inert (see Section 26.2).

Anhydrous $CrCl_3$ (red-violet solid, mp 1425 K) is made from the metal and Cl_2, and is converted to green CrF_3

by heating with HF at 750 K. Solid CrF_3 is isostructural with VF_3, and $CrCl_3$ adopts a BiI_3 structure (Fig. 21.6). The dark green tribromide and triiodide can be prepared from Cr and the respective halogen and are isostructural with $CrCl_3$. Chromium trifluoride is sparingly soluble and may be precipitated as the hexahydrate. The formation of $CrCl_3 \cdot 6H_2O$ and its hydrate isomerism were described in Section 19.8. Although pure $CrCl_3$ is insoluble in water, addition of a trace of Cr(II) (e.g. $CrCl_2$) results in dissolution. The fast redox reaction between Cr(III) in the $CrCl_3$ lattice and Cr(II) in solution is followed by rapid substitution of Cl^- by H_2O at the solid surface since Cr(II) is labile (see Chapter 26).

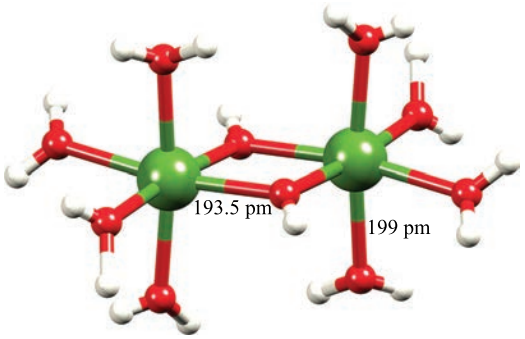
Chromium(III) oxide is made by reacting Cr metal and O_2 at high temperature, by reduction of CrO_3, or by reaction 21.33. It has the corundum structure (Section 13.7) and is semiconducting and antiferromagnetic ($T_N = 310$ K). Commercially, Cr_2O_3 is used in abrasives and is an important green pigment. The dihydrate (*Guignet's green*) is used in paints. Traces of Cr(III) in Al_2O_3 give rise to the red colour of rubies (see Section 20.8).

$$[NH_4]_2[Cr_2O_7] \xrightarrow{\Delta} Cr_2O_3 + N_2 + 4H_2O \qquad (21.33)$$

Large numbers of mononuclear, octahedral Cr(III) complexes are known with magnetic moments close to the spin-only value of 3.87 μ_B (Table 20.11). The electronic absorption spectra of octahedral d^3 complexes contain three absorptions due to '*d–d*' transitions (see Fig. 20.20). Selected examples of octahedral chromium(III) complexes are $[Cr(OH_2)_6]^{3+}$, $[CrF_6]^{3-}$, $[CrCl_6]^{3-}$, $[Cr(NH_3)_6]^{3+}$, $[Cr(acac)_3]$, $[Cr(ox)_3]^{3-}$, $[Cr(en)_3]^{3+}$, $[Cr(bpy)_3]^{3+}$, *cis*- and *trans*-$[Cr(en)_2F_2]^+$, *trans*-$[CrCl_2(MeOH)_4]^+$, $[Cr(CN)_6]^{3-}$ and $[Cr(NH_3)_2(S_5)_2]^-$ ($[S_5]^{2-}$ is bidentate; see Fig. 16.13 for related structures). The dinuclear $[Cr_2Cl_9]^{3-}$ anion is made by reaction 21.34. $[Cr_2Cl_9]^{3-}$ is isostructural with $[V_2Cl_9]^{3-}$ (**21.9**) and magnetic data are consistent with the presence of three unpaired electrons per Cr(III) centre, i.e. *no* Cr–Cr interaction.

$$3CsCl + 2CrCl_3 \xrightarrow{\text{in a melt}} Cs_3[Cr_2Cl_9] \qquad (21.34)$$

Pale violet $[Cr(OH_2)_6]^{3+}$ is obtained in aqueous solution when $[Cr_2O_7]^{2-}$ is reduced by SO_2 or by EtOH and H_2SO_4 below 200 K. The commonest salt containing $[Cr(OH_2)_6]^{3+}$ is chrome alum, $KCr(SO_4)_2 \cdot 12H_2O$. $[Cr(OH_2)_6]^{3+}$ has been structurally characterized in the solid state in a number of salts, e.g. $[Me_2NH_2][Cr(OH_2)_6][SO_4]_2$ (av. Cr–O = 196 pm). From aqueous solutions of Cr(III) salts, alkali precipitates Cr_2O_3 which dissolves to give $[Cr(OH)_6]^{3-}$. The hexaaqua ion is quite acidic ($pK_a \approx 4$) and hydroxido-bridged species are present in solution (see eq. 7.38 and accompanying discussion). Figure 21.14 shows the structure of $[Cr_2(OH_2)_8(\mu\text{-}OH)_2]^{4+}$. Addition of NH_3 to aqueous solutions of $[Cr(OH_2)_6]^{3+}$ results in the slow formation of ammine complexes; it is preferable to use Cr(II)



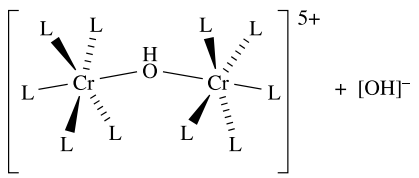


Fig. 21.14. The structure of $[Cr_2(OH_2)_8(\mu\text{-}OH)_2]^{4+}$ determined by X-ray diffraction for the mesitylene-2-sulfonate salt; the *non-bonded* Cr····Cr separation is 301 pm [L. Spiccia *et al.* (1987) *Inorg. Chem.*, vol. 26, p. 474]. Colour code: Cr, green; O, red; H, white.

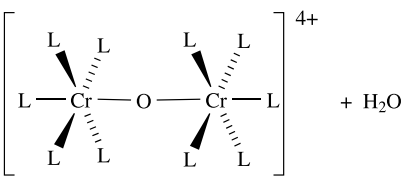
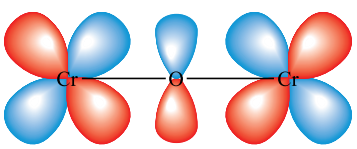


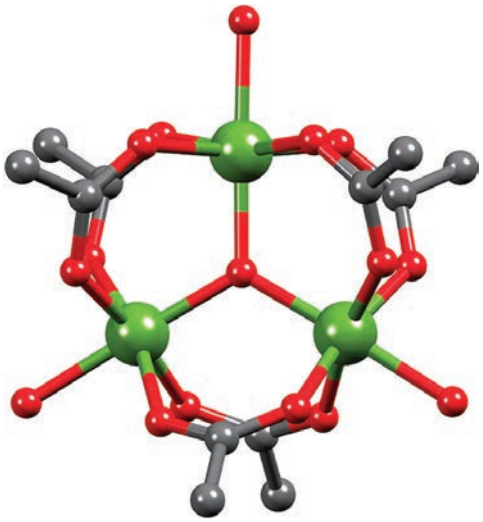
precursors since substitution is faster in Cr(II) than Cr(III) (see Chapter 26). The dinuclear complex **21.16** is reversibly converted to the oxido-bridged **21.17** in the presence of alkali (eq. 21.35).

∠Cr–O–Cr = 166° L = NH_3

(21.16)

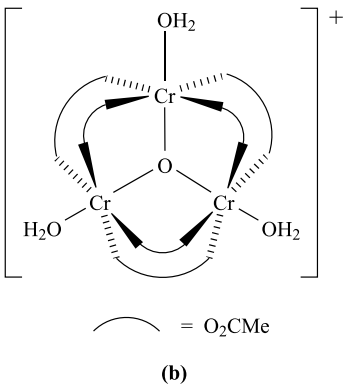


(21.35)



∠Cr–O–Cr = 180° L = NH_3

(21.17)



The two Cr(III) (d^3) centres in complex **21.17** are antiferromagnetically coupled and this is rationalized in terms of (d–p)π-bonding involving Cr d and O p orbitals (diagram **21.18**). Weak antiferromagnetic coupling also occurs between the Cr(III) centres in trinuclear complexes of type $[Cr_3L_3(\mu\text{-}O_2CR)_6(\mu_3\text{-}O)]^+$ (Fig. 21.15).

(21.18)

A representative member of the $[Cr_3L_3(\mu\text{-}O_2CR)_6(\mu_3\text{-}O)]^+$ family of complexes: (a) the structure of $[Cr_3(OH_2)_3(\mu\text{-}O_2CMe)_6(\mu_3\text{-}O)]^+$ (X-ray diffraction) in the hydrated chloride salt [C.E. Anson *et al.* (1997) *Inorg. Chem.*, vol. 36, p. 1265], and (b) a schematic representation of the same complex. In (a), the H atoms are omitted for clarity; colour code: Cr, green; O, red; C, grey.

Chromium(II)

Anhydrous CrF_2, $CrCl_2$ and $CrBr_2$ are made by reacting Cr with HX (X = F, Cl, Br) at >850 K; CrI_2 is formed by heating Cr and I_2. The fluoride and chloride adopt distorted rutile structures (Fig. 6.24), while $CrBr_2$ and CrI_2 crystallize with distorted CdI_2 structures (Fig. 6.25). The distortions arise from the Jahn–Teller effect (high-spin d^4). Crystals of $CrCl_2$ are colourless but dissolve in water to give blue solutions of the strongly reducing hexaaqua ion. Solutions of $[Cr(OH_2)_6]^{2+}$ are usually obtained by dissolving Cr in acids or by reduction (Zn amalgam or electrolytically) of Cr(III)-containing solutions. Hydrated salts such as $Cr(ClO_4)_2{\cdot}6H_2O$, $CrCl_2{\cdot}4H_2O$ and $CrSO_4{\cdot}7H_2O$ may be isolated from solution, but cannot be dehydrated without decomposition.

Self-study exercises

1. CrI_2 adopts a distorted CdI_2 structure. What is the environment about each Cr(II) centre?
[*Ans.* See Fig. 6.25; Cr replaces Cd]

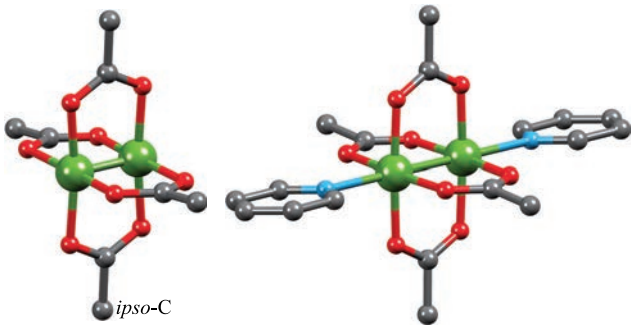
2. In $CrBr_2$, four Cr–Br distances are 254 pm and two are 300 pm. What is the *d* electron configuration of the Cr centre? Explain the origin of the difference in bond lengths. [*Ans.* d^4; see Section 20.3]

3. Distortion of the complex $[Cr(NH_3)_6]^{2+}$ from octahedral symmetry leads to a stabilization of the total orbital energy. Explain (a) what type of distortion occurs and (b) why it leads to an overall orbital stabilization.

For the Cr^{3+}/Cr^{2+} couple, $E^o = -0.41$ V, and Cr(II) compounds slowly liberate H_2 from water, as well as undergo oxidation by O_2 (see worked example 8.4). The potential diagram in Fig. 21.11 shows that Cr(II) compounds are just stable with respect to disproportionation. The study of the oxidation of Cr^{2+} species has played an important role in establishing the mechanisms of redox reactions (see Chapter 26).

Complexes of Cr(II) include halide anions such as $[CrX_3]^-$, $[CrX_4]^{2-}$, $[CrX_5]^{3-}$ and $[CrX_6]^{4-}$. Despite the range of formulae, the Cr(II) centres in the solids are usually octahedrally sited, e.g. $[CrCl_3]^-$ consists of chains of distorted face-sharing octahedra, the distortion being a Jahn–Teller effect. Some of these salts show interesting magnetic properties. For example, salts of $[CrCl_4]^{2-}$ show *ferromagnetic coupling* (as opposed to antiferromagnetic coupling which is a more common phenomenon, see Section 20.10) at low temperatures, with T_C values in the range 40–60 K; communication between the metal centres is through Cr–Cl–Cr bridging interactions.

Cyanido complexes of Cr(II) include $[Cr(CN)_6]^{4-}$ and $[Cr(CN)_5]^{3-}$. $K_4[Cr(CN)_6]$ may be prepared in aqueous solution, but only in the presence of excess cyanide ion; octahedral $[Cr(CN)_6]^{4-}$ is low-spin. The reaction of $[Cr_2(\mu\text{-}O_2CMe)_4]$ (see below) with $[Et_4N][CN]$ leads to the formation of $[Et_4N]_3[Cr(CN)_5]$. In the solid state, both trigonal bipyramidal and square-based pyramidal $[Cr(CN)_5]^{3-}$ ions are present. The small energy difference between the 5-coordinate structures has also been observed for $[Ni(CN)_5]^{3-}$. At 300 K, $[Cr(CN)_5]^{3-}$ exhibits an effective magnetic moment of 4.90 μ_B, consistent with high-spin Cr(II). The $[CN]^-$ ion is a strong-field ligand, and so $[Cr(CN)_5]^{3-}$ represents a rare example of a high-spin cyanido complex, one other being $[Mn(CN)_4]^{2-}$. Theoretical data (a combination of ligand field theory and DFT) indicate that for the 5-coordinate $[Cr(CN)_5]^{3-}$, the promotion energy associated with a change in spin state is smaller than the



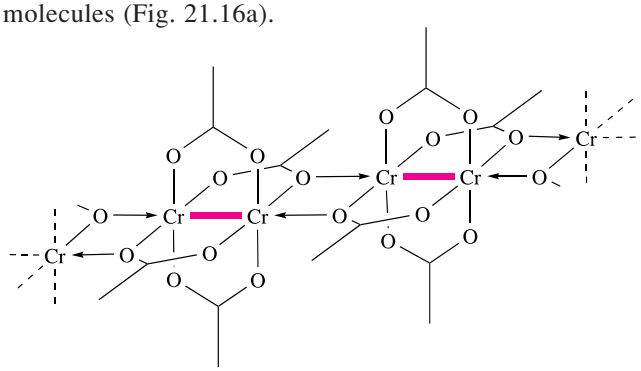


Fig. 21.16. The structures (X-ray diffraction) of (a) $[Cr_2(\mu\text{-}O_2CC_6H_2\text{-}2,4,6\text{-}{}^{i}Pr_3)_4]$ with only the *ipso*-C atoms of the aryl substituents shown [F.A. Cotton *et al.* (2000) *J. Am. Chem. Soc.*, vol. 122, p. 416] and (b) $[Cr_2(py)_2(\mu\text{-}O_2CMe)_4]$ with H atoms omitted for clarity [F.A. Cotton *et al.* (1980) *Inorg. Chem.*, vol. 19, p. 328]. Colour code: Cr, green; O, red; C, grey; N, blue.

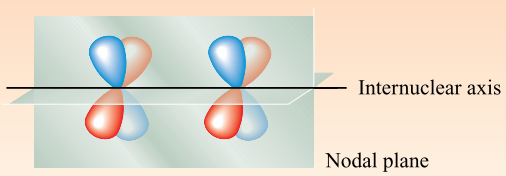
spin-pairing energy and this leads to a high-spin complex. In contrast, for octahedral $[Cr(CN)_6]^{4-}$, the reverse is true and the complex is low-spin.[†]

Chromium–chromium multiple bonds

Chromium(II) carboxylates are dimers of general formula $[Cr_2(\mu\text{-}O_2CR)_4]$ or $[Cr_2L_2(\mu\text{-}O_2CR)_4]$ and are examples of *d*-block metal complexes that involve metal–metal multiple bonding. For example, red $[Cr_2(OH_2)_2(\mu\text{-}O_2CMe)_4]$ is precipitated when aqueous $CrCl_2$ is added to saturated aqueous $Na[MeCO_2]$. Figure 21.16 shows the structures of $[Cr_2(\mu\text{-}O_2CC_6H_2\text{-}2,4,6\text{-}{}^{i}Pr_3)_4]$ and $[Cr_2(py)_2(\mu\text{-}O_2CMe)_4]$. The significant difference between these two compounds is the presence of axial ligands, i.e. the pyridine ligands in the latter complex. Even when no axial ligands are present, association can occur in the solid state as is observed in $[Cr_2(\mu\text{-}O_2CMe)_4]$ (**21.19**). In $[Cr_2(\mu\text{-}O_2CC_6H_2\text{-}2,4,6\text{-}{}^{i}Pr_3)_4]$, the steric demands of the aryl substituents prevent association and the solid contains discrete molecules (Fig. 21.16a).



(21.19)

[†] For details, see: R.J. Deeth (2006) *Eur. J. Inorg. Chem.*, p. 2551 – 'A theoretical rationale for the formation, structure and spin state of pentacyanochromate(II)'.

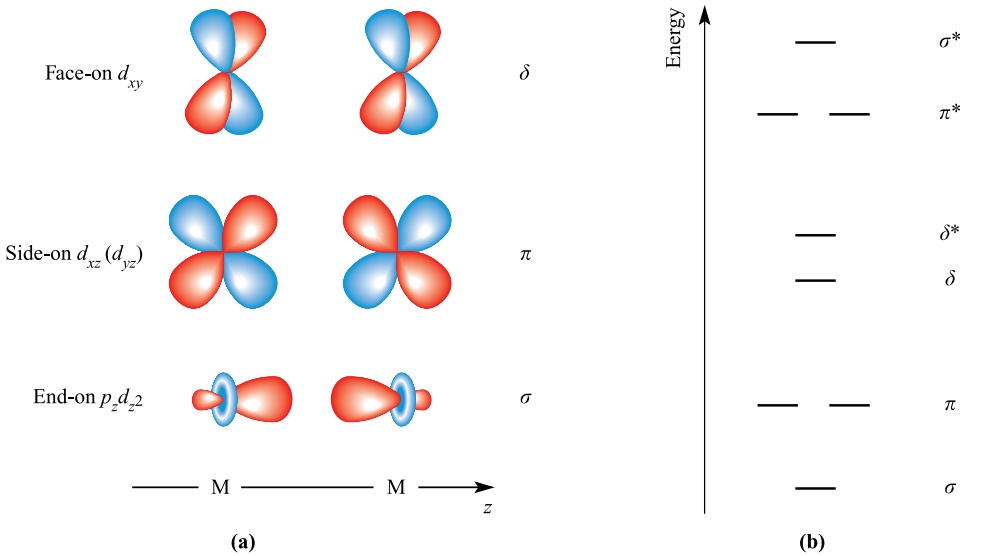
Compounds of the type $[Cr_2(\mu\text{-}O_2CR)_4]$ and $[Cr_2L_2(\mu\text{-}O_2CR)_4]$ (Fig. 21.16) are *diamagnetic*, possess *short* Cr–Cr bonds (cf. 258 pm in Cr metal), and have eclipsed ligand conformations. These properties are consistent with the Cr(II) *d* electrons being involved in *quadruple* bond formation. For the bridging ligands in $[Cr_2(\mu\text{-}O_2CR)_4]$ to be eclipsed is less surprising than in complexes with monodentate ligands, e.g. $[Re_2Cl_8]^{2-}$ (see Section 22.8), but the observation is a key feature in the description of the metal–metal quadruple bond. The bonding in $[Cr_2(\mu\text{-}O_2CR)_4]$ can be described as shown in Fig. 21.17. The Cr atoms are defined to lie on the *z* axis, and each Cr atom uses four (s, p_x, p_y and $d_{x^2-y^2}$)[‡] of its nine atomic orbitals to form Cr–O bonds. Now allow mixing of the p_z and d_{z^2} orbitals to give two hybrid orbitals directed along the *z* axis. Each Cr atom has four orbitals available for metal–metal bonding: d_{xz}, d_{yz}, d_{xy} and one $p_zd_{z^2}$ hybrid, with the second $p_zd_{z^2}$ hybrid being non-bonding and pointing outwards from the Cr–Cr-unit (see below). Figure 21.17a shows that overlap of the metal $p_zd_{z^2}$ hybrid orbitals leads to a σ-bond, while d_{xz}–d_{xz} and d_{yz}–d_{yz} overlap gives a degenerate pair of π-orbitals. Finally, overlap of the d_{xy} orbitals gives rise to a δ-bond. The degree of overlap follows the order $\sigma > \pi > \delta$ and Fig. 21.17b shows an approximate energy level diagram for the σ, π, δ, σ^*, π^* and δ^* MOs. Each Cr(II) centre provides four electrons for Cr–Cr bond formation and these occupy the MOs in Fig. 21.17b to give a $\sigma^2\pi^4\delta^2$ configuration, i.e. a quadruple bond.[*] A consequence of this bonding picture is that the δ component forces the two CrO_4-units to be eclipsed. The red colour of $[Cr_2(\mu\text{-}O_2CMe)_4]$ ($\lambda_{max} = 520$ nm, see Table 19.2) and related complexes can be understood in terms of the δ–δ^* energy gap and a $\sigma^2\pi^4\delta^1\delta^{*1} \leftarrow \sigma^2\pi^4\delta^2$ transition.

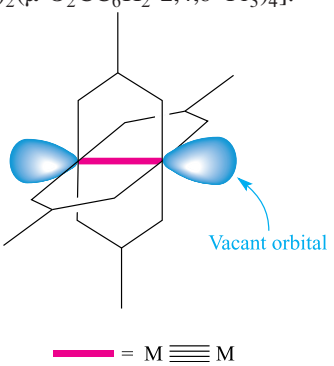
A ***δ-bond*** is formed by the face-on overlap of two d_{xz} (or two d_{yz}, or two d_{xy}) orbitals. The resultant MO possesses *two* nodal planes that contain the internuclear axis:

This bonding description for $[Cr_2(\mu\text{-}O_2CR)_4]$ leaves a non-bonding, outward-pointing $p_zd_{z^2}$ hybrid orbital per Cr atom (**21.20**). Complex formation with donors such as H_2O and

[‡] The choice of the $d_{x^2-y^2}$ orbital for Cr–O bond formation is arbitrary. The d_{xy} could also have been used, leaving the $d_{x^2-y^2}$ orbital available for metal–metal bonding.

[*] For a review of the development of the δ-bond, see: L.R. Falvello, B.M. Foxman and C.A. Murillo (2014) *Inorg. Chem.*, vol. 53, p. 9441 – 'Fitting the pieces of the puzzle: The δ bond'.





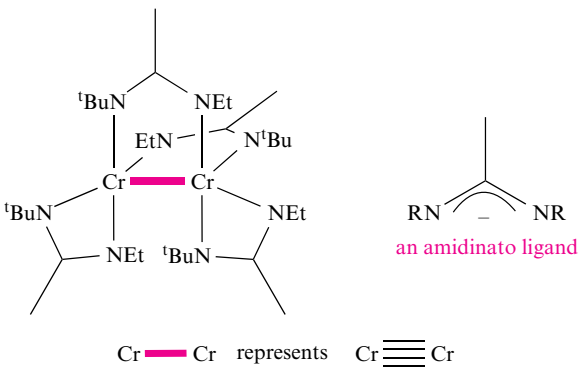


Fig. 21.17. (a) The formation of σ, π and δ components of a metal–metal quadruple bond by overlap of appropriate metal orbitals. *Both* the d_{xz} and d_{yz} atomic orbitals are used to form π-bonds, and the d_{xy} atomic orbital is used for δ-bond formation. (b) Approximate energy levels of the metal–metal bonding and antibonding MOs. This figure is relevant for M_2L_8 or $M_2(\mu\text{-}L)_4$ type complexes.

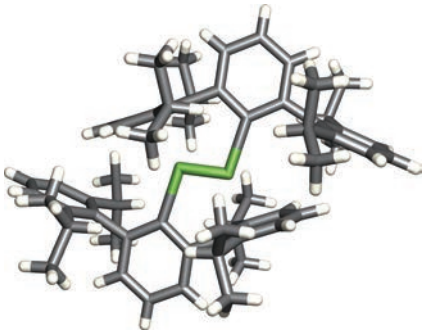
pyridine (Fig. 21.16b) occurs by donation of a lone pair of electrons into each vacant orbital. The Cr—Cr bond length increases significantly when axial ligands are introduced, e.g. 197 to 239 pm on going from $[Cr_2(\mu\text{-}O_2CC_6H_2\text{-}2,4,6\text{-}{}^iPr_3)_4]$ to $[Cr_2(MeCN)_2(\mu\text{-}O_2CC_6H_2\text{-}2,4,6\text{-}{}^iPr_3)_4]$.

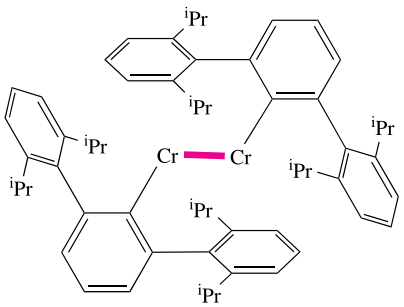
(21.20)

The chromium–chromium quadruple bond is typically considered to be strong, and this is supported by the fact that reactions of $[Cr_2(\mu\text{-}O_2CR)_4]$ with Lewis bases generate adducts without loss of the metal–metal bonding interaction. However, there are examples in which the bond is readily cleaved. $[Li(THF)]_4[Cr_2Me_8]$ contains the $[Cr_2Me_8]^{4-}$ ion, in which the Cr–Cr distance is 198 pm in the solid state. Treatment with the chelating ligand $Me_2NCH_2CH_2NMe_2$ (TMEDA) results in $[Li(TMEDA)]_2[CrMe_4]$. A second example of a weak quadruple bond is found in the amidinato complex **21.21**. In the solid state, **21.21** is diamagnetic and the Cr–Cr bond length is 196 pm. However, in benzene solution, **21.21** dissociates to give paramagnetic monomers $[CrL_2]$.

(21.21)

The diagrams in Fig. 21.17 are relevant for complexes of the type M_2L_8 or $M_2(\mu\text{-}L)_4$ in which one of the metal *d* orbitals is reserved for metal–ligand bonding. However, if the number of ligands is reduced, more metal orbitals and more metal valence electrons become available for metal–metal bonding. Although compound **21.22** is organometallic, we include it here because it was the first example of a metal–metal bond with a bond order of five. Compound **21.22** formally contains two Cr(I) (d^5) centres, and extremely bulky organo-ligands are used to protect the Cr_2-core (Fig. 21.18). Structural data show that the Cr–Cr bond is very short (183.5 pm) and magnetic data indicate the presence of strongly coupled d^5–d^5 bonding electrons. These observations are consistent with the presence of a chromium–chromium quintuple bond. This can be described in terms of the orbital interactions shown in Fig. 21.17 plus an additional δ-bond arising from the face-on overlap of two





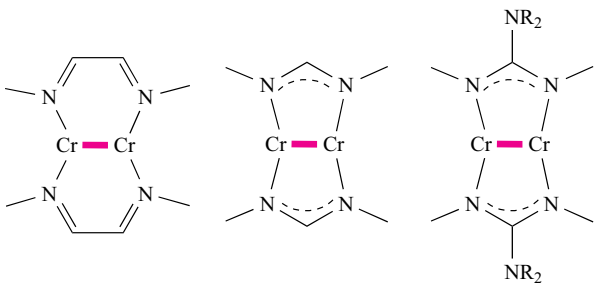


Fig. 21.18. The structure (X-ray diffraction) of $[Cr_2L_2]$ in $[Cr_2L_2]\cdot MeC_6H_5$, where HL = 2,6-bis(2,6-di-isopropylphenyl)benzene [T. Nguyen *et al*. (2005) *Science*, vol. 310, p. 844]. Colour code: Cr, green; C, grey; H, white.

$d_{x^2-y^2}$ orbitals. The quintuple bond therefore has a $\sigma^2\pi^4\delta^4$ configuration. The organo substituent used to stabilize this system is from the same family of R groups used to stabilize E_2R_2 type compounds, where E is a heavy group 13 or 14 element (see Chapter 23). Other examples of Cr–Cr quintuple bond formation are shown in structures **21.23–21.25**.†

Self-study exercise

A quick method of working out the number of electrons available for metal–metal bonding in a complex such as $[Cr_2Me_8]^{4-}$ is to 'remove' each ligand along with an appropriate charge, write down the formula of the 'metal core', and hence determine the number of valence electrons remaining. For example, removal of $8Me^-$ ligands from $[Cr_2Me_8]^{4-}$ leaves $[Cr_2]^{4+}$ which has $(2\times6) - 4 = 8$ valence electrons. These electrons occupy the MOs shown in Fig. 21.17b: $\sigma^2\pi^4\delta^2$. In this method, the removal of *anionic* methyl groups takes care of the electrons required for Cr–C bond formation. Carry out this same exercise for $[Cr_2(\mu\text{-}O_2CMe)_4]$, complex **21.21** and $[Re_2Cl_8]^{2-}$ to confirm the presence of a quadruple bond in each complex.

21.8 Group 7: manganese

The metal

Metallic Mn is slowly attacked by water and dissolves readily in acids (e.g. eq. 21.36). The finely divided metal is pyrophoric in air, but the bulk metal is not attacked unless heated (eq. 21.37). At elevated temperatures, it combines with most non-metals, e.g. N_2 (eq. 21.38), halogens (eq. 21.39), C, Si and B (see Sections 13.10, 14.7 and 15.6).

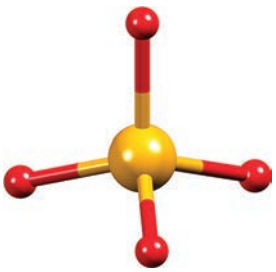
$$Mn + 2HCl \longrightarrow MnCl_2 + H_2 \qquad (21.36)$$

$$3Mn + 2O_2 \xrightarrow{\Delta} Mn_3O_4 \qquad (21.37)$$

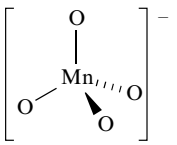
$$3Mn + N_2 \xrightarrow{\Delta} Mn_3N_2 \qquad (21.38)$$

$$Mn + Cl_2 \xrightarrow{\Delta} MnCl_2 \qquad (21.39)$$

Manganese exhibits the widest range of oxidation states of any of the first row *d*-block metals. The lowest states are stabilized by π-acceptor ligands, usually in organometallic complexes (see Chapter 24). However, dissolution of Mn powder in air-free aqueous NaCN gives the Mn(I) complex $Na_5[Mn(CN)_6]$.



This section describes Mn(II)–Mn(VII) species. A potential diagram for manganese was given in Fig. 8.2 and a Frost–Ebsworth diagram was shown in Fig. 8.3. On going from Cr to Mn, there is an abrupt change in the stability with respect to oxidation of M^{2+} (eq. 21.40). The difference in E^o values arises from the much higher third ionization energy of Mn (see Table 21.1). All oxidation states above Mn(II) are powerful oxidizing agents.

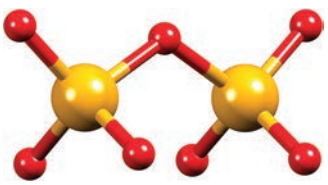


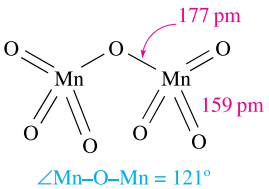
$$M^{3+}(aq) + e^- \rightleftharpoons M^{2+}(aq) \quad \begin{cases} M = Mn,\ E^o = +1.54\,V \\ M = Cr,\ E^o = -0.41\,V \end{cases} \qquad (21.40)$$

Manganese(VII)

Binary halides of Mn(VII) have not been isolated. Halidooxidomanganese(VII) compounds MnO_3F and MnO_3Cl may be made by reacting $KMnO_4$ with HSO_3X (X = F or Cl) at low temperature. Both are powerful oxidants and decompose explosively at room temperature. Both MnO_3F and MnO_3Cl have molecular (C_{3v}) structures. The oxido and imido, $[RN]^{2-}$, groups are isoelectronic, and compounds of the type $Mn(NR)_3Cl$ have been prepared by reacting a complex of $MnCl_3$ with $RNH(SiMe_3)$. The chlorido ligand in $Mn(NR)_3Cl$ can be substituted by a range of anions, e.g. acetato (Fig. 21.19).

Manganese(VII) chemistry is dominated by the manganate(VII) ion (permanganate). The potassium salt, $KMnO_4$, is a strong oxidizing agent and is corrosive to human tissue. It is manufactured on a large scale (see Box 21.4) by conversion of MnO_2 to K_2MnO_4 followed by electrolytic oxidation. In analytical chemistry, Mn determination involves oxidation of Mn(II) to $[MnO_4]^-$ by bismuthate, periodate or peroxydisulfate. Solid $KMnO_4$ forms dark purple-black crystals and is isostructural with $KClO_4$. Tetrahedral $[MnO_4]^-$ ions (**21.26**) have equivalent bonds. Aqueous solutions of $KMnO_4$ deposit MnO_2 on standing. Although $KMnO_4$ is insoluble in benzene, the addition of the cyclic ether 18-crown-6 results in the formation of the soluble [K(18-crown-6)][MnO_4] (see Section 11.8). Potassium permanganate is intensely coloured owing to ligand-to-metal charge transfer (see Fig. 20.17). It also shows weak temperature-independent paramagnetism arising from the coupling of the diamagnetic ground state of $[MnO_4]^-$ with paramagnetic excited states under the influence of a magnetic field.





Mn–O = 163 pm

(21.26)

The free acid $HMnO_4$ can be obtained by low-temperature evaporation of its aqueous solution (made by ion exchange). It is a violent oxidizing agent and explodes above 273 K. The anhydride of $HMnO_4$ is Mn_2O_7, made by the action of concentrated H_2SO_4 on pure $KMnO_4$. It is a green, hygroscopic, highly explosive liquid, unstable above 263 K (eq. 21.41) and has molecular structure **21.27**.

$$2Mn_2O_7 \xrightarrow{>263\ K} 4MnO_2 + 3O_2 \qquad (21.41)$$

∠Mn–O–Mn = 121°

(21.27)

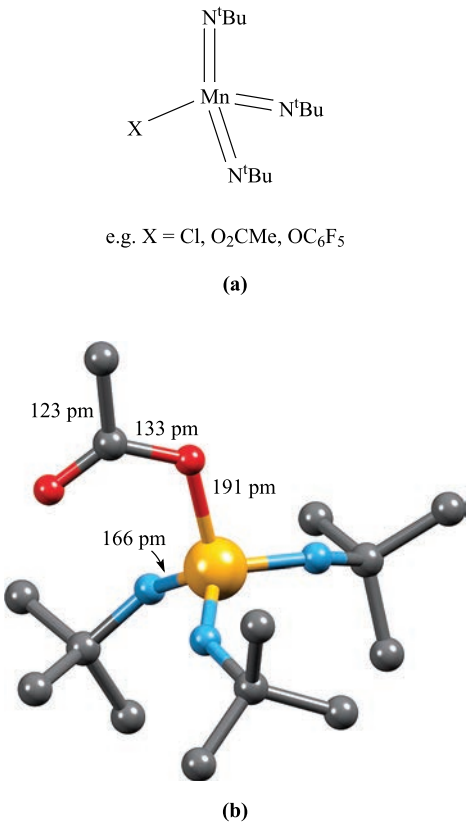
Equations 21.42–21.44 show reductions of $[MnO_4]^-$ to Mn(VI), Mn(IV) and Mn(II) respectively.

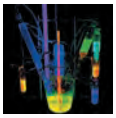
$$[MnO_4]^-(aq) + e^- \rightleftharpoons [MnO_4]^{2-}(aq) \qquad E^o = +0.56\ V \qquad (21.42)$$

$$[MnO_4]^-(aq) + 4H^+ + 3e^- \rightleftharpoons MnO_2(s) + 2H_2O \qquad E^o = +1.69\ V \qquad (21.43)$$

$$[MnO_4]^-(aq) + 8H^+ + 5e^- \rightleftharpoons Mn^{2+}(aq) + 4H_2O \qquad E^o = +1.51\ V \qquad (21.44)$$

The H^+ concentration plays an important part in influencing which reduction takes place (see Section 8.2). Although many reactions of $KMnO_4$ can be understood by considering redox potentials, kinetic factors are also important.





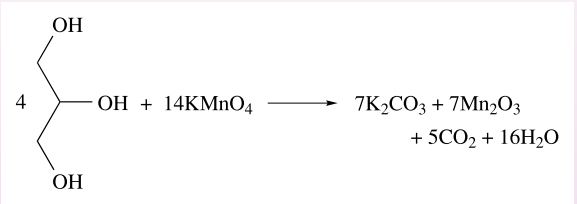


Fig. 21.19. (a) Examples of manganese(VII) imido complexes. (b) The structure of $[Mn(N^tBu)_3(O_2CMe)]$ determined by X-ray diffraction [A.A. Danopoulos *et al.* (1994) *J. Chem. Soc., Dalton Trans.*, p. 1037]. Hydrogen atoms are omitted for clarity; colour code: Mn, yellow; N, blue; O, red; C, grey.

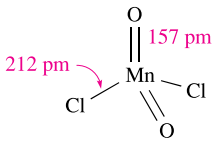
APPLICATIONS

Box 21.4 $KMnO_4$: a powerful oxidant at work

About 0.05 Mt per year of $KMnO_4$ are manufactured worldwide. Although this amount does not compete with those of inorganic chemicals such as CaO, NH_3, TiO_2 and the major mineral acids, the role of $KMnO_4$ as an oxidizing agent is nonetheless extremely important. The photograph shows the vigorous reaction that occurs when propan-1,2,3-triol (glycerol) is dripped onto crystals of $KMnO_4$:

In addition to oxidations of organic compounds in industrial manufacturing processes, $KMnO_4$ is used in water purification where it is preferable to Cl_2 for two reasons: it does not affect the taste of the water, and MnO_2 (produced on reduction) is a coagulant for particulate impurities. The oxidizing power of $KMnO_4$ is also applied to the removal of impurities, for example in the purification of MeOH, EtOH, $MeCO_2H$ and $NC(CH_2)_4CN$ (a precursor in nylon manufacturing). Some commercial bleaching processes use $KMnO_4$, e.g. bleaching some cotton fabrics, jute fibres and beeswax.

The reaction of $KMnO_4$ with propan-1,2,3-triol (glycerol).



Permanganate at pH 0 should oxidize water, but in practice the reaction is extremely slow. It should also oxidize $[C_2O_4]^{2-}$ at room temperature, but reaction 21.45 is very slow unless Mn^{2+} is added or the temperature is raised.

$$2[MnO_4]^- + 16H^+ + 5[C_2O_4]^{2-} \longrightarrow 2Mn^{2+} + 8H_2O + 10CO_2 \quad (21.45)$$

Many studies have been made on the mechanism of such reactions and, as in oxidations by $[Cr_2O_7]^{2-}$, it has been shown that intermediate oxidation states are involved.

Manganese(VI)

No binary halides of Mn(VI) have been isolated, and the only halidooxidomanganese(VI) compound is MnO_2Cl_2 (**21.28**). It is prepared by reducing $KMnO_4$ with SO_2 at low temperature in HSO_3Cl, and is a brown liquid which readily hydrolyses and decomposes at 240 K.

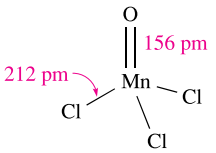
(21.28)

Salts of dark green $[MnO_4]^{2-}$ are made by fusing MnO_2 with group 1 metal hydroxides in the presence of air, or by reaction 21.46. This oxidation may be reversed by reaction 21.47.

$$4[MnO_4]^- + 4[OH]^- \longrightarrow 4[MnO_4]^{2-} + 2H_2O + O_2 \quad (21.46)$$

$$2[MnO_4]^{2-} + Cl_2 \longrightarrow 2[MnO_4]^- + 2Cl^- \quad (21.47)$$

Manganate(VI) is unstable with respect to disproportionation (eq. 21.48) in the presence of even weak acids such as H_2CO_3 and is therefore not formed in the reduction of acidified $[MnO_4]^-$.



$$3[MnO_4]^{2-} + 4H^+ \longrightarrow 2[MnO_4]^- + MnO_2 + 2H_2O \quad (21.48)$$

The $[MnO_4]^{2-}$ ion is tetrahedral (Mn−O = 166 pm), and K_2MnO_4 is isomorphous with K_2CrO_4 and K_2SO_4. At 298 K, the magnetic moment of K_2MnO_4 is 1.75 μ_B (d^1). The tetrahedral anion $[Mn(N^tBu)_4]^{2-}$ (an imido analogue of $[MnO_4]^{2-}$) is made by treating $Mn(N^tBu)_3Cl$ with $Li[NH^tBu]$.

Manganese(V)

Although studies of the MnF_3/F_2 system indicate the existence of MnF_5 in the gas phase, binary halides of Mn(V) have not been isolated. The only halidooxidomanganese(V) compound is $MnOCl_3$ (**21.29**) which is made by reacting $KMnO_4$ with $CHCl_3$ in HSO_3Cl. Above 273 K, $MnOCl_3$

decomposes, and in moist air, it hydrolyses to $[MnO_4]^{3-}$. Salts of $[MnO_4]^{3-}$ are blue and moisture-sensitive; the most accessible are $K_3[MnO_4]$ and $Na_3[MnO_4]$, made by reduction of $[MnO_4]^-$ in concentrated aqueous KOH or NaOH at 273 K. Solutions of $[MnO_4]^{3-}$ must be strongly alkaline to prevent disproportionation which occurs readily in weakly alkaline (eq. 21.49) or acidic (eq. 21.50) media.

(21.29)

$$2[MnO_4]^{3-} + 2H_2O \longrightarrow [MnO_4]^{2-} + MnO_2 + 4[OH]^- \quad (21.49)$$

$$3[MnO_4]^{3-} + 8H^+ \longrightarrow [MnO_4]^- + 2MnO_2 + 4H_2O \quad (21.50)$$

The tetrahedral structure of $[MnO_4]^{3-}$ has been confirmed in the solid state in $Na_{10}Li_2(MnO_4)_4$. The Mn−O bonds are longer (170 pm) than in manganate(VI) or manganate(VII). Magnetic moments of $[MnO_4]^{3-}$ salts are typically ≈2.8 μ_B.

Self-study exercises

1. Values of Δ_{tet} for $[MnO_4]^{3-}$, $[MnO_4]^{2-}$ and $[MnO_4]^-$ have been estimated from electronic absorption spectroscopic data to be 11 000, 19 000 and 26 000 cm^{-1} respectively. Comment on this trend.
[*Ans.* See discussion of trends in Table 20.2]

2. Values of μ_{eff} for K_2MnO_4 and K_3MnO_4 are 1.75 and 2.80 μ_B (298 K) respectively, while $KMnO_4$ is diamagnetic. Rationalize these observations.
[*Ans.* Relate to d^n configuration; see Table 20.11]

3. Explain why $KMnO_4$ is intensely coloured, whereas $KTcO_4$ and $KReO_4$ are colourless.
[*Ans.* See Section 20.7]

Manganese(IV)

The only binary halide of Mn(IV) is MnF_4, prepared from the elements. It is an unstable blue solid which decomposes at ambient temperatures (eq. 21.51). Crystalline MnF_4 is dimorphic. The building blocks in α-MnF_4 are tetramers like those in VF_4 and β-CrF_4 (**21.14**). However, in these three metal fluorides, the assembly of the tetramers differs and in α-MnF_4, they are linked to give a 3-dimensional network.

$$2MnF_4 \longrightarrow 2MnF_3 + F_2 \quad (21.51)$$

Manganese(IV) oxide is polymorphic and often non-stoichiometric (see Section 6.18 for lattice defects). Only the high-temperature β-form has the stoichiometry MnO_2 and adopts a rutile structure (Fig. 6.24). It acts as an oxidizing agent when heated with concentrated acids (e.g. reaction 21.52).

$$MnO_2 + \underset{\text{conc}}{4HCl} \xrightarrow{\Delta} MnCl_2 + Cl_2 + 2H_2O \quad (21.52)$$

Hydrated forms of MnO_2 are extremely insoluble and are often obtained as dark black-brown precipitates in redox reactions involving $[MnO_4]^-$ (eq. 21.43) when the $[H^+]$ is insufficient to allow reduction to Mn^{2+}.

The reaction of Mn_2O_3 with $CaCO_3$ at 1400 K yields Ca_2MnO_4, which formally contains $[MnO_4]^{4-}$. However, Ca_2MnO_4 crystallizes with a layer structure in which each Mn(IV) centre is in an octahedral MnO_6 environment; isolated $[MnO_4]^{4-}$ ions are not present.

The coordination chemistry of Mn(IV) is limited. Mononuclear complexes include $[Mn(CN)_6]^{2-}$ and $[MnF_6]^{2-}$. The cyanido complex is made by oxidizing $[Mn(CN)_6]^{3-}$ and has a magnetic moment of 3.94 μ_B. Salts of $[MnF_6]^{2-}$ also have values of μ_{eff} close to the spin-only value of 3.87 μ_B. $[MnF_6]^{2-}$ is prepared by fluorinating mixtures of chlorides or by reducing $[MnO_4]^-$ with H_2O_2 in aqueous HF. Reaction 21.53 shows the first viable non-electrolytic method of producing F_2.

$$K_2[MnF_6] + 2SbF_5 \xrightarrow{\Delta} MnF_2 + 2K[SbF_6] + F_2 \quad (21.53)$$

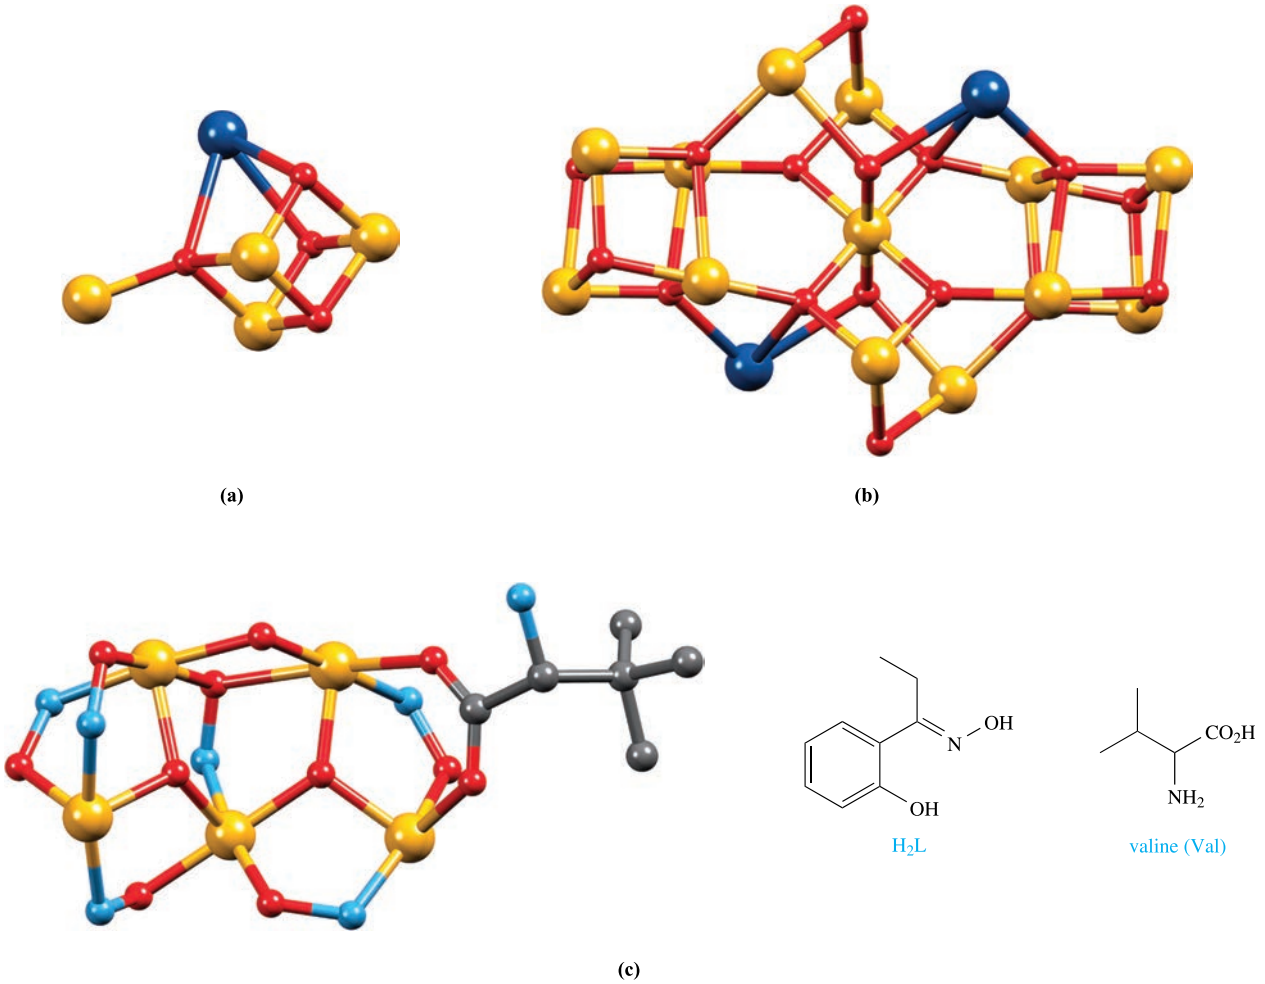
The structure of K_2MnF_6 is a prototype for some AB_2X_6 systems (e.g. Cs_2FeF_6 and K_2PdF_6). It is best considered as a close-packed array of K^+ and F^- ions in an alternating cubic–hexagonal sequence. The Mn^{4+} centres occupy some of the octahedral holes such that they are surrounded by six F^- ions giving $[MnF_6]^{2-}$ ions present in the lattice. Closely related structure types are K_2GeF_6 and K_2PtCl_6 in which the K^+ and X^- ions in each compound form hcp or ccp arrays respectively.

Self-study exercises

1. Calculate μ(spin-only) for $[Mn(CN)_6]^{2-}$.
[*Ans.* 3.87 μ_B]

2. Explain why orbital contributions to the magnetic moments of $[MnF_6]^{2-}$ and $[Mn(CN)_6]^{2-}$ are not important.
[*Ans.* Electronic configuration t_{2g}^3; see Section 20.10]

3. In the electronic absorption spectrum of $[Mn(CN)_6]^{2-}$, one might expect to see three absorptions arising from spin-allowed transitions. What would be the assignments of these transitions?
[*Ans.* See Fig. 20.20 and discussion]



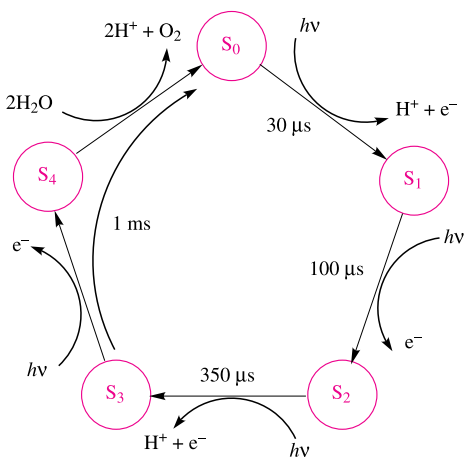


Fig. 21.20. (a) The structure (X-ray diffraction) of the cubane-like Mn_4CaO_4 active site in the oxygen evolving centre (OEC) in Photosystem II [K.N. Ferreira *et al.* (2004) *Science*, vol. 303, p. 1831]. High oxidation state manganese-containing cluster model compounds: the structures (X-ray diffraction) of (b) the $\{Mn_{13}Ca_2O_{16}\}$-core in $[Mn_{13}Ca_2O_{10}(OH)_2(OMe)_2(O_2CPh)_{18}(OH_2)_4]\cdot 10MeCN$ [A. Mishra *et al.* (2005) *Chem. Commun.*, p. 54] and (c) the $\{Mn_5(\mu_3\text{-}O)_2(\mu\text{-}O)_2(\mu\text{-}NO)_6(Val)\}$-core in $[Mn_5O_2(OMe)L_6(Val)]\cdot Val\cdot 1.5H_2O$ [C. Kozoni *et al.* (2009) *Dalton Trans.*, p. 9117] and the structures of the H_2L and amino acid ligands in the complex. Colour code: Mn, yellow; O, red; Ca, dark blue; N, blue; C, grey.

The enzyme Photosystem II (PSII) is responsible for the conversion of H_2O to O_2 during photosynthesis. Reaction 21.54 takes place in the oxygen evolving centre (OEC) in PSII, the active site consisting of a cubane-like Mn_3CaO_4-unit linked to an Mn spike (Fig. 21.20a). The structure was elucidated in 2004 through an X-ray diffraction study of PSII isolated from the cyanobacterium *Thermosynechococcus elongatus*.[†]

$$2H_2O \longrightarrow O_2 + 4H^+ + 4e^- \qquad (21.54)$$

Electron transfer involves the four Mn centres undergoing a sequence of redox steps, the fully oxidized and reduced states being $\{Mn^{IV}{}_3Mn^{III}\}$ and $\{Mn^{III}{}_3Mn^{II}\}$ respectively. The proposed catalytic cycle (called a Kok cycle) by which reaction 21.54 is achieved is shown below, where each of the intermediates S_0 to S_4 represents the Mn_4-unit in different oxidation states:

[†]See: K.N. Ferreira, T.M. Iverson, K. Maghlaoui, J. Barber and S. Iwata (2004) *Science*, vol. 303, p. 1831; J. Barber (2008) *Inorg. Chem.*, vol. 47, p. 1700; J. Yano and V. Yachandra (2014) *Chem. Rev.*, vol. 114, p. 4175.

A variety of discrete molecular complexes has been developed to study the chemistry of the water-splitting centre in PSII. Two examples are shown in Fig. 21.20. The first is $[Mn_{13}Ca_2O_{10}(OH)_2(OMe)_2(O_2CPh)_{18}(OH_2)_4]$ which contains a $\{Mn_{13}Ca_2O_{16}\}$-core comprising two linked cubane units (Fig. 21.20b). In PSII, the $\{Mn_4CaO_4\}$ active site is linked to the protein backbone of the enzyme through amino acid residues (aspartic acid, glutamic acid and histidine). Figure 21.20c shows the cluster core of $[Mn_5O_2(OMe)L_6(Val)]$ which models the interaction between an amino acid (valine) and an $[Mn^{IV}_2\,Mn^{III}_3]$-unit.

Manganese(III)

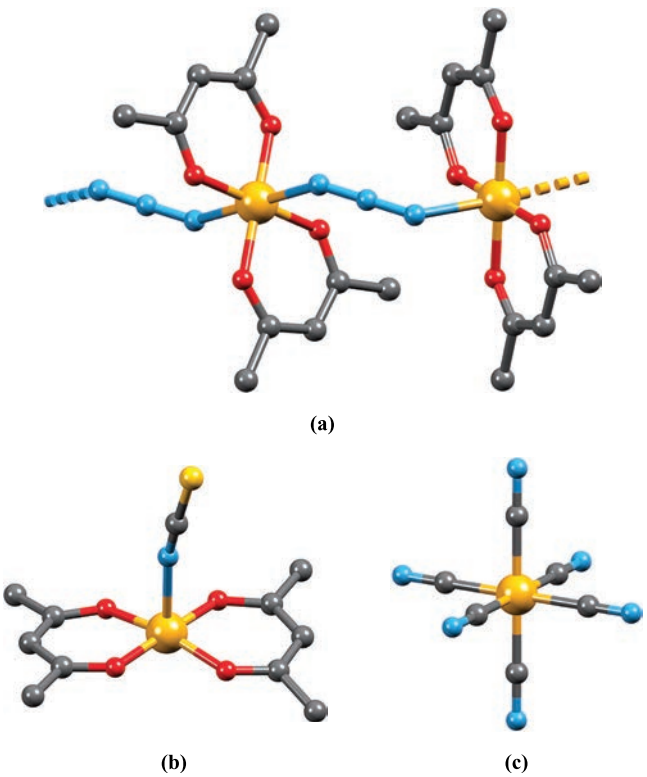
The only binary halide of Mn(III) is the red-purple MnF_3 which is made by the action of F_2 on Mn(II) halides at 520 K. It is thermally stable but is immediately hydrolysed by water. The solid state structure of MnF_3 is related to those of TiF_3, VF_3, CrF_3, FeF_3 and CoF_3 but is Jahn–Teller distorted (high-spin d^4). In MnF_3 there are *three* pairs of Mn–F distances (179, 191 and 209 pm) rather than the distortions shown in structures **20.5** and **20.6**. At room temperature, the magnetic moment of MnF_3 is 4.94 μ_B, but on cooling, MnF_3 becomes antiferromagnetic ($T_N = 43$ K) (see Section 20.10).

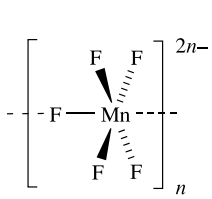
The black oxide Mn_2O_3 (the α-form) is obtained when MnO_2 is heated at 1070 K or (in the hydrous form) by oxidation of Mn(II) in alkaline media. At higher temperatures, it forms Mn_3O_4, a normal spinel ($Mn^{II}Mn^{III}{}_2O_4$, see Box 13.7) but with the Mn(III) centres being Jahn–Teller distorted. The Mn atoms in α-Mn_2O_3 are in distorted octahedral MnO_6 sites (elongated, diagram **20.5**). The structure differs from the corundum structure adopted by Ti_2O_3, V_2O_3 and Cr_2O_3. Whereas Mn_2O_3 is *antiferromagnetic* below 80 K, Mn_3O_4 is *ferrimagnetic* below 43 K.

Most complexes of Mn(III) are octahedral, high-spin d^4 and are Jahn–Teller distorted. The red aqua ion $[Mn(OH_2)_6]^{3+}$ can be obtained by electrolytic oxidation of aqueous Mn^{2+} and is present in the alum $CsMn(SO_4)_2 \cdot 12H_2O$. Surprisingly, the $[Mn(OH_2)_6]^{3+}$ ion shows no Jahn–Teller distortion, at least down to 78 K. In aqueous solution, $[Mn(OH_2)_6]^{3+}$ is appreciably hydrolysed (see Section 7.7) and polymeric cations are present. It is also unstable with respect to disproportionation (eq. 21.55) as expected from the potentials in Figs. 8.2 and 8.3; it is less unstable in the presence of high concentrations of Mn^{2+} or H^+ ions.

$$2Mn^{3+} + 2H_2O \longrightarrow Mn^{2+} + MnO_2 + 4H^+ \qquad (21.55)$$

The Mn^{3+} ion is stabilized by hard ligands including F^-, $[PO_4]^{3-}$, $[SO_4]^{2-}$ or $[C_2O_4]^{2-}$. The pink colour sometimes seen before the end of the permanganate–oxalate titration (eq. 21.45) is due to an oxalato complex of Mn(III). The salt $Na_3[MnF_6]$ is made by heating NaF with MnF_3, and reaction of MnO_2 with KHF_2 in aqueous HF gives $K_3[MnF_6]$. Both salts are violet and have magnetic moments of 4.9 μ_B (298 K), consistent with the spin-only value for high-spin d^4. Reaction of NaF with MnF_3 in aqueous HF yields pink $Na_2[MnF_5]$ which contains chains of distorted octahedral Mn(III) centres (**21.30**) in the solid state. Salts of $[MnF_4]^-$ also crystallize with the Mn centres in Jahn–Teller distorted octahedral sites, e.g. $CsMnF_4$ has a layer structure (**21.31**). However, in salts of $[MnCl_5]^{2-}$ for which solid state data are available, discrete square-based pyramidal anions are present. Contrasting structures are also observed in the related complexes $[Mn(N_3)(acac)_2]$ and $[Mn(NCS\text{-}N)(acac)_2]$; whereas the azido ligand presents two nitrogen donors to adjacent Mn(III) centres to produce a chain polymer, the thiocyanate ligand binds only through the hard *N*-donor leaving the soft *S*-donor uncoordinated (Fig. 21.21). The complex $[Mn(acac)_3]$ (obtained from $MnCl_2$ and $[acac]^-$ followed by oxidation with $KMnO_4$) is also of structural interest. It is dimorphic, crystallizing in one form with an elongated octahedral coordination sphere (**20.5**) while in the other, it is compressed (**20.6**).





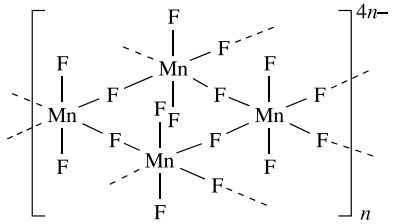


Fig. 21.21. The structures (X-ray diffraction) of the Mn(III) complexes (a) $[Mn(N_3)(acac)_2]$ which forms polymeric chains [B.R. Stults *et al.* (1975) *Inorg. Chem.*, vol. 14, p. 722] and (b) $[Mn(NCS\text{-}N)(acac)_2]$ [B.R. Stults *et al.* (1979) *Inorg. Chem.*, vol. 18, p. 1847]. Hydrogen atoms are omitted for clarity. (c) The structure of the octahedral $[Mn(CN)_6]^{3-}$ anion. Colour code: Mn, yellow; C, grey; O, red; N, blue; S, small yellow.

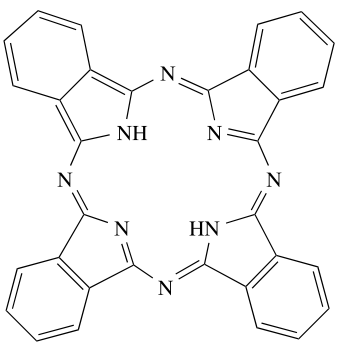
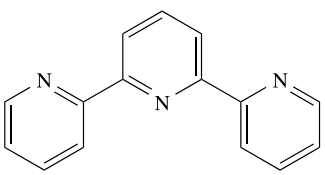


(21.30)

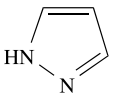
F
Mn
F
F
F

$[(H_3NCH_2CH_2)_2NH_2][MnCl_5]$ has an extended structure containing corner-sharing $MnCl_6$ octahedra. The salt $K_4[MnCl_6]$ contains discrete octahedral anions, and in green-yellow $[Et_4N]_2[MnCl_4]$ and $[PhMe_2(PhCH_2)N]_2[MnCl_4]$, isolated tetrahedral anions are present. The presence of the tetrahedral $[MnCl_4]^{2-}$ ion leads to complexes that are rather more intensely coloured than those containing related octahedral species (see Section 20.7). Tetrahedral $[Mn(CN)_4]^{2-}$ (a rare example of a high-spin cyanido complex) results from the photoinduced, reductive decomposition of $[Mn(CN)_6]^{2-}$. As a solid, the yellow salt $[N(PPh_3)_2]_2[Mn(CN)_4]$ is fairly stable in air. It is also stable in dry, aprotic solvents (e.g. MeCN), but hydrolyses in protic solvents.



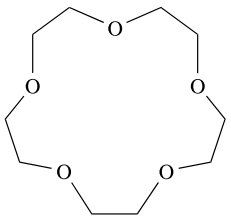
The reactions of $MnCl_2$, $MnBr_2$ and MnI_2 with, for example, *N*-, *O*-, *P*- or *S*-donor ligands have led to the isolation of a wide variety of complexes. A range of coordination geometries is observed as the following examples show (H_2pc = **21.32**; tpy = **21.33**; Hpz = **21.34**:

- tetrahedral: $[MnCl_2(OPPh_3)_2]$, $[Mn(N_3)_4]^{2-}$, $[Mn(Se_4)_2]^{2-}$;
- square planar: [Mn(pc)];
- trigonal bipyramidal: $[MnBr_2\{OC(NHMe)_2\}_3]$, $[MnBr\{N(CH_2CH_2NMe_2)_3\}]^+$, $[MnI_2(THF)_3]$;
- octahedral: *trans*-$[MnBr_2(Hpz)_4]$, *cis*-$[Mn(bpy)_2(NCS\text{-}N)_2]$, *cis*-$[MnCl_2(HOCH_2CH_2OH)_2]$, $[MnI(THF)_5]^+$, *mer*-$[MnCl_3(OH_2)_3]^-$, $[Mn(tpy)_2]^{2+}$, $[Mn(EDTA)]^{2-}$;
- 7-coordinate: $[Mn(EDTA)(OH_2)]^{2-}$, *trans*-$[Mn(\mathbf{21.35})(OH_2)_2]^{2+}$;
- square-antiprism: $[Mn(\mathbf{21.36})_2]^{2+}$;
- dodecahedral: $[Mn(NO_3\text{-}O,O')_4]^{2-}$.



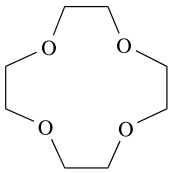
H_2pc = phthalocyanine

(21.32)



tpy = 2,2':6',2"-terpyridine
(free ligand has the *trans,trans*-configuration shown; coordinated ligand has a *cis,cis*-configuration)

(21.33)



Hpz = 1*H*-pyrazole

(21.34)

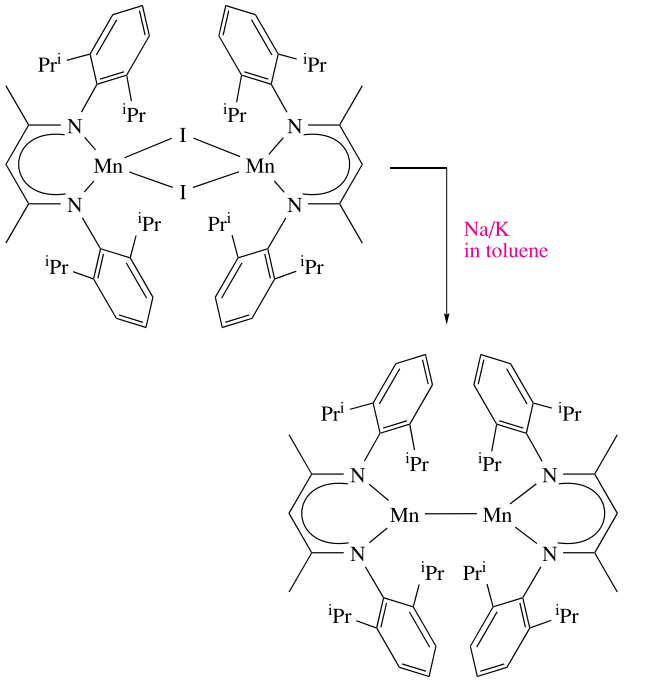
(21.35)

12-crown-4

(21.36)



The only common low-spin complex of Mn(II) is the blue, efflorescent $K_4[Mn(CN)_6]\cdot 3H_2O$ ($\mu_{eff} = 2.18\,\mu_B$) which is prepared in aqueous solution from $MnCO_3$ and KCN. Conversion of $K_4[Mn(CN)_6]$ to $K_3[Mn(CN)_6]$ occurs readily, the presence of the cyanido ligands significantly destabilizing Mn(II) with respect to Mn(III) (see Section 8.3).

Efflorescence is the loss of water from a hydrated salt.

Manganese(I)

Manganese(I) is typically stabilized by π-acceptor ligands in organometallic derivatives, but several compounds deserve a mention here. When Mn powder is dissolved in air-free aqueous NaCN, the Mn(I) complex $Na_5[Mn(CN)_6]$ is formed, the oxidizing agent being water. The low-spin d^6 $[Mn(CN)_6]^{5-}$ ion can also be made by reducing $[Mn(CN)_6]^{4-}$ with Na or K amalgam, again in the absence of O_2. The $[Mn(OH_2)_3(CO)_3]^+$ ion is the first example of a mixed aqua/carbonyl complex containing a first row *d*-block metal. It is an analogue of $[Tc(OH_2)_3(CO)_3]^+$, *in vivo* applications of which are described in Box 22.6. Evidence for $[Mn(OH_2)_3(CO)_3]^+$ existing as the *fac*-isomer comes from the ν(CO) region of the IR spectrum; the observation of two absorptions (2051 and 1944 cm^{-1}, assigned to the A_1 and E vibrational modes, respectively) is consistent with C_{3v} symmetry.

In Chapter 23, we describe many examples of the use of sterically demanding ligands. Structure **21.22** and Fig. 21.18 illustrate the use of a highly bulky ligand to stabilize a Cr–Cr quintuple bond. Reaction 21.57 shows how an Mn(I) complex is stabilized by the use of a bulky β-diketiminato ligand. The product of this reaction is the first example of a 3-coordinate, Mn(I) compound. The molecule formally contains an $\{Mn_2\}^{2+}$ core (Mn–Mn = 272 pm) and magnetic data are consistent with a rare example of a high-spin Mn(I) (d^6) complex in which there is antiferromagnetic coupling between the metal centres.

(21.57)

21.9 Group 8: iron

The metal

Finely divided Fe is pyrophoric in air, but the bulk metal oxidizes in dry air only when heated. In moist air, Fe rusts, forming a hydrated oxide $Fe_2O_3{\cdot}xH_2O$. Rusting is an electrochemical process (Box 8.4 and eq. 21.58) and occurs only in the presence of O_2, H_2O and an electrolyte. The latter may be water, but is more effective if it contains dissolved SO_2 (e.g. from industrial pollution) or NaCl (e.g. from sea-spray or salt-treated roads). Diffusion of the ions formed in reaction 21.58 deposits $Fe(OH)_2$ at places between the points of attack and this is further oxidized to hydrated iron(III) oxide.

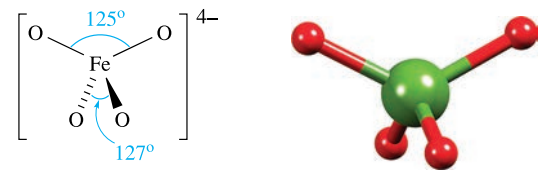
$$\left.\begin{aligned} 2Fe &\longrightarrow 2Fe^{2+} + 4e^- \\ O_2 + 2H_2O + 4e^- &\longrightarrow 4[OH]^- \end{aligned}\right\} \qquad (21.58)$$

Iron reacts with halogens at 470–570 K to give FeF_3, $FeCl_3$, $FeBr_3$ and FeI_2, respectively. The metal dissolves in dilute mineral acids to yield Fe(II) salts, but concentrated HNO_3 and other powerful oxidizing agents make it passive. Iron metal is unaffected by alkalis. When powdered iron and sulfur are heated together, FeS is produced. The formation of iron carbides and alloys is crucial to the steel industry (see Boxes 6.1 and 6.2 and Section 6.7).

Most of the chemistry of Fe involves Fe(II) or Fe(III), with Fe(IV) and Fe(VI) known in a small number of compounds; Fe(V) is rare. Lower formal oxidation states occur with π-acceptor ligands (see Chapter 24).

Iron(VI), iron(V) and iron(IV)

In iron chemistry, Mössbauer spectroscopy is widely used to gain information about the oxidation state and/or spin state of the Fe centres (see Section 4.10 and Fig. 20.31). The highest oxidation states of iron are found in compounds of $[FeO_4]^{2-}$, $[FeO_4]^{3-}$, $[FeO_4]^{4-}$ and $[FeO_3]^{2-}$ although these free ions are not necessarily present. Salts of $[FeO_4]^{2-}$ can be made by hypochlorite oxidation of Fe(III) salts in the presence of alkali (eq. 21.59). They contain discrete tetrahedral ions and are paramagnetic with magnetic moments corresponding to two unpaired electrons. The Na^+ and K^+ salts are deep red-purple and are soluble in water; aqueous solutions decompose (eq. 21.60) but alkaline solutions are stable. Ferrate(VI) is a powerful oxidant (eq. 21.61).



$$Fe_2O_3 + 3[OCl]^- + 4[OH]^- \longrightarrow 2[FeO_4]^{2-} + 3Cl^- + 2H_2O \qquad (21.59)$$

$$4[FeO_4]^{2-} + 6H_2O \longrightarrow 4FeO(OH) + 8[OH]^- + 3O_2 \qquad (21.60)$$

$$[FeO_4]^{2-} + 8H^+ + 3e^- \rightleftharpoons Fe^{3+} + 4H_2O \qquad E^\circ = +2.20\,V \qquad (21.61)$$

The reaction of K_2FeO_4 with KOH in O_2 at 1000 K gives K_3FeO_4, a rare example of an Fe(V) salt (see below).

Iron(IV) ferrates include Na_4FeO_4 (made from Na_2O_2 and $FeSO_4$), Sr_2FeO_4 (prepared by heating Fe_2O_3 and SrO in the presence of O_2) and Ba_2FeO_4 (made from BaO_2 and $FeSO_4$). Na_4FeO_4 and Ba_2FeO_4 contain discrete $[FeO_4]^{4-}$ ions. The high-spin d^4 configuration of Fe(IV) in $[FeO_4]^{4-}$ leads to a Jahn–Teller distortion, reducing the symmetry from T_d to approximately D_{2d} (structure **21.37** with structural data for the Na^+ salt).

(21.37)

In aqueous solution Na_4FeO_4 disproportionates (eq. 21.62).

$$3Na_4FeO_4 + 5H_2O \longrightarrow Na_2FeO_4 + Fe_2O_3 + 10NaOH \qquad (21.62)$$

Compounds formally containing $[FeO_3]^{2-}$ are actually mixed metal oxides; $CaFeO_3$, $SrFeO_3$ and $BaFeO_3$ crystallize with the perovskite structure (Fig. 6.26).

Attempts to stabilize Fe in high oxidation states using fluorido ligands have met with limited success. The reaction of Cs_2FeO_4 with F_2 (40 bar, 420 K) gives Cs_2FeF_6 along with $CsFeF_4$ and Cs_3FeF_6. In the solid state, Cs_2FeF_6 adopts a K_2MnF_6 structure (see Section 21.8, Mn(IV)). There is

current interest in the coordination chemistry of Fe(IV) since Fe(IV) intermediates may be present in bioinorganic processes involving cytochromes P-450 (see Section 29.3). However, the number of Fe(IV) complexes so far isolated and structurally characterized is small. The coordination environment is octahedral or square-based pyramidal, and ligands that stabilize Fe(IV) include dithiocarbamates (Fig. 21.23), dithiolates as in $[Fe(PMe_3)_2(1,2\text{-}S_2C_6H_4)_2]$, porphyrins and phthalocyanines.

Iron(V) is proposed as an intermediate oxidation state in catalytic cycles involving some non-haem oxygenases; see the end of Section 29.3 for haem oxygenases. High oxidation states of Fe are also relevant for nitrogenases (see the discussion associated with Fig. 29.23) and surface {Fe≡N} in the Haber process (see Section 25.8). Discrete compounds containing Fe(V) are difficult to prepare. Structure **21.38** shows a model iron(V) nitride complex isolated in 2011 and structurally characterized (Fig. 21.24). The {Fe≡N} unit is held within a pocket of a tripodal *N*-heterocyclic carbene ligand (carbenes are described in Section 24.13). Cation **21.38** is formed by the oxidation of the analogous Fe(IV) species and the Fe≡N bond shortens upon oxidation (151.2 to 150.2 pm). Evidence for Fe(V) in a low-spin d^3 configuration comes from EPR and Mössbauer spectroscopies (see Sections 4.9 and 4.10).[†]

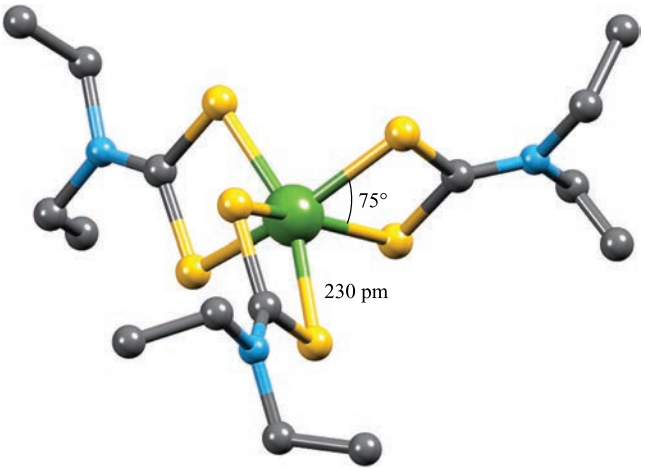


Fig. 21.23. The structure (X-ray diffraction) of the iron(IV) complex $[Fe(S_2CNEt_2)_3]^+$ in the $[I_5]^-$ salt [C.L. Raston *et al.* (1980) *J. Chem. Soc., Dalton Trans.*, p. 1928]. Hydrogen atoms are omitted; colour code: Fe, green; S, yellow; C, grey; N, blue.

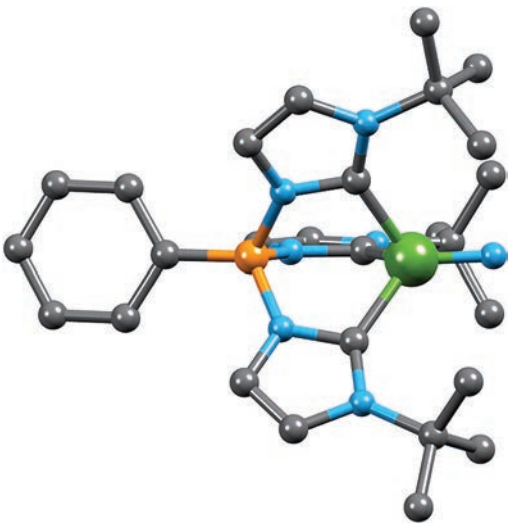

Fig. 21.24. The structure of a model iron(V) nitride cation, isolated as the $[B(3,5\text{-}(CF_3)_2C_6H_3)_4]^-$ salt, and determined by X-ray diffraction [J.J. Scepaniak *et al.* (2011) *Science*, vol. 331, p. 1049]. Hydrogen atoms are omitted for clarity. Colour code: Fe, green; N, blue; B, orange; C, grey.

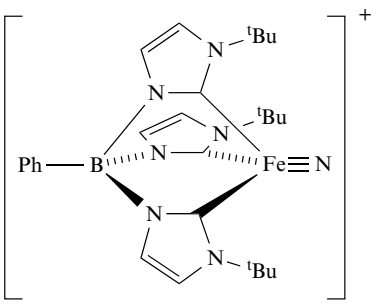
Self-study exercises

1. Explain why $[FeO_4]^{4-}$ (structure **21.37**) suffers from a Jahn–Teller distortion. The distortion is particularly strong. Is this expected?

   [*Ans.* See discussion of the tetrahedral crystal field in Section 20.3]



2. Typically, values of μ_{eff} for salts of $[FeO_4]^{2-}$ lie in the range 2.8–3.0 μ_B. Show that this is consistent with a μ(spin-only) value for tetrahedral Fe(VI) and comment on why orbital contributions to the magnetic moment are not expected.

3. $SrFeO_3$ crystallizes with a perovskite structure. What are the coordination environments of Sr, Fe and O?

   [*Ans.* Relate to $CaTiO_3$ in Fig. 6.26]

4. (a) The Fe(IV) compound Ba_3FeO_5 contains discrete ions in the solid state. Suggest what ions are present. (b) Ba_3FeO_5 is paramagnetic down to 5 K. Illustrate how the molar magnetic susceptibility varies over the temperature range 5–300 K.

   [*Ans.* See J.L. Delattre *et al.* (2002) *Inorg. Chem.*, vol. 41, p. 2834]

(21.38)

[†] See: J.J. Scepaniak *et al.* (2011) *Science*, vol. 331, p. 1049 – 'Synthesis, structure, and reactivity of an iron(V) nitride'.

Iron(III)

The old name for iron(III) is *ferric*. Iron(III) fluoride, chloride and bromide are made by heating Fe with the halogen. The fluoride is a white, involatile solid isostructural with ScF_3 (Fig. 21.5). In the solid state, $FeCl_3$ adopts the BiI_3 structure (Fig. 21.6) but the gas phase (bp 588 K) contains discrete molecules, dimers below 970 K and monomers above 1020 K. Anhydrous $FeCl_3$ forms hygroscopic dark green or black crystals. It dissolves in water to give strongly acidic solutions (see below) from which the orange-brown hydrate $FeCl_3{\cdot}6H_2O$ (properly formulated as *trans*-$[FeCl_2(OH_2)_4]Cl{\cdot}2H_2O$) can be crystallized. The trichloride is a useful precursor in Fe(III) chemistry, and both anhydrous $FeCl_3$ and $FeBr_3$ are used as Lewis acid catalysts in organic synthesis. Anhydrous $FeBr_3$ forms deliquescent, red-brown, water-soluble crystals; the solid adopts a BiI_3 structure (Fig. 21.6), but in the gas phase, molecular dimers are present. Iron(III) iodide readily decomposes (eq. 21.63) but, under inert conditions, it can be isolated from reaction 21.64.

$$2FeI_3 \longrightarrow 2FeI_2 + I_2 \qquad (21.63)$$

$$2Fe(CO)_4I_2 + I_2 \xrightarrow{h\nu} 2FeI_3 + 8CO \qquad (21.64)$$

Iron(III) oxide exists in a number of forms. The paramagnetic α-form (a red-brown solid or grey-black crystals) occurs as the mineral *haematite*[†] and adopts a corundum structure (see Section 13.7) with octahedrally sited Fe(III) centres. The β-form is produced by hydrolysing $FeCl_3{\cdot}6H_2O$, or by chemical vapour deposition (CVD, see Section 28.6) at 570 K from iron(III) trifluoroacetylacetonate. On annealing at 770 K, a β ⟶ α phase change occurs. The γ-form is obtained by careful oxidation of Fe_3O_4 and crystallizes with an extended structure in which the O^{2-} ions adopt a ccp array and the Fe^{3+} ions randomly occupy octahedral and tetrahedral holes. γ-Fe_2O_3 is ferromagnetic and is used in magnetic data storage. Iron(III) oxide is insoluble in water but can be dissolved with difficulty in acids. Several hydrates of Fe_2O_3 exist, and when Fe(III) salts are dissolved in alkali, the red-brown gelatinous precipitate that forms is *not* $Fe(OH)_3$ but $Fe_2O_3{\cdot}H_2O$ (also written as Fe(O)OH). The precipitate is soluble in acids giving $[Fe(OH_2)_6]^{3+}$, and in concentrated aqueous alkalis, $[Fe(OH)_6]^{3-}$ is present. Several forms of Fe(O)OH exist and consist of chain structures with edge-sharing FeO_6 octahedra. The minerals *goethite* and *lepidocrocite* are α- and γ-Fe(O)OH respectively.

Mixed metal oxides derived from Fe_2O_3 and of general formula $M^{II}Fe^{III}{}_2O_4$ or $M^{I}Fe^{III}O_2$ are commonly known as *ferrites* despite the absence of discrete oxoanions. They include compounds of commercial importance by virtue of their magnetic properties, e.g. electromagnetic devices for information storage; for discussion of the magnetic properties of mixed metal oxides, see Chapter 28. Spinel and inverse spinel structures adopted by $M^{II}Fe^{III}{}_2O_4$ oxides were described in Box 13.7 and Section 20.11, e.g. $MgFe_2O_4$ and $NiFe_2O_4$ are inverse spinels while $MnFe_2O_4$ and $ZnFe_2O_4$ are normal spinels. Some oxides of the $M^{I}Fe^{III}O_2$ type adopt structures that are related to NaCl (e.g. $LiFeO_2$, in which the Li^+ and Fe^{3+} ions occupy Na^+ sites and O^{2-} ions occupy Cl^- sites, Fig. 6.18). Among the $M^{I}Fe^{III}O_2$ group of compounds, $CuFeO_2$ and $AgFeO_2$ are noteworthy in being semiconductors. Other ferrites exist with more complex structures: permanent magnets are made using $BaFe_{12}O_{19}$, and the *iron garnet* family includes $Y_3Fe_5O_{12}$ (yttrium iron garnet, YIG) which is used as a microwave filter in radar equipment.

When Fe_2O_3 is heated at 1670 K, it converts to black Fe_3O_4 ($Fe^{II}Fe^{III}{}_2O_4$) which also occurs as the mineral *magnetite*, and possesses an inverse spinel structure (see Box 13.7). Its ferrimagnetic behaviour (see Fig. 20.32) makes Fe_3O_4 commercially important, e.g. it is used in magnetic toner in photocopiers. Mixtures of Fe_3O_4 and γ-Fe_2O_3 are used in magnetic data storage, and this market competes with that of CrO_2 (see Section 21.7).

Self-study exercises

1. Spinel and inverse spinel structures are based on cubic close-packed (ccp) arrangements of O^{2-} ions. Draw a representation of a unit cell of a ccp arrangement of O^{2-} ions. How many octahedral and tetrahedral holes are there in this unit cell? [*Ans.* See Section 6.2]

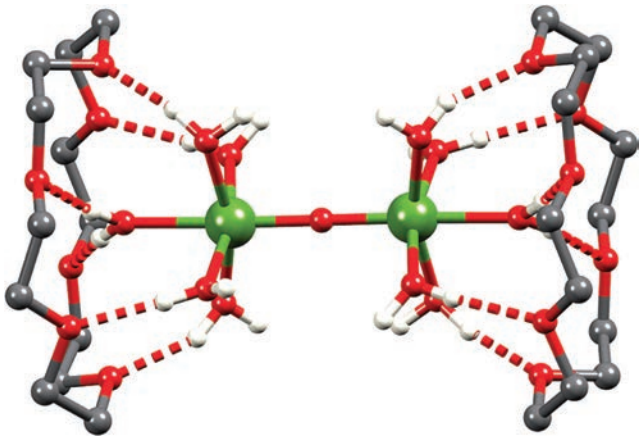
2. Refer to the diagram drawn in question 1. If half of the octahedral and one-eighth of the tetrahedral holes are filled with Fe^{3+} and Zn^{2+} ions respectively, show that the resultant oxide has the formula $ZnFe_2O_4$.

3. The inverse spinel structure of magnetite can be described as follows. Starting with a ccp arrangement of O^{2-} ions, one-quarter of the octahedral holes are filled with Fe^{3+} ions and one-quarter with Fe^{2+} ions; one-eighth of the tetrahedral holes are occupied with Fe^{3+} ions. Show that this corresponds to a formula of Fe_3O_4, and that the compound is charge-neutral.

4. Rationalize why $[Fe(OH_2)_6]^{3+}$ is acidic ($pK_a = 2.0$). [*Ans.* See eq. 7.36]

The chemistry of Fe(III) is well researched and among many commercially available starting materials are the chloride (see above), perchlorate, sulfate and nitrate. ***Hazard: Perchlorates are potentially explosive***. Anhydrous $Fe(ClO_4)_3$ is a yellow solid, but it is commercially available

[†] For an insight into the photocatalytic applications of haematite, see: D.K. Bora, A. Braun and E.C. Constable (2013) *Energy Environ. Sci.*, vol 6, p. 407 – 'In rust we trust'.



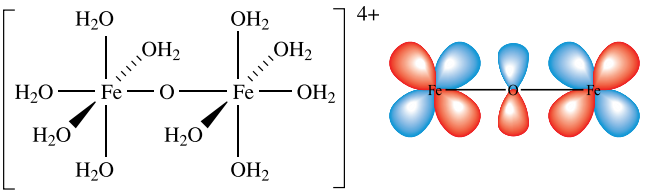


Fig. 21.25. The structure of $[(H_2O)_5Fe(\mu\text{-}O)Fe(OH_2)_5]^{4+}\cdot(18\text{-crown-}6)_2$ present in crystalline $[(H_2O)_5Fe(\mu\text{-}O)Fe(OH_2)_5]\,[ClO_4]_4\cdot(18\text{-crown-}6)_2\cdot 2H_2O$. The structure was determined by X-ray diffraction at 173 K [P.C. Junk *et al.* (2002) *J. Chem. Soc., Dalton Trans.*, p. 1024]; hydrogen atoms are omitted from the crown ethers. Colour code: Fe, green; O, red; C, grey; H, white.

as a hydrate $Fe(ClO_4)_3\cdot xH_2O$ with variable water content. The hydrate is prepared from aqueous $HClO_4$ and $Fe_2O_3\cdot H_2O$ and, depending on contamination with chloride, may be pale violet (<0.005% chloride content) or yellow. Iron(III) sulfate (made by oxidation of $FeSO_4$ with concentrated H_2SO_4) is purchased as the hydrate $Fe_2(SO_4)_3\cdot 5H_2O$. The nitrate is available as $Fe(NO_3)_3\cdot 9H_2O$ (correctly formulated as $[Fe(OH_2)_6][NO_3]_3\cdot 3H_2O$) which forms colourless or pale violet deliquescent crystals. It is made by reaction of iron oxides with concentrated HNO_3. The violet hexahydrate, $Fe(NO_3)_3\cdot 6H_2O$ (correctly written as $[Fe(OH_2)_6][NO_3]_3$), can be obtained by reaction of $Fe_2O_3\cdot H_2O$ with HNO_3. The octahedral $[Fe(OH_2)_6]^{3+}$ ion is also present in crystals of the violet alum $[NH_4]Fe(SO_4)_2\cdot 12H_2O$ (see Section 13.9). These Fe(III) salts are all water-soluble, dissolving to give brown-yellow solutions due to hydrolysis of $[Fe(OH_2)_6]^{3+}$ (eqs. 7.36 and 7.37); solution species include $[(H_2O)_5FeOFe(OH_2)_5]^{4+}$ (**21.39**) which has a *linear* Fe−O−Fe bridge indicative of $(d\text{–}p)\pi$-bonding involving Fe *d* and O *p* orbitals. The structural characterization of **21.39** has been achieved by hydrogen-bonded association of this cation with the crown ether 18-crown-6 (Fig. 21.25) or 15-crown-5 (**21.35**). The average $Fe-O_{bridge}$ and $Fe-O_{aqua}$ bond distances in **21.39** are 179 and 209 pm. The magnetic moment of 5.82 μ_B for $[Fe(OH_2)_6]^{3+}$ is close to the spin-only value for high-spin d^5.

(21.39)

The $[Fe(CN)_6]^{3-}$ ion (Fig. 21.26a) contains low-spin Fe(III) ($\mu_{eff} = 2.25\,\mu_B$) and is made by oxidation of $[Fe(CN)_6]^{4-}$, e.g. by reaction 21.65 or electrolytically. The cyanido ligands in $[Fe(CN)_6]^{3-}$ are more labile than in $[Fe(CN)_6]^{4-}$ and cause the former to be more toxic than the latter.

$$2K_4[Fe(CN)_6] + Cl_2 \longrightarrow 2K_3[Fe(CN)_6] + 2KCl \qquad (21.65)$$

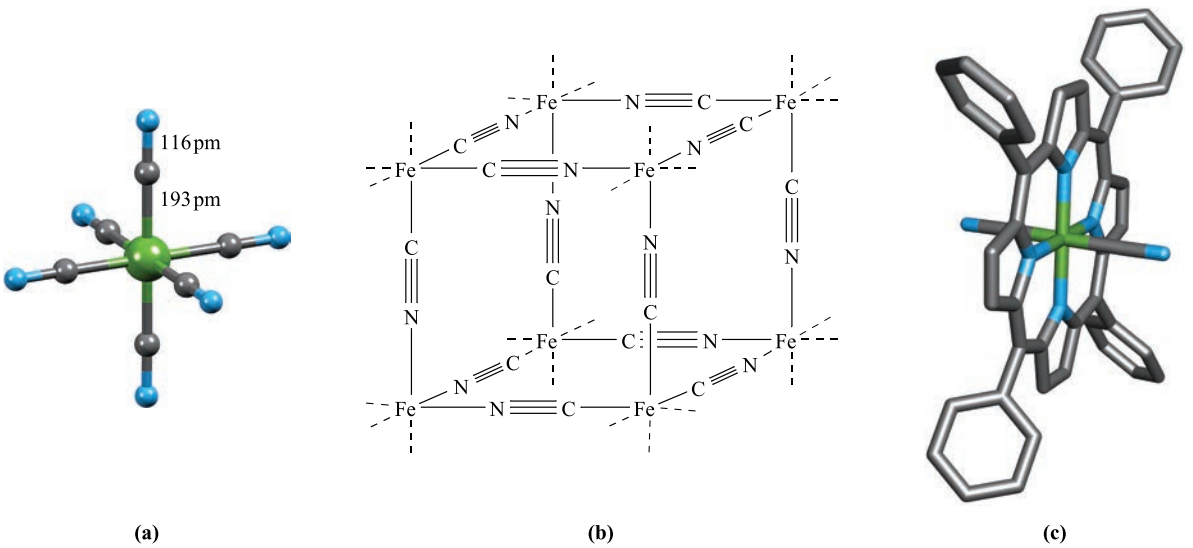

Fig. 21.26. Examples of iron(III) cyanido complexes: (a) the structure of $[Fe(CN)_6]^{3-}$ in the salt $Cs[NH_4]_2[Fe(CN)_6]$ (X-ray diffraction) [D. Babel (1982) *Z. Naturforsch., Teil B*, vol. 37, p. 1534], (b) one-eighth of the unit cell of $KFe[Fe(CN)_6]$ (the K^+ ions occupy the cavities and are omitted from the figure) and (c) the structure (determined by X-ray diffraction) of $[Fe(CN)_2(TPP)]$ where H_2TPP = 5,10,15,20-tetraphenyl-21*H*,23*H*-porphyrin (see Fig. 12.10 for parent porphyrin) [W.R. Scheidt *et al.* (1980) *J. Am. Chem. Soc.*, vol. 102, p. 3017]. Hydrogen atoms are omitted from (c); colour code in (a) and (c): Fe, green; N, blue, C, grey.

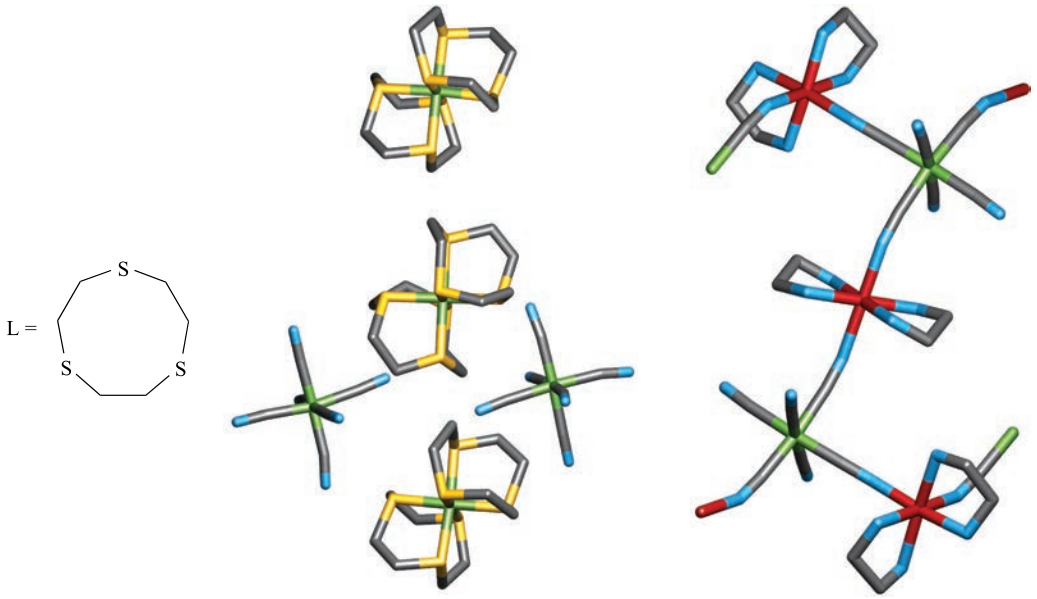

Fig. 21.27. (a) The structure (X-ray diffraction) of $[FeL_2]_3[Fe(CN)_6]_2{\cdot}2H_2O$ (L is defined in the scheme in the figure) in which the Fe(II) and Fe(III) centres are remote from each other ('valence trapped') [V.V. Pavlishchuk *et al.* (2001) *Eur. J. Chem.*, p. 297]. (b) Part of the polymeric structure (X-ray diffraction) of $[Ni(en)_2]_3[Fe(CN)_6]_2{\cdot}2H_2O$ in which Fe^{3+} ions are in $Fe(CN\text{-}C)_6$ environments and Ni^{2+} ions are in $Ni(CN\text{-}N)_2(en)_2$ sites [M. Ohba *et al.* (1994) *J. Am. Chem. Soc.*, vol. 116, p. 11566]. Hydrogen atoms are omitted; colour code: Fe, green; Ni, red; N, blue; S, yellow; C, grey.

The ruby-red salt $K_3[Fe(CN)_6]$ (potassium hexacyanidoferrate(III) or ferricyanide) is commercially available. It is an oxidizing agent although $[Fe(CN)_6]^{3-}$ is less powerful an oxidant than $[Fe(OH_2)_6]^{3+}$ (see Section 8.3). Addition of $[Fe(CN)_6]^{3-}$ to aqueous Fe^{2+} gives the deep blue complex *Turnbull's blue* and this reaction is used as a qualitative test for Fe^{2+}. Conversely, if $[Fe(CN)_6]^{4-}$ is added to aqueous Fe^{3+}, the deep blue complex *Prussian blue* is produced.[†] Both Prussian blue and Turnbull's blue are hydrated salts of formula $Fe^{III}{}_4[Fe^{II}(CN)_6]_3{\cdot}xH_2O$ ($x \approx 14$), and related to them is $KFe[Fe(CN)_6]$, *soluble Prussian blue*. In the solid state, these complexes possess extended structures containing cubic arrangements of Fe^{n+} centres linked by $[CN]^-$ bridges (Fig. 21.26b). The Fe^{3+} cations are high-spin, and $[Fe(CN)_6]^{4-}$ contains low-spin Fe(II). The deep blue colour is the result of electron transfer between Fe(II) and Fe(III). $K_2Fe[Fe(CN)_6]$, which contains only Fe(II), is white. Electron transfer can be prevented by shielding the cation as in the compound $[Fe^{II}L_2]_3[Fe^{III}(CN)_6]_2{\cdot}2H_2O$ (*Ukrainian red*) shown in Fig. 21.27a. Figure 21.26b shows part of the unit cell of $KFe[Fe(CN)_6]$; each Fe^{n+} is in an octahedral environment, either FeC_6 or FeN_6. Turnbull's blue, Prussian blue and Berlin green ($Fe^{III}[Fe^{III}(CN)_6]$) have been widely used in inks and dyes.

Figure 21.26b shows the ability of $[CN]^-$ to act as a bridging ligand and a number of polymeric materials containing either Fe(III) or Fe(II) as well as other metal centres have been made utilizing this property. An example is $[Ni(en)_2]_3[Fe(CN)_6]_2{\cdot}2H_2O$, the solid state structure of which (Fig. 21.27b) consists of interconnected helical chains in which octahedral Ni^{2+} and Fe^{3+} centres are connected by bridging $[CN]^-$ ligands. The latter facilitate electronic communication between the metal centres resulting in a ferromagnetic material (i.e. one in which the magnetic spins are aligned in the same direction, see Fig. 20.32). This is an example of a so-called *molecule-based magnet*. The design and assembly of such materials from paramagnetic building-blocks (both inorganic and organic) have undergone significant development over the past decade.[‡]

Large numbers of Fe(III) complexes are known, and octahedral coordination is common. Examples (Fig. 21.28)

[†] Prussian blue celebrated its 300th birthday in 2005: S.K. Ritter (2005) *Chem. Eng. News*, vol. 83, issue 18, p. 32 – 'Prussian blue: Still a hot topic'.

Miller (2014) *Materials Today*, vol. 17, p. 224; S. Wang, X.-H. Ding, Y.-H. Li and W. Huang (2012) *Coord. Chem. Rev.*, vol. 256, p. 439.

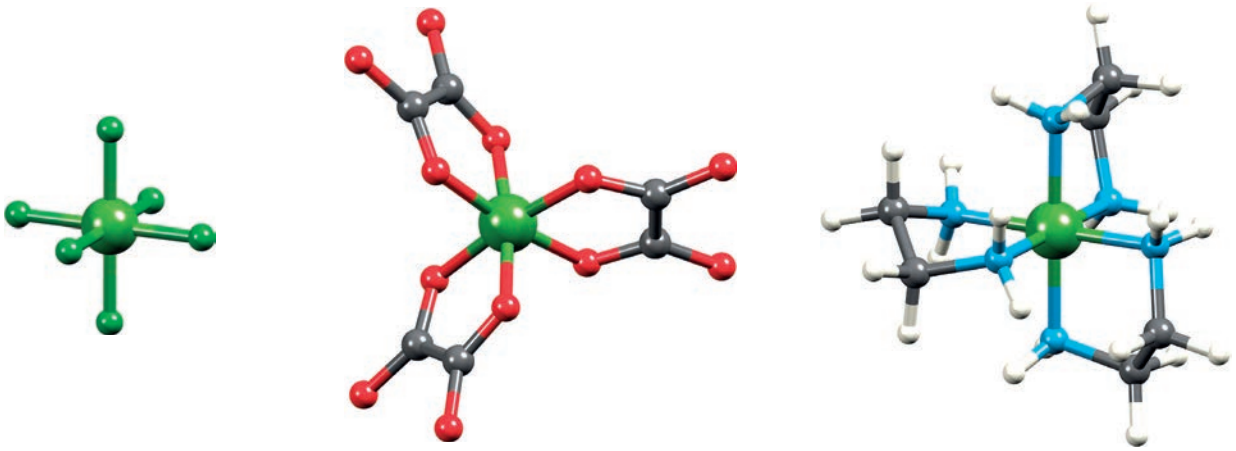

Fig. 21.28. Octahedral structures of (a) $[FeF_6]^{3-}$, (b) $[Fe(ox)_3]^{3-}$ and (c) $[Fe(en)_3]^{3+}$. Colour code: Fe, green; F, green; O, red; N, blue; C, grey; H, white.

of simple complexes (see Table 7.8 for ligand abbreviations) include:

- high-spin octahedral: $[Fe(OH_2)_6]^{3+}$, $[FeF_6]^{3-}$, $[Fe(ox)_3]^{3-}$, $[Fe(acac)_3]$;
- low-spin octahedral: $[Fe(CN)_6]^{3-}$ (Fig. 21.26a), $[Fe(bpy)_3]^{3+}$, $[Fe(phen)_3]^{3+}$, $[Fe(en)_3]^{3+}$;
- 7-coordinate: $[Fe(EDTA)(OH_2)]^-$.

Self-study exercise

Figure. 21.28b shows the structure of the $[Fe(ox)_3]^{3-}$ ion. Explain why this is more correctly written as Δ-$[Fe(ox)_3]^{3-}$. Draw the structure of Λ-$[Fe(ox)_3]^{3-}$.

[*Ans.* See Box 19.2]

The octahedral complex $[Fe(NH_3)_6]^{3+}$ can be prepared in liquid NH_3, but it has low stability in aqueous solutions, decomposing with loss of NH_3. Both bpy and phen stabilize Fe(II) more than they do Fe(III). This is because of the relatively low-lying π^* MOs on the ligands, which allows them to function as π-acceptors. In aqueous solution, both $[Fe(bpy)_3]^{3+}$ and $[Fe(phen)_3]^{3+}$ are more readily reduced than the hexaaqua ion (eqs. 21.66–21.68).

$$Fe^{3+}(aq) + e^- \rightleftharpoons Fe^{2+}(aq) \qquad E^o = +0.77\,V \qquad (21.66)$$

$$\underset{\text{blue}}{[Fe(bpy)_3]^{3+}} + e^- \rightleftharpoons \underset{\text{red}}{[Fe(bpy)_3]^{2+}} \qquad E^o = +1.03\,V \qquad (21.67)$$

$$\underset{\text{blue}}{[Fe(phen)_3]^{3+}} + e^- \rightleftharpoons \underset{\text{red}}{[Fe(phen)_3]^{2+}} \qquad E^o = +1.12\,V \qquad (21.68)$$

The addition of thiocyanate to aqueous solutions of Fe^{3+} produces a blood-red coloration due to the formation of $[Fe(OH_2)_5(SCN\text{-}N)]^{2+}$. Complete exchange of ligands to give $[Fe(SCN\text{-}N)_6]^{3-}$ is best carried out in non-aqueous media.

Iron(III) favours *O*-donor ligands and stable complexes such as the green $[Fe(ox)_3]^{3-}$ (Fig. 21.28b) and red $[Fe(acac)_3]$ are commonly encountered. Iron(III) porphyrinato complexes are of relevance for modelling haemproteins (see Section 29.3) and there is interest in reactions of these complexes with, for example, CO, O_2, NO and $[CN]^-$. The N_4-donor set of a porphyrinato ligand is confined to a plane and this restriction forces the Fe(III) centre to be in a square planar environment with respect to the macrocycle. Other ligands may then enter in axial sites above and below the FeN_4-plane to give either square-based pyramidal or octahedral complexes (Fig. 21.26c).

Low coordination numbers can be stabilized by interaction with amido ligands, e.g. $[Fe\{N(SiMe_3)_2\}_3]$ (Fig. 19.4d).

Self-study exercises

1. In Fig. 21.25, the oxido-bridge atom lies on an inversion centre. Explain what this means.

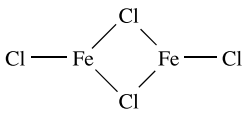
   [*Ans.* See Section 3.2]

2. For $[Fe(tpy)Cl_3]$ (tpy is structure **21.33**), $\mu_{eff} = 5.85\,\mu_B$ at 298 K. Comment on why there is no orbital contribution to the magnetic moment, and determine the number of unpaired electrons. Why does this complex exist only in the *mer*-form?

   [*Ans.* See Section 20.10; see Fig. 2.18 and consider flexibility of ligand]

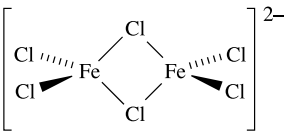
3. In $[Fe(CN)_6]^{3-}$, does the CN^- ligand act as a π-donor or a π-acceptor ligand? Explain how the ligand properties lead to $[Fe(CN)_6]^{3-}$ being low-spin.

   [*Ans.* See Fig. 20.15b and discussion]



4. In the caption to Fig. 21.26b, why is the structure described as being 'one-eighth of the unit cell of $KFe[Fe(CN)_6]$' rather than being a complete unit cell?

Iron(II)



The old name for iron(II) is *ferrous*. Anhydrous FeF_2, $FeCl_2$ and $FeBr_2$ can be prepared by reaction 21.69, while FeI_2 is made by direct combination of the elements.

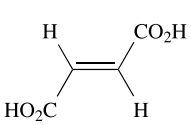
$$Fe + 2HX \xrightarrow{\Delta} FeX_2 + H_2 \qquad (X = F, Cl, Br) \qquad (21.69)$$

Iron(II) fluoride is a sparingly soluble, white solid with a distorted rutile structure (Fig. 6.24); the environment around the high-spin Fe(II) centre (d^6) is surprisingly irregular with 4F at 212 pm and 2F at 198 pm. In the gas phase, FeF_2 is monomeric. Iron(II) chloride forms white, hygroscopic, water-soluble crystals and adopts a $CdCl_2$ structure (see Section 6.11). In the gas phase of $FeCl_2$, monomers and dimers (**21.40**) are present. The pale green hydrate $FeCl_2{\cdot}4H_2O$, properly formulated as octahedral $[FeCl_2(OH_2)_4]$, is a convenient precursor in Fe(II) chemistry. The hexahydrate (which loses water readily) can be obtained by recrystallizing $FeCl_2$ from water below 285 K. The reaction of $FeCl_2$ with Et_4NCl in acetone yields the air-sensitive $[Et_4N]_2[Fe_2Cl_6]$ containing anion **21.41**.

(21.40)

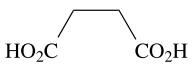
(21.41)

Iron(II) bromide is a deliquescent, yellow or brown solid and adopts a CdI_2 structure (Fig. 6.25). It is very soluble in water and forms hydrates $FeBr_2{\cdot}xH_2O$ where $x = 4$, 6 or 9 depending on crystallization conditions. Dark violet FeI_2 has a CdI_2 layer structure, and is hygroscopic and light-sensitive; it forms a green tetrahydrate. All the halides or their hydrates are commercially available, as are salts such as the perchlorate, sulfate and $[NH_4]_2Fe[SO_4]_2{\cdot}6H_2O$. Iron(II) sulfate is a common source of Fe(II) and is available as the blue-green $FeSO_4{\cdot}7H_2O$, an old name for which is *green*

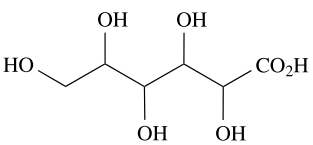


BIOLOGY AND MEDICINE

Box 21.5 Iron complexes fight anaemia



In Chapter 29, the crucial role that iron plays in biological systems is discussed in detail. Anaemia, in which the body suffers from a deficiency of iron, leads to a general state of lethargy and weakness. Iron is usually administered orally to a patient as iron supplement tablets containing an Fe(II) or Fe(III) salt. Iron(II) salts are more typical because they exhibit better solubilities than Fe(III) salts at physiological pH, but Fe(III) has the advantage that, unlike Fe(II), it is not susceptible to oxidation in aqueous solution. Among compounds which are in common use are iron(III) chloride, iron(II) sulfate, iron(II) fumarate, iron(II) succinate and iron(II) gluconate; the structures of fumaric acid, succinic acid and gluconic acid are shown below.



Colorized scanning electron micrograph of red blood cells (magnified ×4000).

Fumaric acid

Succinic acid

Gluconic acid

vitriol. Like most hydrated Fe(II) salts, it dissolves in water to give $[Fe(OH_2)_6]^{2+}$, the electronic absorption spectrum and magnetic moment of which are consistent with high-spin d^6. The salt $[NH_4]_2Fe[SO_4]_2{\cdot}6H_2O$ is an important source of Fe^{2+} because, in the solid state, it is kinetically more stable towards oxidation than most Fe(II) salts.

Iron(II) oxide is a black, insoluble solid with an NaCl structure above its Curie temperature (200 K). The FeO lattice suffers defects because it is always deficient in Fe (see Section 6.18). Below 200 K, FeO undergoes a phase change and becomes antiferromagnetic. It can be made *in vacuo* by thermal decomposition of iron(II) oxalate but the product must be cooled rapidly to prevent disproportionation (eq. 21.70).

$$4FeO \longrightarrow Fe_3O_4 + Fe \qquad (21.70)$$

White $Fe(OH)_2$ is precipitated by adding alkali to solutions of Fe(II) salts but it rapidly absorbs O_2, turning dark green, then brown. The products are a mixed Fe(II)Fe(III) hydroxide and $Fe_2O_3{\cdot}H_2O$. Iron(II) hydroxide dissolves in acids, and from concentrated NaOH solutions, the blue-green $Na_4[Fe(OH)_6]$ can be crystallized.

An interesting distinction between iron(II) oxides and sulfides is that, whereas FeO has an analogue in FeS, there is no peroxide analogue of FeS_2 (*iron pyrites* or *pyrites*). The sulfide FeS is made by heating together the elements; it is found in lunar rock samples and adopts an NiAs structure (Fig. 15.12). Reaction of FeS with hydrochloric acid used to be a common laboratory synthesis of H_2S (eq. 16.37). Pyrites is $Fe^{2+}(S_2)^{2-}$ and contains low-spin Fe(II). The unit cell of FeS_2 is shown in Fig. 21.29. Each Fe atom is octahedrally sited. Each S atom is in a tetrahedral site with one S and three Fe near neighbours.

The coordination chemistry of Fe(II) is well developed and only a brief introduction to simple species is given here. Iron(II) halides combine with gaseous NH_3 to give salts of $[Fe(NH_3)_6]^{2+}$ but this decomposes in aqueous media, precipitating $Fe(OH)_2$. In aqueous solutions, $[Fe(OH_2)_6]^{2+}$ is unstable with respect to oxidation, although, as we saw above, double salts such as $[NH_4]_2Fe[SO_4]_2{\cdot}6H_2O$ are more stable. Displacement of the ligands in $[Fe(OH_2)_6]^{2+}$ leads to a range of complexes. We have already discussed the stabilization of Fe(II) by bpy and phen (eqs. 21.66–21.68). Oxidation of red $[Fe(phen)_3]^{2+}$ to blue $[Fe(phen)_3]^{3+}$ is more difficult than that of $[Fe(OH_2)_6]^{2+}$ to $[Fe(OH_2)_6]^{3+}$, and hence arises the use of $[Fe(phen)_3][SO_4]$ as a redox indicator. Both $[Fe(phen)_3]^{2+}$ and $[Fe(bpy)_3]^{2+}$ are low-spin d^6 and diamagnetic. $[Fe(CN)_6]^{4-}$ is also low-spin. The latter, like $[Fe(CN)_6]^{3-}$ (Fig. 21.26a), is octahedral but the Fe−C bonds in the Fe(II) species are shorter (192 pm) than those in the Fe(III) complex. This provides support for stronger

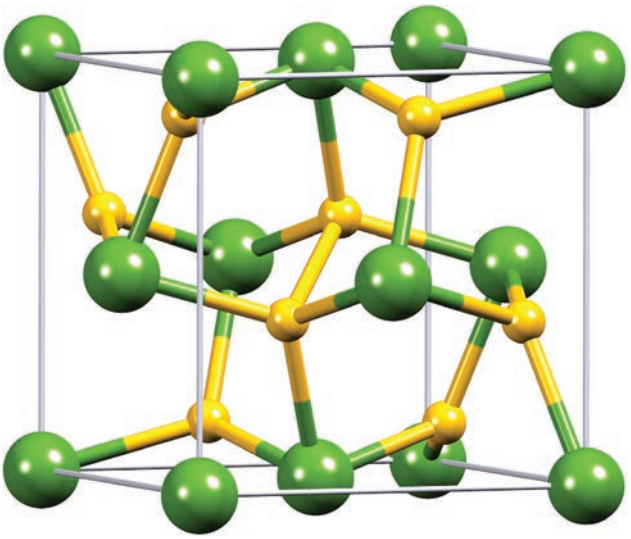


Fig. 21.29. The unit cell of FeS_2. The unit cell contains one complete $[S_2]^{2-}$ ion. Other $[S_2]^{2-}$ ions are completed by considering S atoms in adjacent unit cells. Colour code: Fe, green; S, yellow. The unit cell is defined by the grey lines. [Data from: The American Mineralogist Crystal Structure Database, R.T. Downs and M. Hall-Wallace (2003) *American Mineralogist*, vol. 88, p. 247.]

Fe–C π-bonding in the lower oxidation state complex. However, the C–N bond lengths and stretching frequencies differ little between $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$. There are many known *mono*substitution products of $[Fe(CN)_6]^{4-}$. Sodium nitropentacyanidoferrate(II) (*sodium nitroprusside*), $Na_2[Fe(CN)_5(NO)]{\cdot}2H_2O$, is made by reaction 21.71 or 21.72; among its uses are those as an anti-hypertensive drug (it acts as a vasodilator through release of NO) and as a standard reference for ^{57}Fe Mössbauer spectroscopy (see Section 4.10).

$$[Fe(CN)_6]^{4-} + 4H^+ + [NO_3]^- \longrightarrow [Fe(CN)_5(NO)]^{2-} + CO_2 + [NH_4]^+ \qquad (21.71)$$

$$[Fe(CN)_6]^{4-} + H_2O + [NO_2]^- \longrightarrow [Fe(CN)_5(NO)]^{2-} + [CN]^- + 2[OH]^- \qquad (21.72)$$

Nitrogen monoxide is a radical (structure **15.48**), but $Na_2[Fe(CN)_5(NO)]$ is diamagnetic. In the complex, the N−O distance of 113 pm is shorter, and the stretching wavenumber of 1947 cm^{-1} higher, than in free NO. Thus, the complex is formulated as containing an $[NO]^+$ ligand. The addition of S^{2-} to $[Fe(CN)_5(NO)]^{2-}$ produces the red $[Fe(CN)_5(NOS)]^{4-}$ and this is the basis of a sensitive test for S^{2-}. Similarly, reaction with $[OH]^-$ gives $[Fe(CN)_5(NO_2)]^{4-}$ (eq. 21.73). For details of $[Fe(NO)(OH_2)_5]^{2+}$, see Section 15.8.

$$[Fe(CN)_5(NO)]^{2-} + 2[OH]^- \longrightarrow [Fe(CN)_5(NO_2)]^{4-} + H_2O \qquad (21.73)$$

The active sites of NiFe and Fe-only hydrogenase enzymes (see Figs. 29.19 and 29.21) contain $Fe(CO)_x(CN)_y$ coordination units, and there is active interest in studying model Fe(II) compounds containing both CO and $[CN]^-$ ligands. Besides being a good π-acceptor ligand, $[CN]^-$ is a strong σ-donor and can stabilize carbonyl complexes of Fe(II). More commonly, we associate CO with low oxidation state (≤ 0) compounds (see Chapter 24). The reaction of CO with $FeCl_2$ suspended in MeCN, followed by addition of $[Et_4N][CN]$ leads to salts of $[Fe(CN)_5(CO)]^{3-}$ and *trans*- and *cis*-$[Fe(CN)_4(CO)_2]^{2-}$. Alternatively, *trans*-$[Fe(CN)_4(CO)_2]^{2-}$ can be made by adding $[CN]^-$ to an aqueous solution of $FeCl_2{\cdot}4H_2O$ under an atmosphere of CO, while the same reaction yields $Na_3[Fe(CN)_5(CO)]$ if five equivalents of NaCN are used. Reaction of NaCN with $Fe(CO)_4I_2$ yields the Na^+ salt of *fac*-$[Fe(CO)_3(CN)_3]^-$, and further addition of $[CN]^-$ leads to the formation of *cis*-$[Fe(CN)_4(CO)_2]^{2-}$. Exchanging a CO ligand in $Fe(CO)_5$ by $[CN]^-$ is described in Section 24.7.

In addition to the hexaaqua ion, high-spin Fe(II) complexes include $[Fe(en)_3]^{2+}$. Its magnetic moment of 5.45 μ_B is larger than the spin-only value of 4.90 μ_B and reflects orbital contributions for the configuration $t_{2g}^4e_g^2$. Although iron(II) favours an octahedral arrangement of donor atoms, there are some tetrahedral complexes, for example $[FeCl_4]^{2-}$ (eq. 21.74), $[FeBr_4]^{2-}$, $[FeI_4]^{2-}$ and $[Fe(SCN)_4]^{2-}$.

$$2MCl + FeCl_2 \xrightarrow{\text{in EtOH}} M_2[FeCl_4] \quad (M = \text{group 1 metal}) \qquad (21.74)$$

The amido complex $[Fe\{N(SiMePh_2)_2\}_2]$ is an unusual example of 2-coordinate Fe(II) (see Section 19.7).

Self-study exercises

1. Rationalize why $[Fe(OH_2)_6]^{2+}$ and $[Fe(CN)_6]^{4-}$, both octahedral Fe(II) complexes, are paramagnetic and diamagnetic, respectively.
[*Ans.* See Section 20.3 and Table 20.3]

2. Explain why there is an orbital contribution to the magnetic moment of $[Fe(en)_3]^{2+}$.
[*Ans.* See Section 20.10]

3. The value of $\log \beta_6$ for $[Fe(CN)_6]^{4-}$ is 32.† Calculate a value for $\Delta G^o(298\,K)$ for the process:
$Fe^{2+}(aq) + 6[CN]^-(aq) \longrightarrow [Fe(CN)_6]^{4-}(aq)$
[*Ans.* $-183\,kJ\,mol^{-1}$]

4. To which point group does *fac*-$[Fe(CO)_3(CN)_3]^-$ belong? How many ν(CO) and how many ν(CN) absorptions are expected in the IR spectrum of *fac*-$[Fe(CO)_3(CN)_3]^-$?
[*Ans.* See Table 3.5 and the associated self-study exercises]

5. Confirm that *trans*-$[Fe(CN)_4(CO)_2]$ belongs to the D_{4h} point group. Explain why the IR spectrum of *trans*-$[Fe(CN)_4(CO)_2]$ contains one ν(CO) absorption and one ν(CN) band.

† This system was reassessed in 2003: W.N. Perera and G. Hefter (2003) *Inorg. Chem.*, vol. 42, p. 5917.

Iron in low oxidation states

Low oxidation states of iron are typically associated with organometallic compounds and will be discussed mainly in Chapter 24. However, several iron-containing nitrosyl complexes deserve a mention here. The NO molecule is a radical and, as was described in Section 20.5, the M–N–O unit in a complex is either linear or bent depending on whether the ligand behaves as a 3- or a 1-electron donor, respectively. Formally, the nitrosyl ligand is classified as behaving as $[NO]^-$ (bent) or $[NO]^+$ (linear), but in many cases, the oxidation state of the metal in a nitrosyl complex remains ambiguous. Equation 21.75 shows the formation of the tetrahedral $Fe(NO)_3I$ in which each Fe–N–O bond angle is 166°. Loss of NO from $Fe(NO)_3I$ occurs under vacuum to give $(ON)_2Fe(\mu\text{-}I)_2Fe(NO)_2$.

$$Fe(CO)_4I_2 + 3NO \longrightarrow Fe(NO)_3I + \tfrac{1}{2}I_2 + 4CO \qquad (21.75)$$

Attempts to prepare binary iron nitrosyl complexes by treatment of $Fe(NO)_3Cl$ with $AgPF_6$ or $AgBF_4$ lead to $Fe(NO)_3(PF_6\text{-}\kappa F)$ and $Fe(NO)_3(BF_4\text{-}\kappa F)$ rather than the salts containing 'naked' $[Fe(NO)_3]^+$ ions. The 'κF' notation means that the $[PF_6]^-$ or $[BF_4]^-$ anion coordinates to the metal centre through one F atom.

21.10 Group 9: cobalt

The metal

Cobalt is less reactive than Fe (e.g. see eq. 21.76); Co does not react with O_2 unless heated, although when very finely divided, it is pyrophoric. It dissolves slowly in dilute mineral acids (e.g. reaction 21.77), but concentrated HNO_3 makes it passive; alkalis have no effect on the metal.

$$M^{2+}(aq) + 2e^- \longrightarrow M(s) \quad \begin{cases} M = Fe,\ E^o = -0.44\,V \\ M = Co,\ E^o = -0.28\,V \end{cases} \qquad (21.76)$$

$$Co + H_2SO_4 \longrightarrow CoSO_4 + H_2 \qquad (21.77)$$

Cobalt reacts at 520 K with F_2 to give CoF_3, but with Cl_2, Br_2 and I_2, CoX_2 is formed. Even when heated, cobalt

does not react with H_2 or N_2, but it does combine with B, C (see Section 14.7), P, As and S.

The trend in decreasing stability of high oxidation states on going from Mn to Fe continues along the row (Table 19.3). Cobalt(IV) is the highest oxidation state but it is of far less importance than Co(III) and Co(II). Cobalt(I) and lower oxidation states are stabilized in organometallic species by π-acceptor ligands (see Chapter 24). Among Co(I) complexes containing only phosphane ligands is tetrahedral $[Co(PMe_3)_4]^+$.

Cobalt(IV)

Few Co(IV) species have been established. Yellow $Cs_2[CoF_6]$ is obtained by fluorination of a mixture of CsCl and $CoCl_2$ at 570 K. The fact that $[CoF_6]^{2-}$ (d^5) is *low-spin* contrasts with the *high-spin* nature of $[CoF_6]^{3-}$ (d^6) and the difference reflects the increase in Δ_{oct} with increasing oxidation state. Cobalt(IV) oxide (made by oxidizing Co(II) using alkaline hypochlorite) is poorly defined. Several mixed oxides are known: Ba_2CoO_4 and M_2CoO_3 (M = K, Rb, Cs).

Cobalt(III)

There are few *binary* compounds of Co(III) and only a limited number of Co(III) compounds are commercially available. The only binary halide is brown CoF_3 which is isostructural with FeF_3. It is used as a fluorinating agent, e.g. for preparing perfluorinated organics, and is corrosive and an oxidant. The reaction of N_2O_5 with CoF_3 at 200 K gives the dark green, anhydrous $Co(NO_3)_3$ which has a molecular structure with three bidentate $[NO_3]^-$ groups bound to octahedral Co(III).

Although reports of Co_2O_3 are found in the literature, the anhydrous compound probably does not exist. In contrast, the mixed oxidation state Co_3O_4 ($Co^{II}Co^{III}{}_2O_4$) is well established and is formed when Co is heated in O_2. The insoluble, grey-black Co_3O_4 crystallizes with a normal spinel structure (Box 13.7) containing high-spin Co^{2+} in tetrahedral holes and low-spin Co^{3+} in octahedral holes. It is, therefore, a worse electrical conductor than Fe_3O_4, in which both high-spin Fe^{2+} and high-spin Fe^{3+} are present in the same octahedral environment. A hydrated oxide is precipitated when excess alkali reacts with most Co(III) compounds, or on aerial oxidation of aqueous suspensions of $Co(OH)_2$. Mixed metal oxides $MCoO_2$, where M is an alkali metal, can be made by heating mixtures of the oxides and consist of layer structures built of edge-sharing CoO_6 octahedra with M^+ ions in interlayer sites. Of particular significance is $LiCoO_2$ which is used in lithium-ion batteries (see Box 11.3).

The blue, low-spin $[Co(OH_2)_6]^{3+}$ ion can be prepared *in situ* by electrolytic oxidation of aqueous $CoSO_4$ in acidic solution at 273 K. A more convenient method for routine use is to dissolve solid $[Co(NH_3)_6][Co(CO_3)_3]$ (a stable, sparingly soluble salt, made according to scheme 21.78) in aqueous nitric or perchloric acid. The acid is chosen so as to ensure precipitation of $[Co(NH_3)_6]X_3$ (eq. 21.79), leaving $[Co(OH_2)_6]^{3+}$ in solution.

$$\mathrm{Co(NO_3)_2 \cdot 6H_2O(aq)} \xrightarrow{\text{excess } [HCO_3]^-,\ H_2O_2} \mathrm{[Co(CO_3)_3]^{3-}(aq)} \xrightarrow{[Co(NH_3)_6]Cl_3(aq)} \mathrm{[Co(NH_3)_6][Co(CO_3)_3](s)}$$

green crystals

(21.78)

$$\mathrm{[Co(NH_3)_6][Co(CO_3)_3] + 6HX(aq)} \quad (X^- = ClO_4^-, NO_3^-) \longrightarrow \mathrm{[Co(OH_2)_6]^{3+}(aq) + 3X^-(aq) + 3CO_2(g) + [Co(NH_3)_6]X_3(s)}$$

(21.79)

The $[Co(OH_2)_6]^{3+}$ ion is a powerful oxidant (eq. 21.80) and is unstable in aqueous media, decomposing to Co(II) with the liberation of ozonized O_2. The $[Co(OH_2)_6]^{3+}$ ion is best isolated as the sparingly soluble blue alum $CsCo(SO_4)_2 \cdot 12H_2O$, although this decomposes within hours on standing. Complex formation with, for example, bpy, NH_3, RNH_2 or $[CN]^-$ greatly stabilizes Co(III) as eqs. 21.81–21.84 illustrate.

$$Co^{3+}(aq) + e^- \rightleftharpoons Co^{2+}(aq) \qquad E^o = +1.92\,V \qquad (21.80)$$

$$[Co(bpy)_3]^{3+} + e^- \rightleftharpoons [Co(bpy)_3]^{2+} \qquad E^o = +0.31\,V \qquad (21.81)$$

$$[Co(NH_3)_6]^{3+} + e^- \rightleftharpoons [Co(NH_3)_6]^{2+} \qquad E^o = +0.11\,V \qquad (21.82)$$

$$[Co(en)_3]^{3+} + e^- \rightleftharpoons [Co(en)_3]^{2+} \qquad E^o = -0.26\,V \qquad (21.83)$$

$$[Co(CN)_6]^{3-} + H_2O + e^- \rightleftharpoons [Co(CN)_5(OH_2)]^{3-} + [CN]^- \qquad E^o = -0.83\,V \qquad (21.84)$$

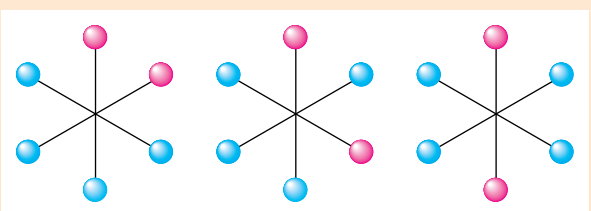
Replacing aqua by ammine ligands, for example, results in a dramatic change in E^o (eqs. 21.80 and 21.82) and shows that the overall stability constant of $[Co(NH_3)_6]^{3+}$ is $\approx 10^{30}$ greater than that of $[Co(NH_3)_6]^{2+}$. Much of this difference arises from LFSEs:

- Δ_{oct} for the ammine complex is greater than for the aqua complex in both oxidation states (Table 20.2);
- both Co(II) complexes are high-spin whereas both Co(III) complexes are low-spin (Table 20.3).

THEORY

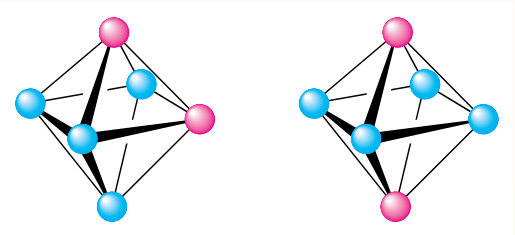
Box 21.6 Alfred Werner

Alfred Werner (working at the University of Zürich) was awarded the Nobel Prize for Chemistry in 1913 for his pioneering work that began to unravel the previous mysteries of the compounds formed between *d*-block metal ions and species such as H_2O, NH_3 and halide ions. A famous problem that led to Werner's theory of coordination concerns the fact that $CoCl_3$ forms a series of complexes with NH_3:



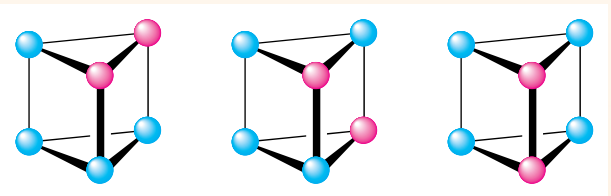
- violet $CoCl_3{\cdot}4NH_3$
- green $CoCl_3{\cdot}4NH_3$
- purple $CoCl_3{\cdot}5NH_3$
- yellow $CoCl_3{\cdot}6NH_3$

and that addition of $AgNO_3$ precipitates different amounts of AgCl per equivalent of Co(III). Thus, one equivalent of $CoCl_3{\cdot}6NH_3$ reacts with an excess of $AgNO_3$ to precipitate *three* equivalents of AgCl, one equivalent of $CoCl_3{\cdot}5NH_3$ precipitates *two* equivalents of AgCl, while one equivalent of either green or violet $CoCl_3{\cdot}4NH_3$ precipitates only *one* equivalent of AgCl. Werner realized that any Cl^- precipitated was free chloride ion and that any other chloride was held in the compound in some other way. The crucial conclusion that Werner drew was that in all these cobalt(III) compounds, the metal was intimately associated with six ligands (NH_3 molecules or Cl^- ions), and that only the remaining Cl^- ions behaved as 'normal' ions, free to react with Ag^+:



$$Ag^+(aq) + Cl^-(aq) \longrightarrow AgCl(s)$$

Werner referred to the oxidation state of the metal ion as its 'primary valence' and to what we now call the coordination number as its 'secondary valence'. The compounds $CoCl_3{\cdot}6NH_3$, $CoCl_3{\cdot}5NH_3$ and $CoCl_3{\cdot}4NH_3$ were thus reformulated as $[Co(NH_3)_6]Cl_3$, $[Co(NH_3)_5Cl]Cl_2$ and $[Co(NH_3)_4Cl_2]Cl$. This picture contrasted greatly with earlier ideas such as the 'chain theory' of Danish chemist Sophus Mads Jørgensen.



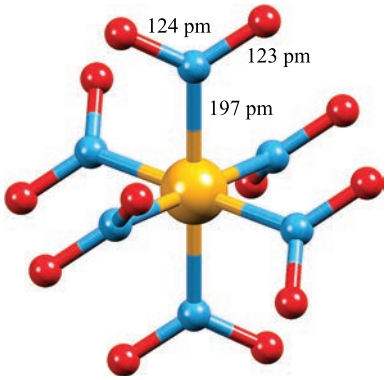
Werner's studies went on to show that the numbers of ions in solution (determined from conductivity measurements) were consistent with the formulations $[Co(NH_3)_6]^{3+}[Cl^-]_3$, $[Co(NH_3)_5Cl]^{2+}[Cl^-]_2$ and $[Co(NH_3)_4Cl_2]^+Cl^-$. The fact that $[Co(NH_3)_4Cl_2]Cl$ existed as two *isomers* (the green and violet forms) was a key to the puzzle of the shape of the $[Co(NH_3)_4Cl_2]^+$ complex. The possible *regular* arrangements for six ligands are planar hexagonal, octahedral and trigonal prismatic. There are three ways of arranging the ligands in $[Co(NH_3)_4Cl_2]^+$ in a hexagon:

There are two ways for an octahedral arrangement (what we now call *cis*- and *trans*-isomers):

and three for a trigonal prismatic arrangement:

From the fact that only two isomers of $[Co(NH_3)_4Cl_2]Cl$ had been isolated, Werner concluded that $[Co(NH_3)_4Cl_2]^+$ had an octahedral structure, and, by analogy, so did other complexes containing six ligands. Werner's work extended well beyond this one system and his contributions to the groundwork of the understanding of coordination chemistry were immense.

Alfred Werner (1866–1919).



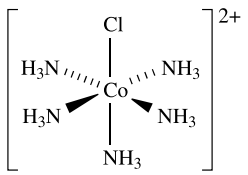


Fig. 21.30. The structure (X-ray diffraction) of $[Co(NO_2\text{-}N)_6]^{3-}$ in the salt $Li[Me_4N]_2[Co(NO_2\text{-}N)_6]$ [R. Bianchi *et al.* (1996) *Acta Crystallogr., Sect. B*, vol. 52, p. 471]. Colour code: Co, yellow; N, blue; O, red.

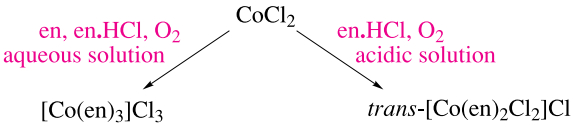
Cobalt(III) complexes played a fundamental role in an early understanding of coordination geometry and isomerism (see Box 21.6). Cobalt(III) has a d^6 configuration and complexes are usually low-spin octahedral and *kinetically inert* (see Section 26.2). The latter means that ligands are not labile and so preparative methods of Co(III) complexes usually involve oxidation of the corresponding or related Co(II) species, often *in situ*. For example:



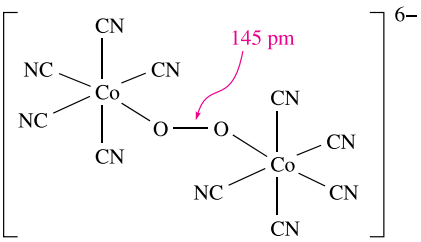
- oxidation by PbO_2 of aqueous Co^{2+} in the presence of excess oxalate gives $[Co(ox)_3]^{3-}$;
- action of excess $[NO_2]^-$ and acid on aqueous Co^{2+} gives $[Co(NO_2\text{-}N)_6]^{3-}$ (Fig. 21.30); some $[NO_2]^-$ acts as oxidant and NO is liberated;
- reaction between $Co(CN)_2$ and excess KCN in aqueous solution with *in situ* oxidation gives yellow $K_3[Co(CN)_6]$ (the intermediate Co(II) species is $[Co(CN)_5]^{3-}$ or $[Co(CN)_5(OH_2)]^{3-}$, see later);
- reaction of aqueous $CoCl_2$ with bpy and Br_2 gives $[Co(bpy)_3]^{3+}$;
- aerial oxidation of aqueous $CoCl_2$ in the presence of NH_3 and $[NH_4]Cl$ gives purple $[Co(NH_3)_5Cl]Cl_2$ containing cation **21.42**.

Co–N = 197 pm; Co–Cl 229 pm

(21.42)

The identity of the product may depend on reaction conditions and in the last example, if charcoal is added as a catalyst, the isolated complex is $[Co(NH_3)_6]Cl_3$ containing the $[Co(NH_3)_6]^{3+}$ ion. Similarly, the preparation of orange-red $[Co(en)_3]Cl_3$ requires careful control of reaction conditions (eq. 21.85).

(21.85)



The $[Co(en)_3]^{3+}$ ion is frequently used to precipitate large anions, and the kinetic inertness of the d^6 ion allows its enantiomers to be separated. The green *trans*-$[Co(en)_2Cl_2]Cl$ is isolated from reaction 21.85 as the salt *trans*-$[Co(en)_2Cl_2]Cl{\cdot}2H_2O{\cdot}HCl$ but this loses HCl on heating. It can be converted to the racemic red *cis*-$[Co(en)_2Cl_2]Cl$ by heating an aqueous solution and removing the solvent. Enantiomers of *cis*-$[Co(en)_2Cl_2]^+$ can be separated using a chiral anion such as (1*S*)- or (1*R*)-3-bromocamphor-8-sulfonate. In aqueous solution, one Cl^- ligand in $[Co(en)_2Cl_2]^+$ is replaced by H_2O to give $[Co(en)_2Cl(OH_2)]^{2+}$. Because ligand substitutions in Co(III) complexes are so slow, these species have been the subject of many kinetic studies (see Chapter 26).

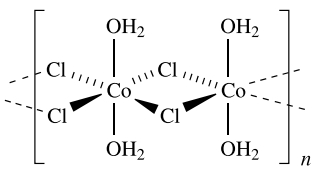
The $[Co(CN)_6]^{3-}$ ion is so stable that if a solution of $K_3[Co(CN)_5]$ containing excess KCN is heated, H_2 is evolved and $K_3[Co(CN)_6]$ is formed. In this reaction, the hydrido complex $[Co(CN)_5H]^{3-}$ is an intermediate. It can be obtained almost quantitatively (reversible reaction 21.86) and can be precipitated as $Cs_2Na[Co(CN)_5H]$.

$$2[Co^{II}(CN)_5]^{3-} + H_2 \rightleftharpoons 2[Co^{III}(CN)_5H]^{3-} \qquad (21.86)$$

The $[Co(CN)_5H]^{3-}$ ion is an effective homogeneous hydrogenation catalyst for alkenes. The process is summarized in eq. 21.87, with reaction 21.86 regenerating the catalyst.

$$\left.\begin{aligned} &[Co(CN)_5H]^{3-} + CH_2{=}CHX \\ &\qquad\qquad \longrightarrow [Co(CN)_5CH_2CH_2X]^{3-} \\ &[Co(CN)_5CH_2CH_2X]^{3-} + [Co(CN)_5H]^{3-} \\ &\qquad\qquad \longrightarrow CH_3CH_2X + 2[Co(CN)_5]^{3-} \end{aligned}\right\} \qquad (21.87)$$

(21.43)



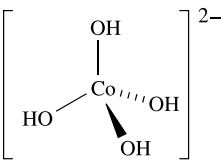
By aerial oxidation of $[Co^{II}(CN)_5]^{3-}$ in aqueous cyanide solution, it is possible to isolate the diamagnetic peroxido

complex $[(CN)_5Co^{III}OOCo^{III}(CN)_5]^{6-}$ (**21.43**) which can be precipitated as the brown potassium salt. Oxidation of $K_6[(CN)_5CoOOCo(CN)_5]$ using Br_2 leads to the paramagnetic, red $K_5[(CN)_5CoOOCo(CN)_5]$. The structure of $[(CN)_5CoOOCo(CN)_5]^{5-}$ resembles that of **21.43**, except that the O−O distance is 126 pm, indicating that oxidation takes place at the peroxido bridge and not at a metal centre. Thus, $[(CN)_5CoOOCo(CN)_5]^{5-}$ is a superoxido complex containing an $[O_2]^-$ bridge and retaining two Co(III) centres. The ammine complexes $[(H_3N)_5CoOOCo(NH_3)_5]^{4+}$ and $[(H_3N)_5CoOOCo(NH_3)_5]^{5+}$ (which have been isolated as the brown nitrate and green chloride salts respectively) are similar, containing peroxido and superoxido ligands respectively; the peroxido complex is stable in solution only in the presence of >2 M NH_3.

One of the few examples of a high-spin Co(III) complex is $[CoF_6]^{3-}$. The blue K^+ salt (obtained by heating $CoCl_2$, KF and F_2) has a magnetic moment of 5.63 μ_B.

Cobalt(II)

In contrast to Co(III), Co(II) forms many simple compounds and all four Co(II) halides are known. Reaction of anhydrous $CoCl_2$ with HF at 570 K gives sparingly soluble, pink CoF_2 which crystallizes with the rutile structure (see Fig. 6.24). Blue $CoCl_2$ is made by combination of the elements and has a $CdCl_2$ structure (see Section 6.11). It turns pink on exposure to moisture and readily forms hydrates. The dark pink hexahydrate is commercially available and is a common starting material in Co(II) chemistry. The di- and tetrahydrates can also be crystallized from aqueous solutions of $CoCl_2$. Crystalline $CoCl_2{\cdot}6H_2O$ contains *trans*-$[CoCl_2(OH_2)_4]$, connected to the extra water molecules through a hydrogen-bonded network. In contrast, the structure of $CoCl_2{\cdot}4H_2O$ consists of hydrogen-bonded *cis*-$[CoCl_2(OH_2)_4]$ molecules, while $CoCl_2{\cdot}2H_2O$ contains chains of edge-sharing octahedra (structure **21.44**).



(21.44)

In aqueous solutions of all forms of $CoCl_2$, the major species are $[Co(OH_2)_6]^{2+}$, $[CoCl(OH_2)_5]^+$ and $[CoCl_4]^{2-}$, with minor amounts of $[CoCl_2(OH_2)_4]$ and $[CoCl_3(OH_2)]^-$. Green $CoBr_2$ (made by heating Co and Br_2) is dimorphic, adopting either the $CdCl_2$ or CdI_2 structure (Fig. 6.25). It is water-soluble and can be crystallized as the purple-blue dihydrate or red hexahydrate. Heating Co metal with HI produces blue-black CoI_2 which adopts a CdI_2 layer structure. The red hexahydrate $CoI_2{\cdot}6H_2O$ can be crystallized from aqueous solutions. Both $CoBr_2{\cdot}6H_2O$ and $CoI_2{\cdot}6H_2O$ contain the octahedral $[Co(OH_2)_6]^{2+}$ ion in the solid state, as do a number of hydrates, e.g. $CoSO_4{\cdot}6H_2O$, $Co(NO_3)_2{\cdot}6H_2O$ and $Co(ClO_4)_2{\cdot}6H_2O$. Aqueous solutions of most simple Co(II) salts contain $[Co(OH_2)_6]^{2+}$ (see below).

Cobalt(II) oxide is an olive-green, insoluble solid but its colour may vary depending on its dispersion. It is best obtained by thermal decomposition of the carbonate or nitrate in the absence of air, and has the NaCl structure; CoO is used as a pigment in glasses and ceramics (see Box 21.7). When heated in air at 770 K, CoO converts to Co_3O_4.

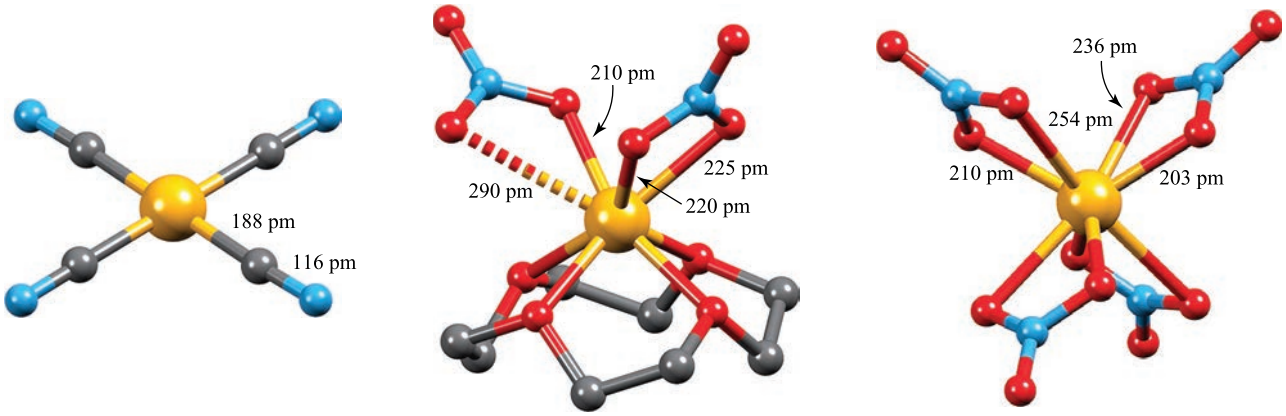
The sparingly soluble $Co(OH)_2$ may be pink or blue, with the pink form being the more stable. Freshly precipitated blue $Co(OH)_2$ turns pink on standing. The change in colour is presumably associated with a change in coordination about the Co(II) centre. Cobalt(II) hydroxide is amphoteric and dissolves in hot, concentrated alkalis to give salts of $[Co(OH)_4]^{2-}$ (**21.45**).

(21.45)

Whereas the coordination chemistry of Co^{3+} is essentially that of octahedral complexes, that of Co^{2+} is structurally variable since LFSEs for the d^7 configuration do not tend to favour a particular ligand arrangement. The variation in coordination geometries is shown in the following examples:

- linear: $[Co\{N(SiMe_3)_2\}_2]$;
- trigonal planar: $[Co\{N(SiMe_3)_2\}_2(PPh_3)]$, $[Co\{N(SiMe_3)_2\}_3]^-$;
- tetrahedral: $[Co(OH)_4]^{2-}$, $[CoCl_4]^{2-}$, $[CoBr_4]^{2-}$, $[CoI_4]^{2-}$, $[Co(NCS\text{-}N)_4]^{2-}$, $[Co(N_3)_4]^{2-}$, $[CoCl_3(NCMe)]^-$;
- square planar: $[Co(CN)_4]^{2-}$ (Fig. 21.31a), [Co(pc)] (H_2pc = **21.32**);
- trigonal bipyramidal: $[Co\{N(CH_2CH_2PPh_2)_3\}(SMe)]^+$;
- square-based pyramidal: $[Co(CN)_5]^{3-}$;
- octahedral: $[Co(OH_2)_6]^{2+}$, $[Co(NH_3)_6]^{2+}$, $[Co(en)_3]^{2+}$;
- pentagonal bipyramidal: $[Co(15\text{-crown-}5)L_2]^{2+}$ (L = H_2O or MeCN; see **21.50**);
- irregular 7-coordinate: $[Co(12\text{-crown-}4)(NO_3)_2]$ (Fig. 21.31b);
- dodecahedral: $[Co(NO_3\text{-}O,O')_4]^{2-}$ (Fig. 21.31c).

Aqueous solutions of simple salts usually contain $[Co(OH_2)_6]^{2+}$ but there is evidence for the existence of equilibrium 21.88, although $[Co(OH_2)_6]^{2+}$ is by far the



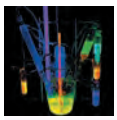


Fig. 21.31. The structures (X-ray diffraction) of (a) $[Co(CN)_4]^{2-}$ in the salt $[(Ph_3P)_2N]_2[Co(CN)_4]\cdot 4DMF$; there is also a *weak* interaction with a solvate molecule in an axial site [S.J. Carter *et al.* (1984) *J. Am. Chem. Soc.*, vol. 106, p. 4265]; (b) $[Co(12\text{-crown-}4)(NO_3)_2]$ [E.M. Holt *et al.* (1981) *Acta Crystallogr., Sect. B*, vol. 37, p. 1080]; and (c) $[Co(NO_3)_4]^{2-}$ in the $[Ph_4As]^+$ salt [J.G. Bergman *et al.* (1966) *Inorg. Chem.*, vol. 5, p. 1208]. Hydrogen atoms are omitted; colour code: Co, yellow; N, blue; C, grey; O, red.

dominant species; speciation in aqueous $CoCl_2$ was discussed earlier.

$$\underset{\text{octahedral}}{[Co(OH_2)_6]^{2+}} \rightleftharpoons \underset{\text{tetrahedral}}{[Co(OH_2)_4]^{2+}} + 2H_2O \qquad (21.88)$$

Whereas $[Co(OH_2)_6]^{2+}$ is a stable complex, $[Co(NH_3)_6]^{2+}$ is easily oxidized (eqs. 21.80 and 21.82). The same is true of amine complexes. $[Co(en)_3]^{2+}$ can be prepared from $[Co(OH_2)_6]^{2+}$ and en in an inert atmosphere and is usually made *in situ* when needed. The $[Co(bpy)_3]^{2+}$ ion is stable enough to be isolated in a number of salts, e.g. orange $[Co(bpy)_3]Cl_2\cdot 2H_2O\cdot EtOH$ which has been crystallographically characterized (Co−N = 213 pm). Among the stable complexes of Co(II) is tetrahedral $[CoX_4]^{2-}$ (X = Cl, Br, I). Addition of concentrated HCl to solutions of pink $[Co(OH_2)_6]^{2+}$ produces the intensely blue $[CoCl_4]^{2-}$. Many salts of $[CoCl_4]^{2-}$ are known; of note is Cs_3CoCl_5 which is actually $Cs_3[CoCl_4]Cl$ and does

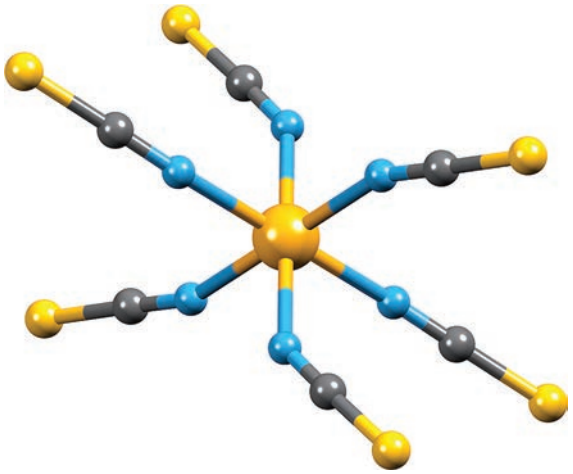
APPLICATIONS

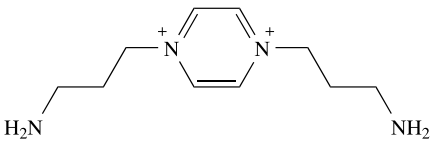
Box 21.7 Cobalt blues

Blue glass and ceramic glazes and enamels are in high demand for decorative wear, and the source of colour is very often a cobalt-based pigment. Cobalt(II) oxide is the form that is incorporated into the molten glass, but initial sources vary. Black Co_3O_4 is transformed in ≈93% yield to CoO at ≈1070 K. Purple $CoCO_3$ can also be used as the raw material but has lower conversion yields. Only very small amounts of the oxide are required to obtain a discernible blue pigment. Variations in colour are achieved by combining with other oxides, e.g. purple shades result if manganese oxide is added. Cobalt oxide is also used to counter the yellow colouring in glazes that arises from iron impurities. Blue pigmentation can also be obtained using $(Zr,V)SiO_4$ (see Section 28.5).

While the importance of cobalt-based pigments in ceramics is well established, it has also been shown that thin films of Co_3O_4 provide an effective coating for solar collectors that operate at high temperatures. The properties of black Co_3O_4 that make it suitable for this application are its high solar absorbance and low IR emittance.

Cobalt blue glass.





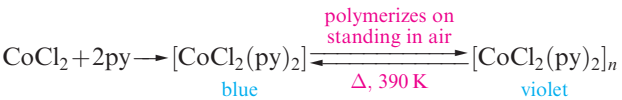


Fig. 21.32. The structure (X-ray diffraction) of the cobalt(II) isothiocyanato complex $[Co(NCS\text{-}N)_6]^{4-}$ in the salt with cation **21.46** [T.N. Mali *et al.* (1991) *J. Chem. Soc., Dalton Trans.*, p. 1161]. The Co–N–C bond angles are in the range 145–165°, and N–C–S bond angles are all close to 180°.

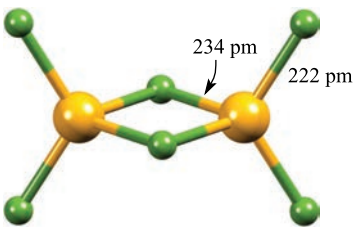
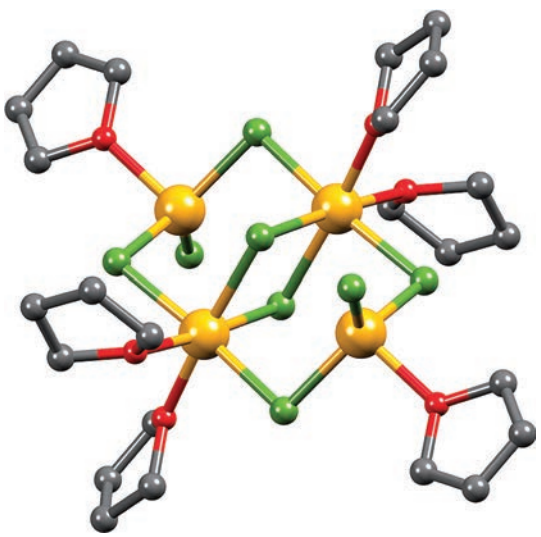
not contain $[CoCl_5]^{3-}$. Both $[Co(OH_2)_6]^{2+}$ and $[CoCl_4]^{2-}$, like most Co(II) complexes, are high-spin with magnetic moments higher than the spin-only value. Typically, for high-spin Co^{2+}, μ_{eff} lies in the range 4.3–5.2 μ_B for octahedral complexes and 4.2–4.8 μ_B for tetrahedral species. Among other tetrahedral complexes is $[Co(NCS\text{-}N)_4]^{2-}$, isolated in blue $[Me_4N]_2[Co(NCS\text{-}N)_4]$ ($\mu_{eff} = 4.40\,\mu_B$) and $K_2[Co(NCS\text{-}N)_4]\cdot 4H_2O$ ($\mu_{eff} = 4.38\,\mu_B$). The insoluble mercury(II) salt of $[Co(NCS\text{-}N)_4]^{2-}$ is the standard calibrant for magnetic susceptibility measurements. By using cation **21.46**, it has been possible to isolate a red salt of the octahedral $[Co(NCS\text{-}N)_6]^{4-}$ (Fig. 21.32).



(21.46)



The ability of chlorido ligands to bridge between two metal centres allows the formation of dinuclear species such as $[Co_2Cl_6]^{2-}$ (Fig. 21.33a), as well as higher nuclearity complexes such as polymer **21.44**. The complex $[CoCl_2(py)_2]$ exists in two modifications: one is monomer **21.47** containing a tetrahedral Co(II) centre, while the other contains edge-sharing octahedra in polymer **21.48**. Equation 21.89 summarizes the formation of $[CoCl_2(py)_2]$ and $[CoCl_2(py)_2]_n$. Similar tetrahedral–octahedral interconversions are seen for some Ni(II) complexes of type L_2NiX_2 where X^- has the propensity for bridge formation (see Section 21.11).

(21.89)

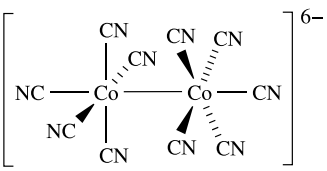
(b)

Fig. 21.33. The structures (X-ray diffraction) of (a) $[Co_2Cl_6]^{2-}$ in the salt $[Co(15\text{-crown-}5)(NCMe)_2][Co_2Cl_6]$; the cation is shown in structure **21.50** [O.K. Kireeva *et al.* (1992) *Polyhedron*, vol. 11, p. 1801] and (b) $[Co_4Cl_2(\mu\text{-}Cl)_6(THF)_6]$ [P. Sobota *et al.* (1993) *Polyhedron*, vol. 12, p. 613]. Hydrogen atoms are omitted; colour code: Co, yellow; Cl, green; C, grey; O, red.

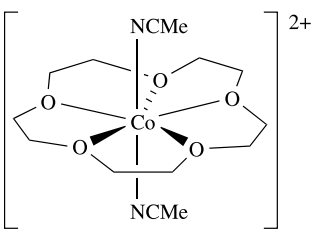
py = pyridine

(21.47)



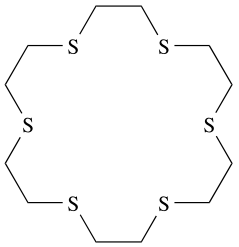
(21.48)

Heating a solution of $CoCl_2$ in THF at reflux produces the dark blue $[Co_4Cl_2(\mu\text{-}Cl)_6(THF)_6]$ in which bridging chlorido ligands support the tetranuclear framework (Fig. 21.33b). Two Co(II) centres are octahedrally coordinated and two are in 4-coordinate environments. At 300 K, the magnetic moment is 4.91 μ_B, typical of isolated high-spin Co(II) centres. On lowering the temperature to 4.2 K, the value of μ_{eff} increases to 7.1 μ_B. Such behaviour indicates ferromagnetic coupling between the metal centres which are able to communicate through the bridging ligands (see Section 20.10).

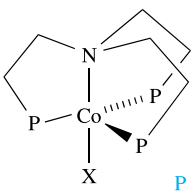


Chloride is just one example of a ligand which may coordinate to a metal centre in a terminal or bridging mode; other ligands may be equally versatile. For example, $[Co(acac)_2]$ is prepared from $CoCl_2$, Hacac and $Na[O_2CMe]$ in aqueous methanol. In the solid state, the blue anhydrous salt is tetrameric with a structure related to that of the trimer $[\{Ni(acac)_2\}_3]$ (see Fig. 21.34b).

Low-spin cyanido complexes of Co(II) provide examples of square-based pyramidal and square planar species. The addition of an excess of $[CN]^-$ to aqueous Co^{2+} yields $[Co(CN)_5]^{3-}$. That this is formed in preference to $[Co(CN)_6]^{4-}$ (which has not been isolated) can be understood by considering Fig. 20.15b. For the strong-field cyanido ligands, Δ_{oct} is large and for a hypothetical octahedral d^7 complex, partial occupancy of the e_g^* MOs would be unfavourable since it would impart significant *antibonding* character to the complex. The brown $K_3[Co(CN)_5]$ is paramagnetic, but a violet, diamagnetic salt $K_6[Co_2(CN)_{10}]$ has also been isolated. The $[Co_2(CN)_{10}]^{6-}$ ion, **21.49**, possesses a Co–Co single bond and a staggered conformation; it is isoelectronic and isostructural with $[Mn_2(CO)_{10}]$ (see Fig. 24.13). By using the large cation $[(Ph_3P)_2N]^+$, it has been possible to isolate a salt of the square planar complex $[Co(CN)_4]^{2-}$ (Fig. 21.31a). This is an unusual example of a square planar Co(II) species where the geometry is *not* imposed by the ligand. In complexes such as [Co(pc)], the phthalocyanine ligand (**21.32**) has a rigid framework and forces the coordination environment to be square planar.



(21.49)



The highest coordination numbers for Co(II) are 7 and 8. The effects of a coordinatively restricted macrocyclic ligand give rise to pentagonal bipyramidal structures for $[Co(15\text{-crown-}5)(NCMe)_2]^{2+}$ (**21.50**) and $[Co(15\text{-crown-}5)(OH_2)_2]^{2+}$. Larger macrocycles are more flexible, and in the complex $[Co(\mathbf{21.51})]^{2+}$, the S_6-donor set is octahedrally arranged. Figure 21.31b shows the solid state structure of $[Co(12\text{-crown-}4)(NO_3)_2]$ in which the Co(II) centre is 7-coordinate. In $[Co(NO_3)_4]^{2-}$, a dodecahedral arrangement of donor atoms is observed, although as Fig. 21.31c shows, each $[NO_3]^-$ ligand is bound asymmetrically with one oxygen donor interacting more strongly than the other. These nitrato complexes illustrate that caution is sometimes needed in interpreting coordination geometries and a further example concerns $[LCoX]^+$ complexes where L is the tripodal ligand $N(CH_2CH_2PPh_2)_3$. For $X^- = [MeS]^-$ or $[EtO(O)_2S]^-$, the Co(II) centre in $[LCoX]^+$ is 5-coordinate (**21.52**) with a Co–N distance of 213 or 217 pm, respectively. However, for $X^- = Cl^-$, Br^- or I^-, there is only a weak interaction between the nitrogen and metal centre (**21.53**) with Co···N in the range 268–273 pm. These data refer to the *solid state* and say nothing about solution species.

Self-study exercises

1. For octahedral Co^{2+}, what is the ground state term that arises from the $t_{2g}^5 e_g^2$ electronic configuration? [*Ans.* $^4T_{1g}$; see Fig. 20.20]

2. The electronic absorption spectrum of $[Co(OH_2)_6]^{2+}$ shows absorptions at 8100, 16 000 and 19 400 cm^{-1}. The middle band is assigned to the transition $^4T_{1g}(P) \leftarrow {}^4T_{1g}(F)$. Assign the remaining two transitions. [*Ans.* See Fig. 20.20]

3. For tetrahedral Co^{2+}, what is the ground state electronic configuration, and to what ground state term does this correspond? [*Ans.* $e^4t_2^3$; $^4A_2$]

4. Explain why, rather than using the spin-only formula, the magnetic moments of tetrahedral Co^{2+} complexes may be estimated using the following equation:

$$\mu_{eff} = 3.87\left(1 - \frac{4\lambda}{\Delta_{oct}}\right)$$

21.11 Group 10: nickel

The metal

The reactivity of Ni metal resembles that of Co (e.g. eq. 21.90). It is attacked by dilute mineral acids, made passive by concentrated HNO_3, and is resistant to aqueous alkalis.

$$M^{2+}(aq) + 2e^- \longrightarrow M(s) \qquad \begin{cases} M = Ni,\ E^o = -0.25\,V \\ M = Co,\ E^o = -0.28\,V \end{cases} \qquad (21.90)$$

The bulk metal is oxidized by air or steam only at high temperatures, but *Raney nickel* (see Section 21.2) is pyrophoric. Nickel reacts with F_2 to give a coherent coating of NiF_2 which prevents further attack; hence the use of nickel and its alloy *Monel metal* (68% Ni and 32% Cu) in apparatus for handling F_2 or xenon fluorides. With Cl_2, Br_2 and I_2, Ni(II) halides are formed. At elevated temperatures, Ni reacts with P, S and B and a range of different phosphide (see Section 15.6), sulfide and boride (see Section 13.10) phases are known.

Nickel(II) is far the most important oxidation state for the metal (Table 19.3). Low oxidation states are most common in organometallic species (Chapter 24), but other Ni(0) species include $[Ni(PF_3)_4]$ and $[Ni(CN)_4]^{4-}$. Yellow $K_4[Ni(CN)_4]$ is made by reduction of $K_2[Ni(CN)_4]$ in liquid NH_3 using excess K, but oxidizes immediately on exposure to air.

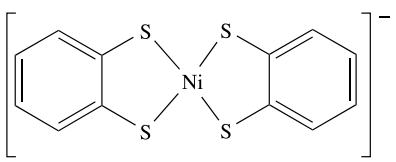
Nickel(IV) and nickel(III)

The formation of nickel(IV) requires the use of extremely strong oxidants. $K_2[NiF_6]$ is prepared from $NiCl_2$, F_2 and KCl. The salt $[Xe_2F_{11}]_2[NiF_6]$ (Fig. 18.5) is made from XeF_2, KrF_2 and NiF_2. Octahedral $[NiF_6]^{2-}$ is diamagnetic (low-spin d^6) and the red K^+ salt crystallizes with the $K_2[PtF_6]$ structure (see Mn(IV), Section 21.8). Above 620 K, $K_2[NiF_6]$ decomposes to $K_3[NiF_6]$. Salts of $[NiF_6]^{2-}$ are powerful oxidants, and $[NF_4]_2[NiF_6]$ has been used as an oxidizing agent in some solid propellants. It decomposes on heating according to eq. 21.91. Nickel(IV) fluoride can be prepared from $K_2[NiF_6]$ and BF_3 or AsF_5, but is unstable above 208 K (eq. 21.92).

$$[NF_4]_2[NiF_6] \xrightarrow{\text{anhydrous HF}} 2NF_3 + NiF_2 + 3F_2 \qquad (21.91)$$

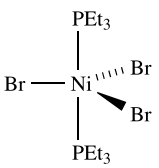
$$2NiF_4 \longrightarrow 2NiF_3 + F_2 \qquad (21.92)$$

Nickel(IV) is present in $KNiIO_6$, formally a salt of $[IO_6]^{5-}$ (see Section 17.9). This compound is formed by oxidation of $[Ni(OH_2)_6]^{2+}$ by $[S_2O_8]^{2-}$ in the presence of $[IO_4]^-$. The structure of $KNiIO_6$ can be considered as an hcp array of O atoms with K, Ni and I occupying octahedral sites.



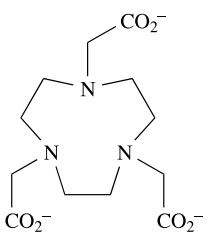
Impure NiF_3 is made by reaction 21.92. It is a black solid, and is a strong fluorinating agent, but decomposes when heated (eq. 21.93).

$$2NiF_3 \xrightarrow{\Delta} 2NiF_2 + F_2 \qquad (21.93)$$



Reaction of $NiCl_2$, KCl and F_2 produces violet $K_3[NiF_6]$. Octahedral $[NiF_6]^{3-}$ is low-spin d^7 ($t_{2g}^6e_g^1$) and shows the expected Jahn–Teller distortion.

The black hydrous oxide Ni(O)OH is obtained by alkaline hypochlorite oxidation of aqueous Ni(II) salts is used in NiCd rechargeable batteries (eq. 21.5). It is a strong oxidizing agent, liberating Cl_2 from hydrochloric acid. Mixed metal oxides of Ni(IV) include $BaNiO_3$ and $SrNiO_3$, which are isostructural and contain chains of face-sharing NiO_6 octahedra.



Nickel(III) is a very good oxidizing agent, but is stabilized by σ-donor ligands. Complexes include $[Ni(1,2\text{-}S_2C_6H_4)_2]^-$ (**21.54**) and $[NiBr_3(PEt_3)_2]$ (**21.55**). The latter has a magnetic moment of 1.72 μ_B, indicative of low-spin Ni(III); the solid compound is stable for only a few hours. Other ligands used to stabilize Ni(III) include porphyrins and aza-macrocycles. In [Ni(**21.56**)], each set of three *N*-donors and three *O*-donors is in a *fac*-arrangement about an octahedral Ni(III) centre.

(21.54)

(21.55)

(21.56)

Nickel(II)

Nickel(II) fluoride is made by fluorination of $NiCl_2$, and is a yellow solid with a rutile structure (Fig. 6.24). Both NiF_2 and its green tetrahydrate are commercially available. Anhydrous $NiCl_2$, $NiBr_2$ and NiI_2 are made by direct combination of the elements. $NiCl_2$ and NiI_2 adopt a $CdCl_2$ structure, while $NiBr_2$ has a CdI_2 structure (see Section 6.11). The chloride is a useful precursor in Ni(II) chemistry and can be purchased as the yellow anhydrous salt or green hydrate. The hexahydrate contains the $[Ni(OH_2)_6]^{2+}$ ion in the solid state, but the dihydrate (obtained by partial dehydration of $NiCl_2{\cdot}6H_2O$) has a polymeric structure analogous to **21.44**. Anhydrous $NiBr_2$ is yellow and can be crystallized as a number of hydrates. Black NiI_2 forms a green hexahydrate.

The water-insoluble, green NiO is obtained by thermal decomposition of $NiCO_3$ or $Ni(NO_3)_2$ and crystallizes with the NaCl structure. Thin amorphous films of NiO exhibiting electrochromic behaviour (see Box 22.3) may be deposited by CVD (*chemical vapour deposition*, see Section 28.6) starting from $[Ni(acac)_2]$. Nickel(II) oxide is antiferromagnetic ($T_N = 520\,K$), and its conducting properties are discussed in Section 28.2. Nickel(II) oxide is basic, reacting with acids, e.g. reaction 21.94.

$$NiO + H_2SO_4 \longrightarrow NiSO_4 + H_2O \qquad (21.94)$$

Oxidation of NiO by hypochlorite yields Ni(O)OH (see earlier). Aerial oxidation converts NiS to Ni(S)OH, a fact that explains why, although NiS is not precipitated in acidic solution, after exposure to air it is insoluble in dilute acid. Addition of $[OH]^-$ to aqueous solutions of Ni^{2+} precipitates green $Ni(OH)_2$ which has a CdI_2 structure (Fig. 6.25); it is used in NiCd batteries (eq. 21.5). Nickel(II) hydroxide is insoluble in aqueous NaOH except at very high hydroxide concentrations when it forms soluble $Na_2[Ni(OH)_4]$. $Ni(OH)_2$ is soluble in aqueous NH_3 with formation of $[Ni(NH_3)_6]^{2+}$. The pale green basic carbonate, $2NiCO_3{\cdot}3Ni(OH)_2{\cdot}4H_2O$, forms when Na_2CO_3 is added to aqueous Ni^{2+} and it is this carbonate that is usually bought commercially.

A range of coordination geometries is observed for nickel(II) complexes with coordination numbers from 4 to 6 being common. Octahedral and square planar geometries are most usual. Examples include:

- tetrahedral: $[NiCl_4]^{2-}$, $[NiBr_4]^{2-}$, $[Ni(NCS\text{-}N)_4]^{2-}$;
- square planar: $[Ni(CN)_4]^{2-}$, $[Ni(Hdmg)_2]$ (H_2dmg = dimethylglyoxime);
- trigonal bipyramidal: $[Ni(CN)_5]^{3-}$ (cation-dependent), $[NiCl\{N(CH_2CH_2NMe_2)_3\}]^+$;
- square-based pyramidal: $[Ni(CN)_5]^{3-}$ (cation-dependent);
- octahedral: $[Ni(OH_2)_6]^{2+}$, $[Ni(NH_3)_6]^{2+}$, $[Ni(bpy)_3]^{2+}$, $[Ni(en)_3]^{2+}$, $[Ni(NCS\text{-}N)_6]^{4-}$ (see Fig. 21.32 for Co analogue), $[NiF_6]^{4-}$.

Some structures are complicated by interconversions between square planar and tetrahedral, or square planar and octahedral coordination as we discuss later. In addition, the potential of some ligands to bridge between metal centres may cause ambiguity. For example, alkali metal salts of $[NiF_3]^-$, $[NiF_4]^{2-}$ and $[NiCl_3]^-$ crystallize with extended structures, whereas salts of $[NiCl_4]^{2-}$ and $[NiBr_4]^{2-}$ contain discrete tetrahedral anions. The compounds $KNiF_3$ and $CsNiF_3$ are obtained by cooling melts containing NiF_2 and MHF_2. $KNiF_3$ has a perovskite structure (Fig. 6.26) and is antiferromagnetic, while $CsNiF_3$ possesses chains of face-sharing NiF_6 octahedra and is ferrimagnetic. A similar chain structure is adopted by $CsNiCl_3$. The antiferromagnetic K_2NiF_4 contains layers of corner-sharing octahedral NiF_6 units (Fig. 21.34a) separated by K^+ ions.

In Section 21.10, we noted that $[Co(acac)_2]$ is tetrameric. Similarly, $[Ni(acac)_2]$ oligomerizes, forming trimers (Fig. 21.34b) in which $[acac]^-$ ligands are in chelating and bridging modes. Reaction of $[\{Ni(acac)_2\}_3]$ with aqueous $AgNO_3$ yields $Ag[Ni(acac)_3]$ containing the octahedral $[Ni(acac)_3]^-$ ion.

Solid, hydrated nickel(II) salts and their aqueous solutions usually contain green $[Ni(OH_2)_6]^{2+}$, the electronic absorption spectrum of which was shown in Fig. 20.21 with that of

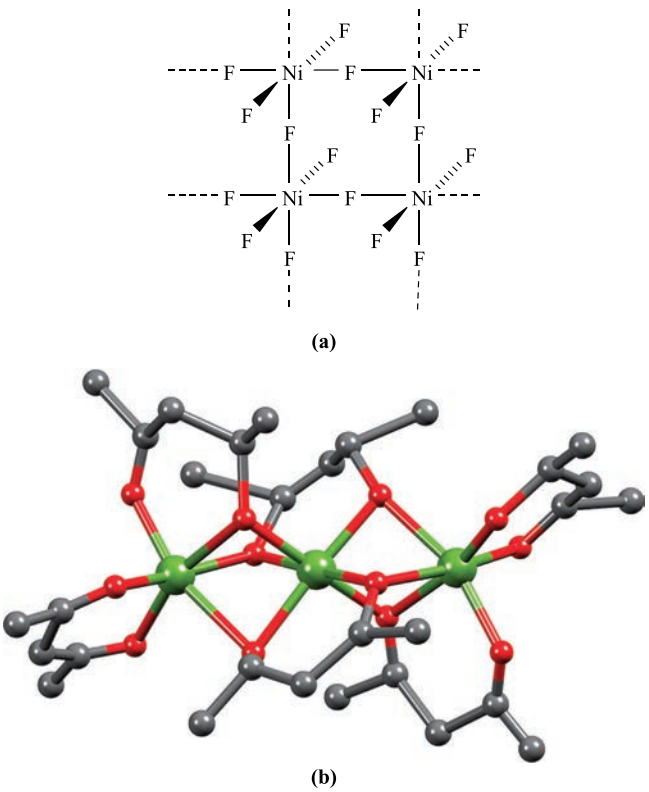


Fig. 21.34. (a) Representation of part of a layer of corner-sharing NiF_6 octahedra in K_2NiF_4. (b) The structure of $[\{Ni(acac)_2\}_3]$ (X-ray diffraction) with H atoms omitted [G.J. Bullen *et al.* (1965) *Inorg. Chem.*, vol. 4, p. 456]. Colour code: Ni, green; C, grey; O, red.

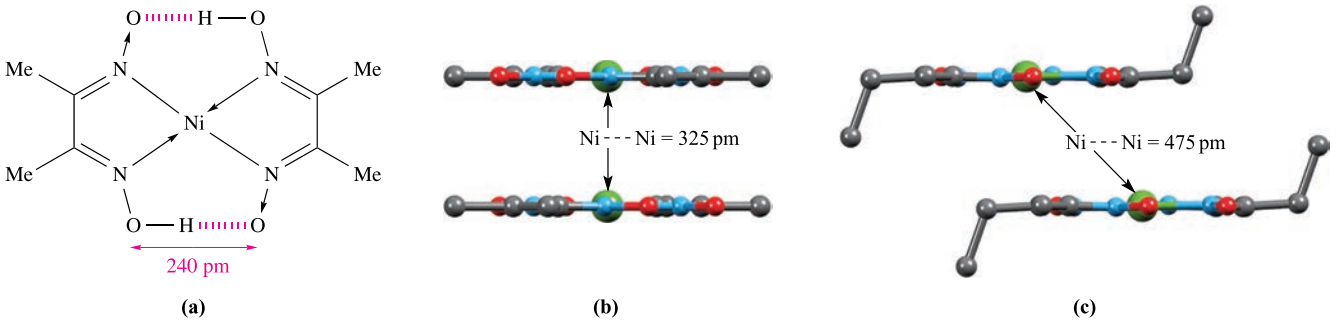

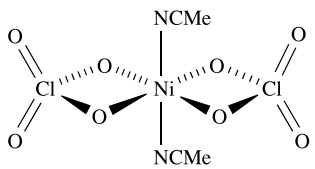

Fig. 21.35. (a) Representation of the square planar structure of bis(dimethylglyoximato)nickel(II), $[Ni(Hdmg)_2]$; (b) in the solid state, molecules of $[Ni(Hdmg)_2]$ pack in vertical columns with relatively short Ni····Ni distances [X-ray diffraction data: D.E. Williams *et al.* (1959) *J. Am. Chem. Soc.*, vol. 81, p. 755]; but (c) in bis(ethylmethylglyoximato)nickel(II) the packing is not so efficient [X-ray diffraction data: E. Frasson *et al.* (1960) *Acta Crystallogr.*, vol. 13, p. 893]. Hydrogen atoms are omitted; colour code: Ni, green; N, blue; O, red; C, grey.

$[Ni(NH_3)_6]^{2+}$. Salts of the latter are typically blue, giving violet solutions. In aqueous solution, $[Ni(NH_3)_6]^{2+}$ is stable only in the presence of excess NH_3 without which mixed aqua/ammine species such as $[Ni(NH_3)_4(OH_2)_2]^{2+}$ form. The violet chloride, bromide or perchlorate salts of $[Ni(en)_3]^{2+}$ are obtained as racemates, the cation being kinetically labile (see Section 26.2). The octahedral complexes *trans*-$[Ni(ClO_4\text{-}O,O')_2(NCMe)_2]$ (**21.57**) and *trans*-$[Ni(ClO_4\text{-}O)_2(py)_4]$ illustrate the ability of perchlorate ions to act as bidentate or monodentate ligands respectively. The latter complex is discussed again later.

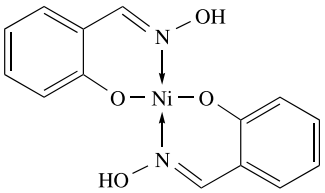
(21.57)

Magnetic moments of *octahedral* Ni(II) complexes are usually close to the spin-only value of 2.83 μ_B. In contrast, *tetrahedral* complexes possess magnetic moments $\approx 4\,\mu_B$ due to orbital contributions (see Section 20.10), and *square planar* complexes such as $[Ni(CN)_4]^{2-}$ (eq. 21.95) are *diamagnetic*. These differences in magnetic moments are invaluable in providing information about the coordination geometry in a Ni(II) complex.

$$[Ni(OH_2)_6]^{2+} + 4[CN]^- \longrightarrow \underset{\text{yellow}}{[Ni(CN)_4]^{2-}} + 6H_2O \qquad (21.95)$$

The red square planar complex bis(dimethylglyoximato) nickel(II), $[Ni(Hdmg)_2]$[†] (Fig. 21.35a), is used for gravimetric determination of nickel; Ni(II) is precipitated along with Pd(II) when the ligand H_2dmg in weakly ammoniacal solution is used as a reagent. The specificity for Ni^{2+} arises from the low solubility of $[Ni(Hdmg)_2]$, *not* its high stability constant. All complexes of type $[M(Hdmg)_2]$, where M^{2+} is a first row *d*-block metal ion, have stability constants of the same order. The low solubility of $[Ni(Hdmg)_2]$ can be rationalized in terms of its solid state structure. Strong hydrogen bonding links the two ligands (Fig. 21.35a) and plays a role in determining a square planar structure. As a consequence of the molecular framework being planar, molecules in the crystalline solid are able to assemble into 1-dimensional stacks such that intermolecular Ni····Ni separations are 325 pm (Fig. 21.35b; but contrast $[Cu(Hdmg)_2]$ in Section 21.12). Bis(ethylmethylglyoximato)nickel(II) has a related structure, but the bulkier ligand forces the molecules to pack less efficiently (Fig. 21.35c). The fact that the latter complex is more soluble than $[Ni(Hdmg)_2]$ supports a structure–solubility relationship.

For some Ni(II) complexes, there is only a small energy difference between structure types. In Section 19.7, we stated that *both* trigonal bipyramidal and square-based pyramidal $[Ni(CN)_5]^{3-}$ ions (eq. 21.96) are present in crystals of $[Cr(en)_3][Ni(CN)_5]\cdot 1.5H_2O$. In the anhydrous salt, however, the anions are square-based pyramidal. It is impossible to give a simple interpretation of these observations which may be attributed to a subtle balance of steric and electronic effects.



$$[Ni(CN)_4]^{2-} + \text{excess } [CN]^- \longrightarrow [Ni(CN)_5]^{3-} \qquad (21.96)$$

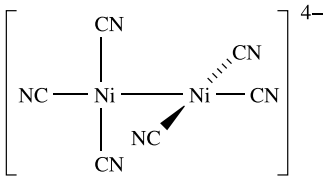
The preference between different 4- and 6-coordination geometries for a number of Ni(II) systems is often marginal and examples are as follows.

[†] For an introduction to the use of $[Ni(Hdmg)_2]$ and related complexes in template syntheses of macrocycles, see: E.C. Constable (1999) *Coordination Chemistry of Macrocyclic Compounds*, OUP, Oxford (Chapter 4).

Octahedral-planar

- $[Ni(ClO_4)_2(py)_4]$ exists in a blue, paramagnetic *trans*-octahedral form and as a yellow diamagnetic salt containing square planar $[Ni(py)_4]^{2+}$ ions.
- Salicylaldoxime ($2\text{-}HOC_6H_4CH{=}NOH$) reacts with Ni(II) to give colourless crystals of the square planar complex **21.58**, but on dissolving in pyridine, a green solution of the paramagnetic octahedral $[Ni(2\text{-}OC_6H_4CH{=}NOH)_2(py)_2]$ forms.

(21.58)



Tetrahedral-planar

- Halides of type NiL_2X_2 are generally planar when L = trialkylphosphane, but tetrahedral when L is triarylphosphane; when X = Br and L = $PEtPh_2$ or $P(CH_2Ph)Ph_2$, both forms are known (scheme 21.97).

$$\begin{array}{c} NiBr_2 + PEtPh_2 \\ \downarrow \text{ethanol} \\ [NiBr_2(PEtPh_2)_2] \\ \text{green, tetrahedral} \\ \mu_{eff} = 3.18\,\mu_B \\ \text{slow isomerization at 298 K} \rightleftharpoons \text{dissolve in } CS_2 \\ [NiBr_2(PEtPh_2)_2] \\ \text{brown, square planar} \\ \text{diamagnetic} \end{array} \qquad (21.97)$$

Nickel(I)

Nickel(I) complexes are rather rare, but this oxidation state is thought to be involved in the catalytic function of nickel-containing enzymes such as [NiFe]-hydrogenase (see Fig. 29.19). Dark red $K_4[Ni_2(CN)_6]$ can be prepared by Na amalgam reduction of $K_2[Ni(CN)_4]$. It is diamagnetic and the anion has structure **21.59** in which the $Ni(CN)_3$ units are mutually perpendicular. The reaction of $K_4[Ni_2(CN)_6]$ with water liberates H_2 and forms $K_2[Ni(CN)_4]$.

(21.59)

Self-study exercises

1. Sketch and label an Orgel diagram for an octahedral d^8 ion. Include the multiplicities in the term symbols.
[*Ans.* See Fig. 20.20; multiplicity = 3]

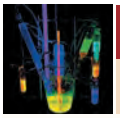
2. Why are tetrahedral Ni(II) complexes paramagnetic whereas square planar complexes are diamagnetic? Give an example of each type of complex.
[*Ans.* See worked example 20.1]

3. Draw the structure of H_2dmg. Explain how the presence of intramolecular hydrogen bonding in $[Ni(Hdmg)_2]$ results in a preference for a square planar over tetrahedral structure.
[*Ans.* See Fig. 21.35a; O–H···O not possible in tetrahedral structure]

21.12 Group 11: copper

The metal

Copper is the least reactive of the first row metals. It is not attacked by non-oxidizing acids in the absence of air (eq. 21.98), but it reacts with hot concentrated sulfuric acid (eq. 21.99) and with HNO_3 of all concentrations (eqs. 15.118 and 15.119).



$$Cu^{2+} + 2e^- \rightleftharpoons Cu \qquad E^o = +0.34\,V \qquad (21.98)$$

$$Cu + 2H_2SO_4 \xrightarrow{\text{conc}} SO_2 + CuSO_4 + 2H_2O \qquad (21.99)$$

In the presence of air, Cu reacts with many dilute acids (the green patina on roofs in cities is basic copper sulfate) and also dissolves in aqueous NH_3 to give $[Cu(NH_3)_4]^{2+}$. When heated strongly, Cu combines with O_2 (eq. 21.100).

$$2Cu + O_2 \xrightarrow{\Delta} 2CuO \xrightarrow{>1300\,K} Cu_2O + \tfrac{1}{2}O_2 \qquad (21.100)$$

Heating Cu with F_2, Cl_2 or Br_2 produces the corresponding dihalide.

APPLICATIONS

Box 21.8 Copper: from antiquity to present day

5000–4000 BC	Copper metal used in tools and utensils; heat is used to make the metal malleable.
4000–2000 BC	In Egypt, copper is cast into specific shapes; bronze (an alloy with tin) is made; first copper mining in Asia Minor, China and North America.
2000 BC–0	Bronze weapons are introduced; bronze is increasingly used in decorative pieces.
0–AD 200	Brass (an alloy of copper and zinc) is developed.
AD 200–1800	A period of little progress.
1800–1900	Deposits of copper ores in Michigan, US, are mined, increasing dramatically the US output and availability of the metal. The presence of copper in plants and animals is first discovered.
1900–1960	The electrical conducting properties of copper are discovered and, as a result, many new applications.
1960 onwards	North American production continues to increase but the world market also reaps the benefits of mining in many other countries, in particular Chile; copper recycling becomes important. From mid-1980s, materials such as $YBa_2Cu_3O_{7-x}$ are discovered to be high-temperature superconductors (see Section 28.4).

Table adapted from: R.R. Conry and K.D. Karlin (1994) 'Copper: inorganic & coordination chemistry' in *Encyclopedia of Inorganic Chemistry*, ed. R.B. King, Wiley, Chichester, vol. 2, p. 829.

Copper beer-brewing tanks at the Heineken brewery museum in Amsterdam, the Netherlands.

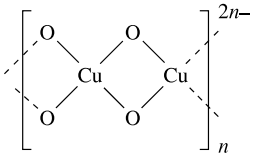
Copper is the only first row *d*-block metal to exhibit a *stable* +1 oxidation state. In aqueous solution, Cu(I) is unstable by a relatively small margin with respect to Cu(II) and the metal (eqs. 21.98, 21.101 and 21.102).

$$Cu^+ + e^- \rightleftharpoons Cu \qquad E^o = +0.52\,V \qquad (21.101)$$

$$Cu^{2+} + e^- \rightleftharpoons Cu^+ \qquad E^o = +0.15\,V \qquad (21.102)$$

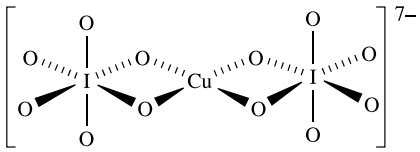
This disproportionation is usually fast, but when aqueous Cu(I) is prepared by reduction of Cu(II) with V(II) or Cr(II), decomposition in the absence of air takes several hours. Copper(I) can be stabilized by the formation of an insoluble compound (e.g. CuCl) or a complex (e.g. $[Cu(CN)_4]^{3-}$) (see Section 8.4). The stable oxidation state may depend on reaction conditions: e.g. when Cu powder reacts with aqueous $AgNO_3$, reaction 21.103 takes place, but in MeCN reaction 21.104 occurs.

$$Cu + 2Ag^+ \xrightarrow{\text{aq. solution}} Cu^{2+} + 2Ag \qquad (21.103)$$



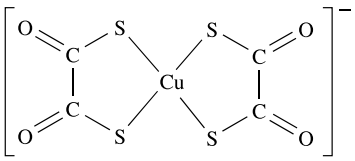
$$Cu + [Ag(NCMe)_4]^+ \longrightarrow [Cu(NCMe)_4]^+ + Ag \qquad (21.104)$$

Copper(0) is rarely stabilized in compounds. The unstable $Cu_2(CO)_6$ has been isolated in a matrix at low temperature. The highest oxidation state attained for copper is +4.



Copper(IV) and copper(III)

Copper(IV) is rare. Although CuF_4 is unknown, the salts $Cs_2[CuF_6]$ and $Rb_2[CuF_6]$ containing the $[CuF_6]^{2-}$ ion have been prepared; the reaction of the copper(II) compound $CsCuCl_3$ with F_2 at 520 K leads to $Cs_2[CuF_6]$. The $[CuF_6]^{2-}$ ion is low-spin d^7 and has a Jahn–Teller distorted octahedral structure. Copper(IV) oxide has been prepared in a matrix by vaporizing the metal and co-depositing it with O_2. Spectroscopic data are consistent with a linear structure, O=Cu=O.



High-pressure fluorination of a mixture of CsCl and $CuCl_2$ gives $Cs_3[CuF_6]$ containing Cu(III). Green $K_3[CuF_6]$ is similarly prepared and has a magnetic moment of 3.01 μ_B indicative of octahedral Cu(III). The diamagnetic compounds $K[CuO_2]$ and $K_7[Cu(IO_6)_2]$ contain square planar Cu(III) (structures **21.60** and **21.61**).

(21.60)

(21.61)

(21.62)

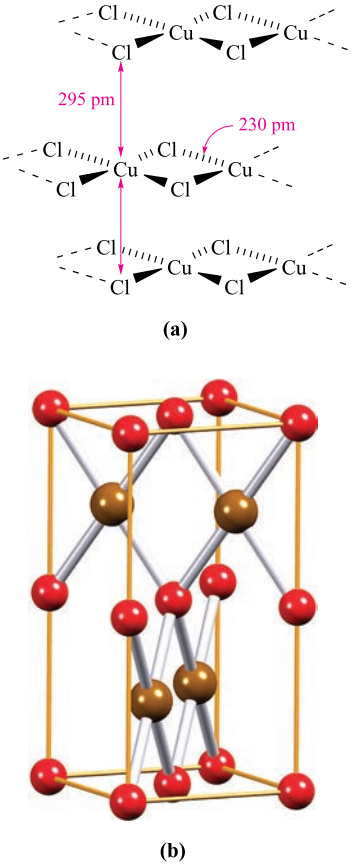
Ligands that stabilize Cu(III) include 1,2-dithiooxalate. Reaction of $[C_2O_2S_2]^{2-}$ with $CuCl_2$ produces $[Cu^{II}(C_2O_2S_2)_2]^{2-}$, oxidation of which by $FeCl_3$ gives $[Cu^{III}(C_2O_2S_2)_2]^-$ (**21.62**). This readily undergoes a photoinduced two-electron intramolecular transfer, cleaving one of the C–C bonds and releasing two equivalents of SCO.

Probably the most important use of Cu(III) species is in high-temperature superconductors such as $YBa_2Cu_3O_{7-x}$ ($x \approx 0.1$) which are discussed in Chapter 28.

Copper(II)

Cupric is the old name for copper(II). Throughout copper(II) chemistry, Jahn–Teller distortions are observed as predicted for an octahedral d^9 ion, although the degree of distortion varies considerably.

White CuF_2 (made, like $CuCl_2$ and $CuBr_2$, from the elements) has a distorted rutile structure (Fig. 6.24) with elongated CuF_6-units (four Cu–F = 193 pm, two Cu–F = 227 pm). In moist air, CuF_2 turns blue as it forms the dihydrate. Copper(II) chloride forms yellow or brown deliquescent crystals and forms the green-blue $CuCl_2{\cdot}2H_2O$ on standing in moist air. The structure of anhydrous $CuCl_2$ (Fig. 21.36a) consists of chains so stacked that each Cu(II) centre is in a distorted octahedral site. In solid $CuCl_2{\cdot}2H_2O$ (**21.63**), *trans*-square planar molecules are arranged so that there are weak intermolecular Cu···Cl interactions. Above



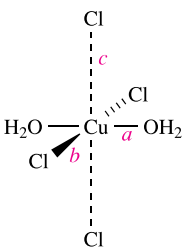


Fig. 21.36. (a) Representation of the solid state structure of $CuCl_2$ in which chains stack to place each Cu(II) centre in a distorted octahedral environment; (b) the *cooperite* (PtS) structure adopted by CuO with Cu^{2+} (square planar) and O^{2-} (distorted tetrahedral) centres shown in brown and red respectively. The edges of the unit cell are defined by the yellow lines.

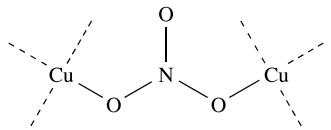
570 K, $CuCl_2$ decomposes to CuCl and Cl_2. Black $CuBr_2$ has a distorted CdI_2 structure (Fig. 6.25). Copper(II) iodide is not known; I^- reduces Cu(II) to Cu(I), and therefore CuI forms rather than CuI_2 if Cu^{2+} is combined with I^-.

$a = 193$; $b = 228$; $c = 291$ pm

(21.63)

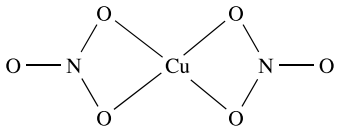
Black CuO is made by heating the elements (eq. 21.100) or by thermal decomposition of solid $Cu(NO_3)_2$ or $CuCO_3$ (eq. 21.105). Its structure consists of square planar CuO_4

units linked by bridging O atoms into chains; these lie in a criss-cross arrangement so that each O atom is in a distorted tetrahedral site. Figure 21.36b shows a unit cell of this lattice which is an example of the *cooperite* (PtS) structure type. Below 225 K, CuO is antiferromagnetic. One use of CuO is as a black pigment in ceramics.



$$CuCO_3 \xrightarrow{\Delta} CuO + CO_2 \qquad (21.105)$$

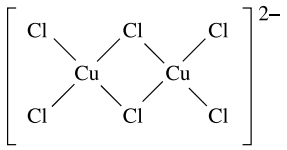
Blue $Cu(OH)_2$ precipitates when $[OH]^-$ is added to aqueous solutions of Cu^{2+}. $Cu(OH)_2$ dissolves in acids and also in concentrated aqueous alkalis in which an ill-defined hydroxido species is formed. Copper(II) hydroxide is readily dehydrated to CuO.



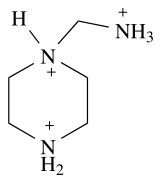
Aqueous solutions of Cu^{2+} contain the $[Cu(OH_2)_6]^{2+}$ ion and this has been isolated in several salts including $Cu(ClO_4)_2{\cdot}6H_2O$ and the Tutton salt $[NH_4]_2Cu[SO_4]_2{\cdot}6H_2O$ (see Section 21.6). The solid state structures of both salts reveal distortions of $[Cu(OH_2)_6]^{2+}$ such that there are *three* pairs of Cu−O distances, e.g. in $Cu(ClO_4)_2{\cdot}6H_2O$ the Cu−O bond lengths are 209, 216 and 228 pm. Crystals of the blue hydrated sulfate $CuSO_4{\cdot}5H_2O$ (*blue vitriol*) contain square planar $[Cu(OH_2)_4]^{2+}$ units with two sulfate O atoms completing the remaining sites in an elongated octahedral coordination sphere. The solid state structure consists of a hydrogen-bonded assembly which incorporates the non-coordinated H_2O molecules. The pentahydrate loses water in stages on heating (eq. 21.106 and self-study exercise 2 after worked example 4.2) and finally forms the white, hygroscopic anhydrous $CuSO_4$.

$$CuSO_4{\cdot}5H_2O \xrightarrow[-2H_2O]{300\,K} CuSO_4{\cdot}3H_2O \xrightarrow[-2H_2O]{380\,K} CuSO_4{\cdot}H_2O \xrightarrow[-H_2O]{520\,K} CuSO_4 \qquad (21.106)$$

Copper(II) sulfate and nitrate are commercially available and, in addition to uses as precursors in Cu(II) chemistry, they are used as fungicides, e.g. *Bordeaux mixture* contains $CuSO_4$ and $Ca(OH)_2$ and when added to water forms a basic copper(II) sulfate which acts as the antifungal agent. Copper(II) nitrate is widely used in the dyeing and printing industries. It forms hydrates $Cu(NO_3)_2{\cdot}xH_2O$ where $x = 2.5$, 3 or 6. The blue hexahydrate readily loses water at 300 K to give green $Cu(NO_3)_2{\cdot}3H_2O$. Anhydrous $Cu(NO_3)_2$ is made from Cu and N_2O_4. The solid state structure of α-$Cu(NO_3)_2$ consists of Cu(II) centres linked into an infinite lattice by bridging $[NO_3]^-$ ligands (**21.64**). At 423 K, the solid volatilizes *in vacuo* giving molecular $Cu(NO_3)_2$ (**21.65**).



(21.64)



(21.65)

The salt $Cu(O_2CMe)_2{\cdot}H_2O$ is dimeric and is structurally similar to $[Cr_2(OH_2)_2(\mu\text{-}O_2CMe)_4]$ (see Fig. 21.16 for structure type) but lacks the strong metal–metal bonding. The distance between the two Cu centres of 264 pm is greater than in bulk Cu metal (256 pm). The magnetic moment of 1.4 μ_B per Cu(II) centre (i.e. less than μ(spin-only) of 1.73 μ_B) suggests that in $[Cu_2(OH_2)_2(\mu\text{-}O_2CMe)_4]$ there is only weak antiferromagnetic coupling between the unpaired electrons. On cooling, the magnetic moment decreases. These observations can be explained in terms of the two unpaired electrons giving a singlet ground state ($S = 0$) and a low-lying triplet excited state ($S = 1$) which is thermally populated at 298 K but which becomes less populated as the temperature is lowered (see Section 20.6 for singlet and triplet states).

Vast numbers of copper(II) complexes are known and this discussion covers only simple species. Jahn–Teller distortions are generally observed (d^9 configuration). Halido complexes include $[CuCl_3]^-$, $[CuCl_4]^{2-}$ and $[CuCl_5]^{3-}$ but the solid state structures of species possessing these stoichiometries are highly dependent on the counter-ions. For example, $[Ph_4P][CuCl_3]$ contains dimers (**21.66**), whereas $K[CuCl_3]$ and $[Me_3NH]_3[CuCl_3][CuCl_4]$ contain chains of distorted, face-sharing octahedra (Fig. 21.37a). The latter salt also contains discrete tetrahedral $[CuCl_4]^{2-}$ ions. $[PhCH_2CH_2NH_2Me]_2[CuCl_4]$ crystallizes in two forms, one with distorted tetrahedral and the other with square planar $[CuCl_4]^{2-}$ ions (Figs. 21.37b and 21.37c). The salt $[NH_4]_2[CuCl_4]$ has a polymeric structure containing distorted octahedral Cu(II) centres. Dimeric $[Cu_2Cl_8]^{4-}$ (with edge-sharing trigonal bipyramidal Cu(II) centres) may be stabilized by very bulky cations, e.g. $[M(en)_3]_2[Cu_2Cl_8]Cl_2$ (M = Co, Rh or Ir, Fig. 21.37d). The $[CuCl_5]^{3-}$ ion is trigonal bipyramidal in the Cs^+ and $[Me_3NH]^+$ salts, but in **[21.67]**$[CuCl_5]$, it is square-based pyramidal.

(21.66)

(21.67)

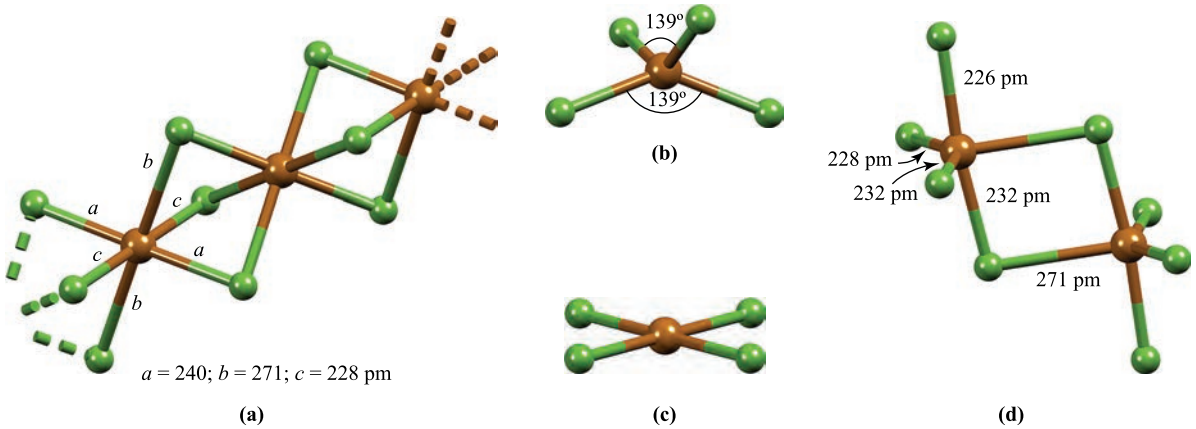


Fig. 21.37. The structures (X-ray diffraction) of (a) polymeric $[CuCl_3]_n^{n-}$ in the salt $[Me_3NH]_3[CuCl_3][CuCl_4]$; the $[CuCl_4]^{2-}$ ion in this salt is tetrahedral [R.M. Clay *et al.* (1973) *J. Chem. Soc., Dalton Trans.*, p. 595], (b) the distorted tetrahedral $[CuCl_4]^{2-}$ ion in one form of $[PhCH_2CH_2NH_2Me][CuCl_4]$ (four Cl–Cu–Cl angles are 97° and two are 139°) [R.L. Harlow *et al.* (1975) *Inorg. Chem.*, vol. 14, p. 1768], (c) the square planar $[CuCl_4]^{2-}$ ion in the second form of $[PhCH_2CH_2NH_2Me][CuCl_4]$ (Cl–Cu–Cl = 90°) [R.L. Harlow *et al.* (1974) *Inorg. Chem.*, vol. 13, p. 2106] and (d) the $[Cu_2Cl_8]^{4-}$ ion in the salt $[Rh(en)_3]_2[Cu_2Cl_8]Cl_2{\cdot}2H_2O$ [S.K. Hoffmann *et al.* (1985) *Inorg. Chem.*, vol. 24, p. 1194]. Colour code: Cu, brown; Cl, green.

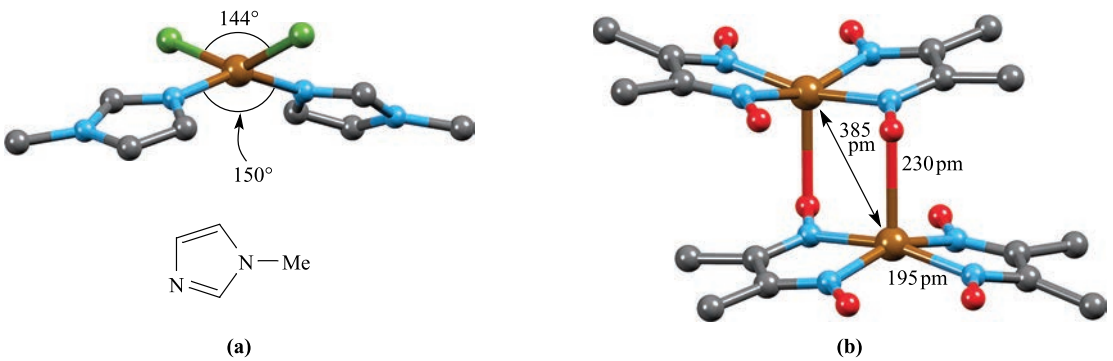
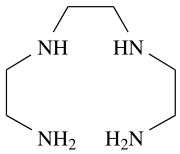
Complexes containing *N*- and *O*-donor ligands are very common, and coordination numbers of 4, 5 and 6 predominate. We have already mentioned the aqua species $[Cu(OH_2)_6]^{2+}$ and $[Cu(OH_2)_4]^{2+}$. When NH_3 is added to aqueous Cu^{2+}, only four aqua ligands in $[Cu(OH_2)_6]^{2+}$ are replaced (see Section 20.12), but salts of $[Cu(NH_3)_6]^{2+}$ can be made in liquid NH_3. $[Cu(en)_3]^{2+}$ is formed in very concentrated aqueous solutions of 1,2-ethanediamine. Deep blue aqueous $[Cu(NH_3)_4](OH)_2$ (formed when $Cu(OH)_2$ is dissolved in aqueous NH_3) has the remarkable property of dissolving cellulose, and if the resulting solution is squirted into acid, the synthetic fibre *rayon* is produced as cellulose is precipitated. The reaction is historically important as a means of producing rayon.

Further examples of complexes with *N*- and *O*-donor ligands are:

- tetrahedral (flattened): $[Cu(NCS\text{-}N)_4]^{2-}$; $[CuCl_2(Meim)_2]$ (Fig. 21.38a);
- square planar: $[Cu(ox)_2]^{2-}$; *cis*- and *trans*-$[Cu(H_2NCH_2CO_2)_2]$; $[Cu(en)(NO_3\text{-}O)_2]$;
- trigonal bipyramidal: $[Cu(NO_3\text{-}O)_2(py)_3]$ (equatorial nitrates); $[Cu(CN)\{N(CH_2CH_2NH_2)_3\}]^+$ (axial cyanide);
- square-based pyramidal: $[Cu(NCS\text{-}N)(\mathbf{21.68})]^+$ (ligand **21.68** is tetradentate in the basal sites); $[Cu(OH_2)(phen)(\mathbf{21.69})]$ (apical H_2O), $[CuCl_2(OH_2)_2(MeOH)]$ (apical MeOH, *trans* Cl in the basal sites);





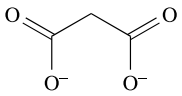


Fig. 21.38. (a) The flattened tetrahedral structure of $[CuCl_2(Meim)_2]$ (determined by X-ray diffraction) and a schematic representation of the *N*-methylimidazole (Meim) ligand [J.A.C. van Ooijen *et al.* (1979) *J. Chem. Soc., Dalton Trans.*, p. 1183]; (b) $[Cu(Hdmg)_2]$ forms dimers in the solid state, in contrast to $[Ni(Hdmg)_2]$ (Fig. 21.35); structure determined by X-ray diffraction [A. Vaciago *et al.* (1970) *J. Chem. Soc. A*, p. 218]. Colour code: Cu, brown; N, blue; Cl, green; O, red; C, grey.

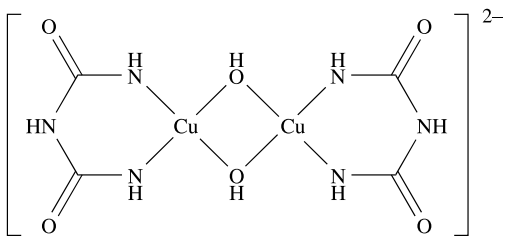
- octahedral: $[Cu(HOCH_2CH_2OH)_3]^{2+}$; $[Cu(bpy)_3]^{2+}$; $[Cu(phen)_3]^{2+}$; *trans*-$[CuCl(OH_2)(en)_2]^+$; *trans*-$[Cu(BF_4)_2(en)_2]$ (see p. 793).



(21.68)

(21.69)

Jahn–Teller distortions are apparent in many complexes. In $[Cu(bpy)_3]^{2+}$, the distortion is particularly severe with equatorial Cu−N bonds of 203 pm, and axial distances of 223 and 245 pm. The complex *trans*-$[Cu(BF_4)_2(en)_2]$ illustrates the ability of $[BF_4]^-$ to act as a monodentate ligand; the long Cu−F bonds (256 pm) indicate rather weak Cu−F interactions. In Section 21.11, we described the structure of $[Ni(Hdmg)_2]$; $[Cu(Hdmg)_2]$ also exhibits hydrogen bonding between the ligands but, in the solid state, molecules are associated in *pairs* with the coordination sphere being square-based pyramidal (Fig. 21.38b).

A practical application of the coordination of *N*,*O*-donors to Cu(II) is the *biuret test* for peptides and proteins. Compounds containing peptide linkages form a violet complex ($\lambda_{max} = 540$ nm) when treated in NaOH solution with a few drops of aqueous $CuSO_4$. The general form of the complex can be represented by that of **21.70**, in which the ligand is the doubly deprotonated form of biuret, $H_2NC(O)NHC(O)NH_2$.

(21.70)

When a Cu(II) salt is treated with excess KCN at room temperature, cyanogen is evolved and the copper reduced (eq. 21.107). However, in aqueous methanol at low temperatures, violet square planar $[Cu(CN)_4]^{2-}$ forms.

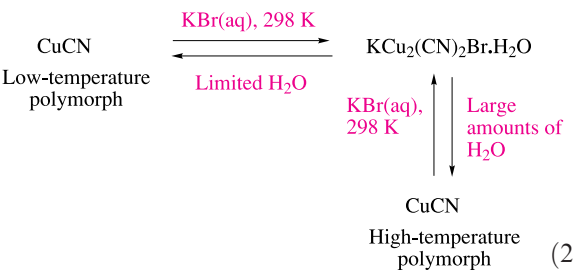
$$2Cu^{2+} + 4[CN]^- \longrightarrow 2CuCN(s) + C_2N_2 \qquad (21.107)$$

Some copper-containing complexes are studied as models for bioinorganic systems (see Chapter 29).

Copper(I)

Cuprous is the old name for copper(I). The Cu^+ ion has a d^{10} configuration and salts are diamagnetic and colourless except when the counter-ion is coloured or when charge transfer absorptions occur in the visible region, e.g. in red Cu_2O.

Copper(I) fluoride is not known although the CuF unit is stabilized in the tetrahedral complex $[CuF(PPh_3)_3]$. CuCl, CuBr and CuI are white solids and are made by reduction of a Cu(II) salt in the presence of halide ions, e.g. CuBr forms when SO_2 is bubbled through an aqueous solution of $CuSO_4$ and KBr. Copper(I) chloride has a zinc blende structure (see Fig. 6.21). The γ-forms of CuBr and CuI adopt the zinc blende structure but convert to the β-forms (wurtzite structure, Fig. 6.23) at 660 and 690 K respectively. Values of K_{sp}(298 K) for CuCl, CuBr and CuI are 1.72×10^{-7}, 6.27×10^{-9} and 1.27×10^{-12}. Copper(I) iodide precipitates when any Cu(II) salt is added to KI solution (eq. 21.108).



$$2Cu^{2+} + 4I^- \longrightarrow 2CuI + I_2 \qquad (21.108)$$

Anions and ligands available in solution strongly influence the relative stabilities of Cu(I) and Cu(II) species. The very low solubility of CuI is crucial to reaction 21.108 which occurs despite the fact that the E^o values of the Cu^{2+}/Cu^+ and I_2/I^- couples are +0.15 and +0.54 V respectively. However, in the presence of 1,2-ethanediamine or tartrate, which form stable complexes with Cu^{2+}, I_2 oxidizes CuI.

Copper(I) cyanide (eq. 21.107) is commercially available. This polymorph converts to a high-temperature form at 563 K. Both polymorphs contain chains (**21.71**). In the high-temperature form, the chains are linear (as in AgCN and AuCN), but in the low-temperature form, each chain adopts an unusual 'wave-like' configuration. The two polymorphs can be interconverted at room temperature by use of aqueous KBr under the conditions shown in scheme 21.109.

(21.71)

(21.109)

Copper(I) hydride is obtained by reduction of Cu(II) salts with H_3PO_2 and crystallizes with the wurtzite structure. It decomposes when treated with acids, liberating H_2. Polyhydrido copper cluster compounds include the red, hexameric $[(Ph_3P)_6Cu_6H_6]$ which is commercially available as Stryker's reagent and is used widely as a mild

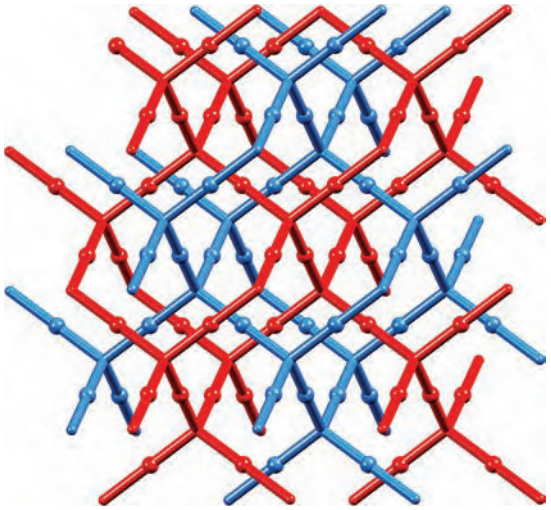


Fig. 21.39. The solid state structure of Cu_2O (cuprite) consists of two interpenetrating 3-dimensional networks (shown in red and blue). Each network has an anti-cristobalite structure with Cu and O in linear and tetrahedral coordination environments, respectively.

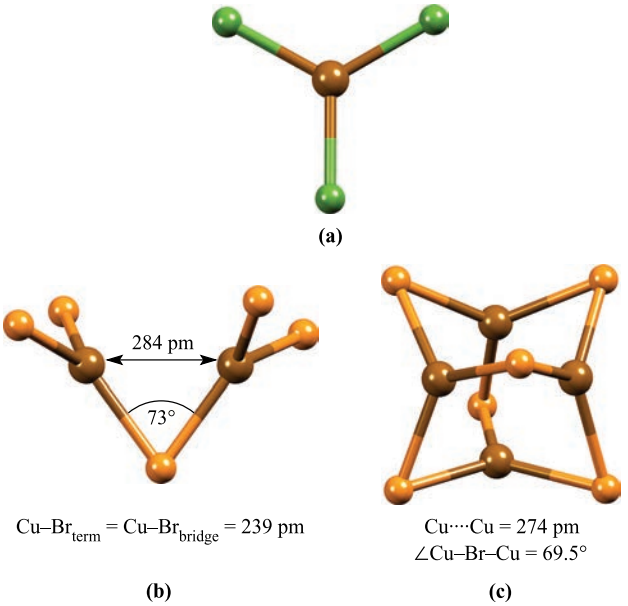

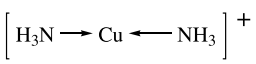

Fig. 21.40. The structures (X-ray diffraction) of (a) $[CuCl_3]^-$ in the $[Me_4P]^+$ salt [S. Andersson *et al.* (1998) *Acta Chem. Scand. A*, vol. 42, p. 691], (b) $[Cu_2Br_5]^{3-}$ in the $[Me_4N]^+$ salt [M. Asplund *et al.* (1985) *Acta Chem. Scand., Ser. A*, vol. 39, p. 47] and (c) $[Cu_4Br_6]^{2-}$ in the $[^nPr_4N]^+$ salt [M. Asplund *et al.* (1984) *Acta Chem. Scand. Ser. A*, vol. 38, p. 725]. In all the ions, the Cu(I) centres are in trigonal planar environments and in $[Cu_4Br_6]^{2-}$, the copper atoms are in a tetrahedral arrangement; the Cu····Cu distances are longer than in the bulk metal. Colour code: Cu, brown; Br, orange; Cl, green.

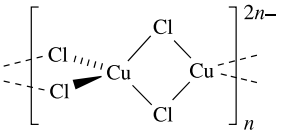
source of hydride or as a catalyst in organic transformations.†

Red copper(I) oxide may be made by oxidation of Cu (reaction 21.99), but is more readily obtained by reduction of Cu(II) compounds in alkaline media. When Fehling's solution (Cu^{2+} in aqueous alkaline sodium tartrate) is added to a reducing sugar such as glucose, Cu_2O precipitates. This is a qualitative test for reducing sugars. The solid state structure of Cu_2O is based on an anti-β-cristobalite (SiO_2, Fig. 6.22c) i.e. with Cu(I) in linear sites and O^{2-} in tetrahedral sites. Because the Cu_2O framework is particularly open, the crystal consists of two interpenetrating frameworks (Fig. 21.39), and the Cu_2O, *cuprite*, structure is a structural prototype. Copper(I) oxide is used as a red pigment in ceramics, porcelain glazes and glasses. Cu_2O has fungicidal properties and is added to certain paints as an antifouling agent. It is insoluble in water, but dissolves in aqueous NH_3 to give colourless $[Cu(NH_3)_2]^+$ (**21.72**); the solution readily absorbs O_2 and turns blue as $[Cu(NH_3)_4]^{2+}$ forms.

(21.72)

In acidic solutions, Cu_2O disproportionates (eq. 21.110).



$$Cu_2O + H_2SO_4 \longrightarrow CuSO_4 + Cu + H_2O \qquad (21.110)$$

Complex **21.72** illustrates a linear environment for Cu(I). The most common geometry is tetrahedral, and 3-coordinate species also occur. Halide complexes exhibit great structural diversity and the identity of the cation is often crucial in determining the structure of the anion. For example, $[CuCl_2]^-$ (formed when CuCl dissolves in concentrated HCl) may occur as discrete, linear anions (**21.73**) or as a polymer with tetrahedral Cu(I) centres (**21.74**). Trigonal planar $[CuCl_3]^{2-}$ has been isolated, e.g. in $[Me_4P]_2[CuCl_3]$ (Fig. 21.40a), but association into discrete, halido-bridged anions is also possible, e.g. $[Cu_2I_4]^{2-}$ (**21.75**), $[Cu_2Br_5]^{3-}$ (Fig. 21.40b) and $[Cu_4Br_6]^{2-}$ (Fig. 21.40c). An unusual *linear* Cu−Br−Cu bridge links two cubane-like sub-units in the mixed-valence anion $[Cu_8Br_{15}]^{6-}$ (Fig. 21.41). This ion formally contains one Cu(II) and seven Cu(I) centres, but structural and EPR spectroscopic properties and theoretical calculations are consistent with delocalized bonding. Complexation between Cu(I) and $[CN]^-$ can lead to $[Cu(CN)_2]^-$ (polymeric **21.76** as in the K^+ salt), $[Cu(CN)_3]^{2-}$ (trigonal planar, **19.2**) or $[Cu(CN)_4]^{3-}$ (tetrahedral).

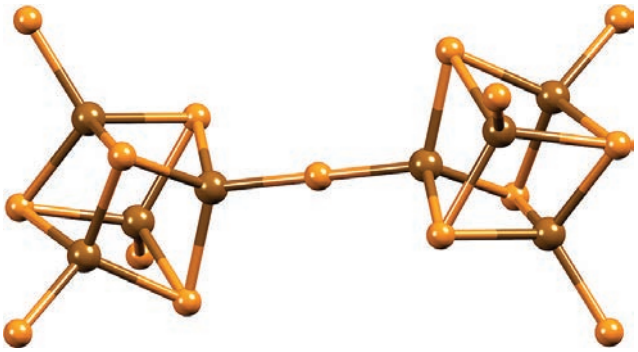

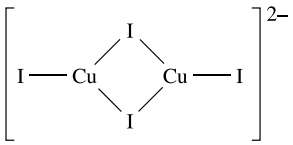

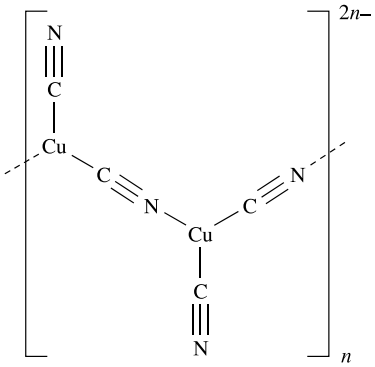

Fig. 21.41. The structure (X-ray diffraction at 203 K) of the mixed-valence $[Cu_8Br_{15}]^{6-}$ ion in the compound $[MePh_3P]_6[Cu_8Br_{15}]$ [G.A. Bowmaker *et al.* (1999) *Inorg. Chem.*, vol. 38, p. 5476]. Colour code: Cu, brown; Br, orange.

(21.75)

(21.76)

Copper(I) is a soft metal centre (Table 7.9) and tends to interact with soft donor atoms such as S and P, although complex formation with *O*- and *N*-donor ligands is well documented. Many complexes with *S*-donor ligands are known, and the propensity of sulfur to form bridges leads to many multinuclear complexes, e.g. $[(S_6)Cu(\mu\text{-}S_8)Cu(S_6)]^{4-}$ (Fig. 16.13), $[Cu_4(SPh)_6]^{2-}$ (which is structurally related to $[Cu_4Br_6]^{2-}$ (Fig. 21.40c) with $[SPh]^-$ replacing Br^- bridges), and $[\{Cu(S_2O_3)_2\}_n]$ (structurally related to **21.74** with *S*-bonded thiosulfates replacing Cl^- bridges). We have seen several times in this chapter how macrocyclic ligands may impose unusual coordination numbers on metal ions, or, if the ring is large enough, may wrap around a metal ion, e.g. in $[Co(\mathbf{21.51})]^{2+}$. In $[Cu(\mathbf{21.51})]^+$ (Fig. 21.42), the preference for the Cu^+ ion to be tetrahedrally coordinated means that it interacts with only four of the six donor atoms of the macrocycle.

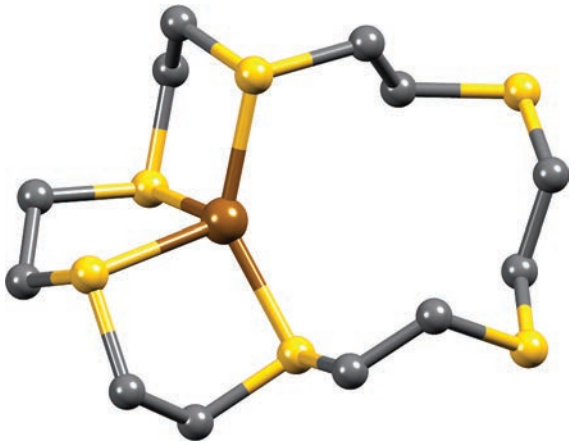

Fig. 21.42. The structure of $[Cu(\mathbf{21.51})]^+$ (ligand **21.51** is an S_6-macrocycle) determined by X-ray diffraction for the $[BF_4]^-$ salt; the Cu^+ is in a distorted tetrahedral environment [J.R. Hartman *et al.* (1986) *J. Am. Chem. Soc.*, vol. 108, p. 1202]. Hydrogen atoms are omitted; colour code: Cu, brown; S, yellow; C, grey.

Self-study exercises

1. 'Octahedral' Cu(II) complexes are often described as having a (4 + 2)-coordination pattern. An example is $[CuCl_6]^{4-}$. Suggest the origin of this description.

   [*Ans.* See structure **20.5** and discussion]

2. Values of $\log K_n$ for the displacement of H_2O ligands in $[Cu(OH_2)_6]^{2+}$ by NH_3 ligands are 4.2, 3.5, 2.9, 2.1 and −0.52 for $n = 1$, 2, 3, 4 and 5 respectively. A value for $n = 6$ cannot be measured in aqueous solution. Comment on these data.

   [*Ans.* See Fig. 20.37 and discussion]

3. CuO adopts a cooperite structure. Confirm the stoichiometry of the compound from the unit cell shown in Fig. 21.36b.

4. The $[Cu_3Cl_{12}]^{6-}$ ion contains one tetragonally distorted, octahedral Cu(II) centre and two tetrahedral Cu(II) centres. The ion is centrosymmetric. Draw the structure of the anion, and comment on what is meant by a 'tetragonally distorted octahedral' environment.

   [*Ans.* See M. Wei *et al.* (2004) *Inorg. Chem.*, vol. 43, p. 4534]

5. In liquid NH_3, the standard reduction potentials of the couples Cu^{2+}/Cu^+ and $Cu^+/Cu(s)$ (relative to $H^+/H_2(g)$) are +0.44 and +0.36 V, respectively. These values are +0.15 and +0.52 V under aqueous conditions. Calculate K for the equilibrium:

   $$2Cu^+ \rightleftharpoons Cu^{2+} + Cu(s)$$

   in liquid NH_3 and in aqueous solution at 298 K, and comment on the significance of the results.

   [*Ans.* K(liquid NH_3) = 0.045; K(aq) = 1.8×10^6]

21.13 Group 12: zinc

The metal

Zinc is not attacked by air or water at room temperature, but the hot metal burns in air and decomposes steam, forming ZnO. Zinc is much more reactive than Cu (compare eqs. 21.111 and 21.98), liberating H_2 from dilute mineral acids and from alkalis (eq. 21.112). With hot concentrated sulfuric acid, reaction 21.113 occurs. The products of reactions with HNO_3 depend on temperature and acid concentration. On heating, Zn reacts with all the halogens to give ZnX_2, and combines with elemental S and P.

$$Zn^{2+} + 2e^- \rightleftharpoons Zn \qquad E^\circ = -0.76\,V \qquad (21.111)$$

$$Zn + 2NaOH + 2H_2O \longrightarrow Na_2[Zn(OH)_4] + H_2 \qquad (21.112)$$

$$Zn + 2H_2SO_4 \xrightarrow[\text{hot, conc}]{} ZnSO_4 + SO_2 + 2H_2O \qquad (21.113)$$

The first (Sc) and last (Zn) members of the first row of the *d*-block exhibit a more restricted range of oxidation states than the other metals, and the chemistry of Zn is essentially confined to that of Zn(II)[†]. The $[Zn_2]^{2+}$ ion (analogues of which are well established for the heavier group 10 metals) has only been established in a yellow diamagnetic glass obtained by cooling a solution of metallic Zn in molten $ZnCl_2$. It rapidly disproportionates (eq. 21.114).

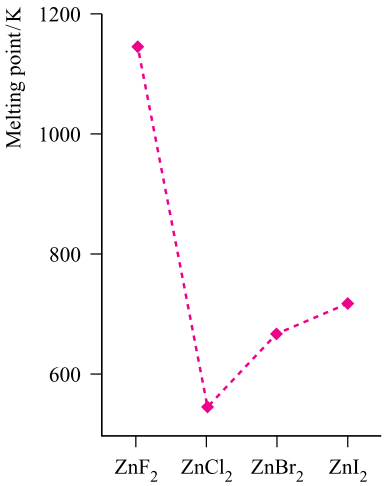
$$[Zn_2]^{2+} \longrightarrow Zn^{2+} + Zn \qquad (21.114)$$

Since the electronic configuration of Zn^{2+} is d^{10}, compounds are colourless and diamagnetic. There is no LFSE associated with the d^{10} ion and, as the discussion below shows, no particular geometry is preferred for Zn^{2+}. There are some similarities with Mg, and many compounds of Zn are isomorphous with their Mg analogues.

Zinc(II)

Binary halides are best made by action of HF, HCl, Br_2 or I_2 on hot Zn. ZnF_2 is also prepared by thermal decomposition of $Zn(BF_4)_2$. In the vapour phase, ZnX_2 (X–F, Cl, Br, I), consists of linear molecules. Solid ZnF_2 adopts a rutile structure (Fig. 6.24) and has a high lattice energy and melting point. Evidence for significant covalent character is apparent in the structures and properties of $ZnCl_2$, $ZnBr_2$ and ZnI_2 which possess layer structures, have lower melting points than ZnF_2 (Fig. 21.43) and are soluble in a range of organic solvents. The water solubility of ZnF_2 is low, but $ZnCl_2$, $ZnBr_2$ and ZnI_2 are highly soluble. Uses

[†] The possibilty of zinc existing in the +3 oxidation state has been claimed, but was not upheld in an independent investigation: D. Samanta and P. Jena (2012) *J. Am. Chem. Soc.*, vol. 134, p. 8400; T. Schlöder, M. Kaupp and S. Riedel (2012) *J. Am. Chem. Soc.*, vol. 134, p. 11977.



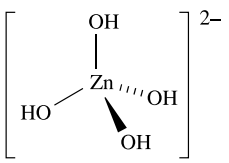


Fig. 21.43. Trend in melting points of the zinc halides.

of $ZnCl_2$ are varied, e.g. in some fireproofings, wood preservation, as an astringent, in deodorants and, combined with NH_4Cl, as a soldering flux.

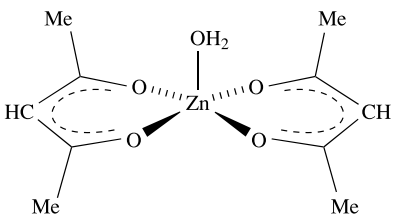
Zinc hydride is made by reaction 21.115 (or from LiH and $ZnBr_2$) and is a fairly stable solid at 298 K.

$$ZnI_2 + 2NaH \xrightarrow{THF} ZnH_2 + 2NaI \qquad (21.115)$$

Zinc is of great commercial significance and ZnO (made from Zn and O_2) is the most important compound of zinc (see Section 21.2). It is a white solid with the wurtzite structure (Fig. 6.23) at 298 K. It turns yellow on heating and in this form is a semiconductor owing to loss of oxygen and production of some interstitial Zn atoms. Zinc oxide is amphoteric, dissolving in acids to give solutions containing $[Zn(OH_2)_6]^{2+}$ or derivatives thereof (some anions coordinate to Zn^{2+}). Hydrolysis of $[Zn(OH_2)_6]^{2+}$ occurs to give various solution species resulting from H^+ loss. In alkalis, ZnO forms zincates such as $[Zn(OH)_4]^{2-}$ (**21.77**). This ion also forms when $Zn(OH)_2$ dissolves in aqueous alkalis. Zinc hydroxide is water-insoluble; there are five polymorphs of which ε-$Zn(OH)_2$ (distorted β-cristobalite structure, Fig. 6.22c) is thermodynamically the most stable.

(21.77)

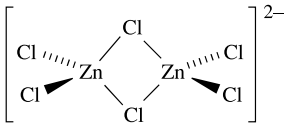
Zinc sulfide occurs naturally as the minerals *zinc blende* and, more rarely, *wurtzite*. These are structural prototypes (see Section 6.11). It is a light-sensitive white solid and, on exposure to cathode- or X-rays, it fluoresces and is used in fluorescent paints and radar screens. Adding Cu to ZnO



results in a green phosphorescence after exposure to light, and other colour variations are achieved by using different additives. The conversion of ZnS to ZnO by roasting in air is the commercial method of producing the oxide.

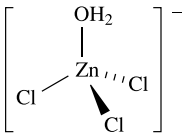
Other Zn(II) compounds that are commercially available include the carbonate, sulfate and nitrate. The sulfate is very soluble in water. Crystals of $ZnSO_4 \cdot 7H_2O$ form on evaporating solutions from reactions of Zn, ZnO, $Zn(OH)_2$ or $ZnCO_3$ with aqueous H_2SO_4. Dehydration initially occurs on heating, followed by decomposition (eq. 21.116).

$$ZnSO_4 \cdot 7H_2O \xrightarrow[-7H_2O]{520\ K} ZnSO_4 \xrightarrow{1020\ K} ZnO + SO_3 \qquad (21.116)$$



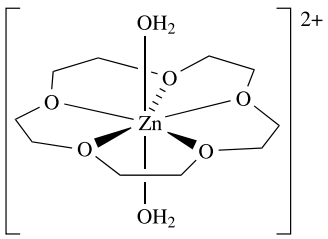
Insoluble $ZnCO_3$ occurs naturally as *smithsonite*, but the mineral tends to be coloured owing to the presence of, for example, Fe(II). The carbonate is usually purchased as the basic salt $ZnCO_3 \cdot 2Zn(OH)_2 \cdot xH_2O$ and is used in calamine lotion.

Zinc nitrate can be obtained as one of several hydrates, of which $Zn(NO_3)_2 \cdot 6H_2O$ is the most common. Anhydrous $Zn(NO_3)_2$ is made from Zn and N_2O_4 since heating the hydrates yields hydroxy salts. The hexahydrates of $Zn(NO_3)_2$ and $Zn(ClO_4)_2$ contain octahedral $[Zn(OH_2)_6]^{2+}$ in the solid state. Similarly, it is possible to isolate salts containing $[Zn(NH_3)_6]^{2+}$ from reactions done in liquid NH_3, e.g. $ZnCl_2 \cdot 6NH_3$. However, in aqueous solution, $[Zn(NH_3)_6]^{2+}$ exists in equilibrium with tetrahedral $[Zn(NH_3)_4]^{2+}$. Equation 9.25 showed the formation of $[Zn(NH_2)_4]^{2-}$. Basic zinc acetate $[Zn_4(\mu_4\text{-}O)(\mu\text{-}O_2CMe)_6]$ is isostructural with its Be(II) analogue (Fig. 12.7), but is more readily hydrolysed in water. In $Zn(acac)_2 \cdot H_2O$ (**21.78**), the coordination of Zn^{2+} is square-based pyramidal.

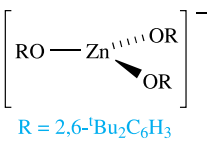


(21.78)

Our discussion of Zn(II) compounds has introduced complexes including $[Zn(OH_2)_6]^{2+}$, $[Zn(NH_3)_6]^{2+}$, $[Zn(NH_3)_4]^{2+}$, $[Zn(OH)_4]^{2-}$ and $[Zn(acac)_2(OH_2)]$, exemplifying octahedral, tetrahedral and square-based pyramidal coordination. Large numbers of Zn(II) complexes are known (some interest arises from developing models for Zn-containing bioinorganic systems, see Chapter 29) and coordination numbers of 4 to 6 are the most common. Zinc(II) is a borderline hard/soft ion and readily complexes with ligands containing a range of donor atoms, e.g. hard *N*- and *O*- and soft *S*-donors.



(21.79)



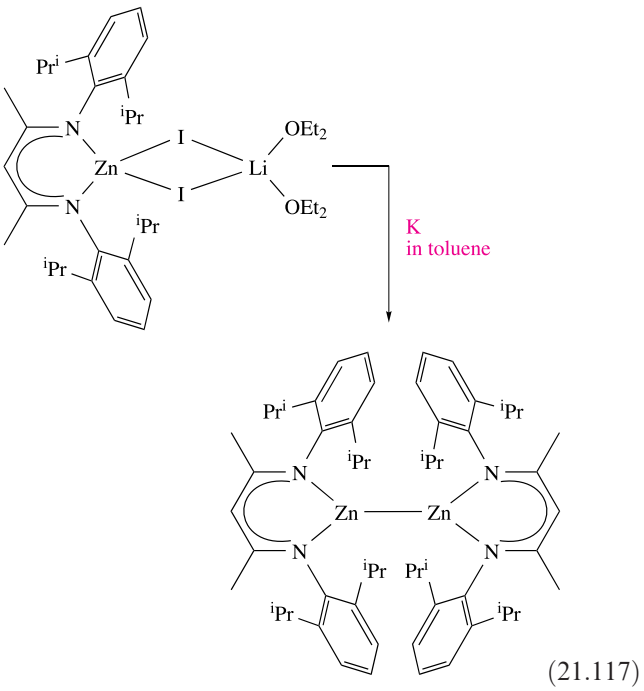
(21.80)

Tetrahedral $[ZnCl_4]^{2-}$ and $[ZnBr_4]^{2-}$ can be formed from $ZnCl_2$ and $ZnBr_2$ and many salts are known. Salts of $[ZnI_4]^{2-}$ are stabilized using large cations. Crystallographic data for '$[ZnCl_3]^-$' salts usually reveal the presence of $[Zn_2Cl_6]^{2-}$ (**21.79**), and in coordinating solvents, tetrahedral $[ZnCl_3(solv)]^-$ is present. Salts such as $K[ZnCl_3] \cdot H_2O$ contain $[ZnCl_3(OH_2)]^-$ (**21.80**) in the solid state. A similar picture is true for '$[ZnBr_3]^-$' and '$[ZnI_3]^-$' salts; both $[Zn_2Br_6]^{2-}$ and $[Zn_2I_6]^{2-}$ have been confirmed in the solid state.

The structure of $Zn(CN)_2$ is an *anticuprite* lattice with $[CN]^-$ groups bridging between tetrahedral Zn(II) centres, and two interpenetrating networks. (See Fig. 21.39 for the cuprite structure.) In contrast, $[Zn(CN)_4]^{2-}$ exists as discrete tetrahedral ions, as do $[Zn(N_3)_4]^{2-}$ and $[Zn(NCS\text{-}N)_4]^{2-}$. Just as it is possible to isolate both $[Zn(NH_3)_4]^{2+}$ and $[Zn(NH_3)_6]^{2+}$, pairs of tetrahedral $[ZnL_2]^{2+}$ and octahedral $[ZnL_3]^{2+}$ complexes (L = en, bpy, phen) are also known.

(21.81)

(21.82)



Examples of high coordination numbers for Zn^{2+} are rare, but include pentagonal bipyramidal $[Zn(15\text{-crown-}5)(OH_2)_2]^{2+}$ (**21.81**), and dodecahedral $[Zn(NO_3)_4]^{2-}$ (structurally similar to $[Co(NO_3)_4]^{2-}$, Fig. 21.31c).

By using a sterically demanding aryloxide ligand, it is possible to isolate a 3-coordinate (trigonal planar) Zn(II) complex, structure **21.82**.

Zinc(I)

In eq. 21.57, we illustrated the use of a β-diketiminato ligand, L, to stabilize Mn(I) in a dinuclear complex. The same ligand is capable of stabilizing the Zn_2L_2 complex shown in scheme 21.117. The complex formally contains a $\{Zn_2\}^{2+}$ core, in which the Zn–Zn bond distance is

236 pm. This is the second example of a compound containing a Zn–Zn bond, the first being the organometallic species $(\eta^5\text{-}C_5Me_5)_2Zn_2$ (Zn–Zn = 230.5 pm, see Fig. 24.26).

(21.117)

Self-study exercises

1. Explain why Zn(II) compounds are diamagnetic, irrespective of the coordination environment of the Zn^{2+} ion.

[*Ans.* d^{10} and see Figs. 20.8 and 20.11]

2. Do you expect Zn^{2+} to form stable, octahedral complexes with π-acceptor ligands? Give reasons for your answer.

[*Ans.* See end of Section 20.4]

3. Explain the relationship between the cooperate and anticooperite structures using Cu_2O and $Zn[CN]_2$ as examples.

KEY TERMS

The following terms were introduced in this chapter. Do you know what they mean?

- ❑ isopolyanion
- ❑ polyoxometallate
- ❑ homopolyanion
- ❑ heteropolyanion
- ❑ thermochromic

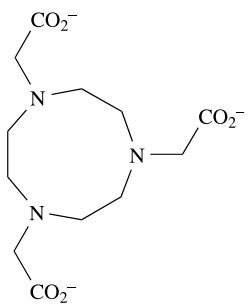
PROBLEMS

21.1 Write out, in sequence, the first row *d*-block elements and give the valence electronic configuration of each metal and of its M^{2+} ion.

21.2 Comment on the variation in oxidation states of the first row metals.

21.3 In the complex $[Ti(BH_4)_3(MeOCH_2CH_2OMe)]$, the Ti(III) centre is 8-coordinate. Suggest modes of coordination for the ligands.



21.4 Comment on each of the following observations. (a) Li_2TiO_3 forms a continuous range of solid solutions with MgO. (b) When $TiCl_3$ is heated with concentrated aqueous NaOH, H_2 is evolved.

21.5 An acidified solution of 0.1000 mol dm^{-3} ammonium vanadate (25.00 cm^3) was reduced by SO_2 and, after boiling off excess reductant, the blue solution remaining was found to require addition of 25.00 cm^3 0.0200 mol dm^{-3} $KMnO_4$ to give a pink colour to the solution. Another 25.00 cm^3 portion of the vanadate solution was shaken with Zn amalgam and then immediately poured into excess of the ammonium vanadate solution; on titration of the resulting solution with the $KMnO_4$ solution, 74.5 cm^3 of the latter was required. Deduce what happened in these experiments.

21.6 Give equations to describe what happens to VBr_3 on heating.

21.7 The magnetic moment of $[NH_4]V(SO_4)_2{\cdot}12H_2O$ is 2.8 μ_B and the electronic absorption spectrum of an aqueous solution contains absorptions at 17 800, 25 700 and 34 500 cm^{-1}. Explain these observations.

21.8 Suggest the formula and structure of the mononuclear complex formed between Cr^{3+} and ligand **21.83**. Comment on possible isomerism.

(21.83)

21.9 Use data from Appendix 11 to predict qualitatively the outcome of the following experiment at 298 K: Cr is dissolved in excess of molar $HClO_4$ and the solution is shaken in air.

21.10 Figure 21.44 shows the change in concentration of $[MnO_4]^-$ with time during a reaction with acidified oxalate ions. (a) Suggest a method of monitoring the reaction. (b) Explain the shape of the curve.

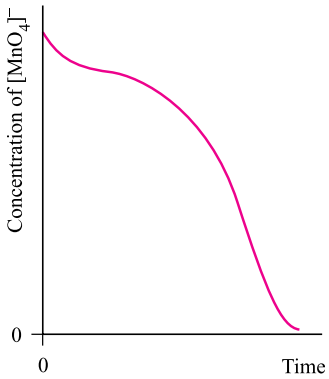


Fig. 21.44. Figure for problem 21.10.

21.11 Comment on the modes of bonding of the ligands in the Mn(II) complexes listed at the end of Section 21.8, drawing attention to any conformational restrictions.

21.12 How would you (a) distinguish between the formulations $Cu^{II}Fe^{II}S_2$ and $Cu^{I}Fe^{III}S_2$ for the mineral *chalcopyrite*, (b) show that Fe^{3+} is a hard cation, and (c) show that the blue compound precipitated when a solution of $[MnO_4]^-$ in concentrated aqueous KOH is reduced by $[CN]^-$ contains Mn(V)?

21.13 Give equations for the following reactions: (a) heating Fe with Cl_2; (b) heating Fe with I_2; (c) solid $FeSO_4$ with concentrated H_2SO_4; (d) aqueous Fe^{3+} with $[SCN]^-$; (e) aqueous Fe^{3+} with $K_2C_2O_4$; (f) FeO with dilute H_2SO_4; (g) aqueous $FeSO_4$ and NaOH.

21.14 How would you attempt to (a) estimate the crystal field stabilization energy of FeF_2, and (b) determine the overall stability constant of $[Co(NH_3)_6]^{3+}$ in aqueous solution given that the overall formation constant for $[Co(NH_3)_6]^{2+}$ is 10^5, and:

$$Co^{3+}(aq) + e^- \rightleftharpoons Co^{2+}(aq) \qquad E^o = +1.92\,V$$

$$[Co(NH_3)_6]^{3+}(aq) + e^- \rightleftharpoons [Co(NH_3)_6]^{2+}(aq) \qquad E^o = +0.11\,V$$

21.15 Suggest why Co_3O_4 adopts a normal rather than inverse spinel structure.

21.16 Give explanations for the following observations. (a) The complex $[Co(en)_2Cl_2]_2[CoCl_4]$ has a room temperature magnetic moment of 3.71 μ_{eff}. (b) The room temperature magnetic moment of $[CoI_4]^{2-}$ (e.g. 5.01 μ_B for the $[Et_4N]^+$ salt) is larger than that of salts of $[CoCl_4]^{2-}$.

21.17 (a) When $[CN]^-$ is added to aqueous Ni^{2+} ions, a green precipitate forms; if excess KCN is added, the precipitate dissolves to give a yellow solution and at high concentrations of $[CN]^-$, the solution becomes red. Suggest an explanation for these observations. (b) If the yellow compound from part (a) is isolated and reacted with Na in liquid NH_3, a red, air-sensitive, diamagnetic product can be isolated. Suggest its identity.

21.18 Treatment of an aqueous solution of $NiCl_2$ with $H_2NCHPhCHPhNH_2$ gives a blue complex ($\mu_{eff} = 3.30\,\mu_B$) which loses H_2O on heating to form a yellow, diamagnetic compound. Suggest explanations for these observations and comment on possible isomerism in the yellow species.

21.19 Give equations for the following reactions: (a) aqueous NaOH with $CuSO_4$; (b) CuO with Cu in concentrated HCl at reflux; (c) Cu with concentrated HNO_3; (d) addition of aqueous NH_3 to a precipitate of $Cu(OH)_2$; (e) $ZnSO_4$ with aqueous NaOH followed by addition of excess NaOH; (f) ZnS with dilute HCl.

21.20 (a) Compare the solid state structures of $[M(Hdmg)_2]$ for M = Ni and Cu and comment on the fact that $[Cu(Hdmg)_2]$ is more soluble in water than is $[Ni(Hdmg)_2]$. (b) Suggest the likely structural features of $[Pd(Hdmg)_2]$.

21.21 Copper(II) chloride is not completely reduced by SO_2 in concentrated HCl solution. Suggest an explanation for this observation and state how you would try to establish if the explanation is correct.

21.22 When the ligands do not sterically control the coordination geometry, do 4-coordinate complexes of (a) Pd(II), (b) Cu(I) and (c) Zn(II) prefer to be square planar or tetrahedral? Explain your answer. In the absence of crystallographic data, how could you distinguish between a square planar or tetrahedral structure for a Ni(II) complex?

21.23 Write down formulae for the following ions: (a) manganate(VII); (b) manganate(VI); (c) dichromate(VI); (d) vanadyl; (e) vanadate (*ortho* and *meta*); (f) hexacyanidoferrate(III). Give an alternative name for manganate(VII).

21.24 Give a brief account of the variation in properties of binary oxides of the first row *d*-block metals on going from Sc to Zn.

21.25 Give an overview of the formation of halido complexes of type $[MX_n]^{m-}$ by the first row *d*-block metal ions, noting in particular whether discrete ions are present in the solid state.

21.26 When iron(II) oxalate (oxalate = ox^{2-}) is treated with H_2O_2, H_2ox and K_2ox, a green compound **X** is obtained. **X** reacts with aqueous NaOH to give hydrated Fe_2O_3, and is decomposed by light with production of iron(II) oxalate, K_2ox and CO_2. Analysis of **X** shows it contains 11.4% Fe and 53.7% ox^{2-}. Deduce the formula of **X** and write equations for its reaction with alkali and its photochemical decomposition. State, with reasons, whether you would expect **X** to be chiral.

21.27 Dimethyl sulfoxide (DMSO) reacts with cobalt(II) perchlorate in EtOH to give a pink compound **A** which is a 1:2 electrolyte and has a magnetic moment of 4.9 μ_B. Cobalt(II) chloride also reacts with DMSO, but in this case the dark blue product, **B**, is a 1:1 electrolyte, and the magnetic moment of **B** is 4.6 μ_B per Co centre. Suggest a formula and structure for **A** and **B**.

21.28 When H_2S is passed into a solution of copper(II) sulfate acidified with H_2SO_4, copper(II) sulfide precipitates. When concentrated H_2SO_4 is heated with metallic Cu, the principal sulfur-containing product is SO_2 but a residue of copper(II) sulfide is also formed. Account for these reactions.

OVERVIEW PROBLEMS

21.29 (a) Write an equation to represent the discharge of an alkaline electrolyte cell containing a Zn anode and $BaFeO_4$ cathode.

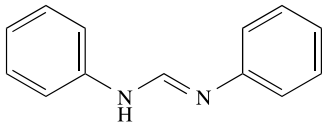
(b) The first charge transfer band for $[MnO_4]^-$ occurs at 18 320 cm^{-1}, and that for $[MnO_4]^{2-}$ at 22 940 cm^{-1}. Explain the origin of these absorptions, and comment on the trend in relative energies on going from $[MnO_4]^{2-}$ to $[MnO_4]^-$.

(c) Explain why FeS_2 adopts a NaCl structure rather than a structure in which the cation : anion ratio is 1:2.

21.30 (a) The value of μ_{eff} for $[CoF_6]^{3-}$ is 5.63 μ_B. Explain why this value does not agree with the

value for μ calculated from the spin-only formula.

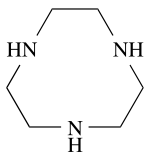
(b) By using a simple MO approach, rationalize why one-electron oxidation of the bridging ligand in $[(CN)_5CoOOCo(CN)_5]^{6-}$ leads to a shortening of the O–O bond.



(c) Salts of which of the following complex ions might be expected to be formed as racemates: $[Ni(acac)_3]^-$, $[CoCl_3(NCMe)]^-$, *cis*-$[Co(en)_2Cl_2]^+$, *trans*-$[Cr(en)_2Cl_2]^+$?

21.31 (a) The electronic absorption spectrum of $[Ni(DMSO)_6]^{2+}$ (DMSO = Me_2SO) exhibits three absorptions at 7728, 12 970 and 24 038 cm^{-1}. Assign these absorptions.

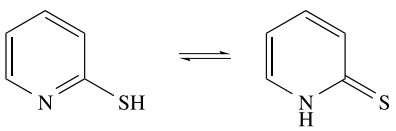
(b) CuF_2 has a distorted rutile structure (four Cu–F = 193 pm and two Cu–F = 227 pm per Cu centre); $[CuF_6]^{2-}$ and $[NiF_6]^{3-}$ are distorted octahedral ions. Explain the origins of these distortions.



(c) Dissolution of vanadium metal in aqueous HBr leads to a complex '$VBr_3{\cdot}6H_2O$'. X-ray diffraction data reveal that the compound contains a complex cation containing a centre of symmetry. Suggest a formulation for the compound, and a structure for the cation.

21.32 The complex $[V_2L_4]$, where HL is diphenylformamidine (see structure opposite-above), is diamagnetic. Each L^- ligand acts as a bridging, *N*,*N*'-donor such that the complex is structurally similar to complexes of the type $[Cr_2(O_2CR)_4]$. (a) Describe a bonding scheme for the $[V_2]^{4+}$ core and derive the formal metal–metal bond order in $[V_2L_4]$. (b) The reaction of $[V_2L_4]$ with KC_8 in THF results in the formation of $K(THF)_3[V_2L_4]$. What is the role of KC_8 in this reaction? (c) Do you expect the V–V bond length to increase or decrease on going from $[V_2L_4]$ to $K(THF)_3[V_2L_4]$? Rationalize your answer.

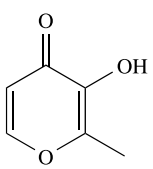
Diphenylformamidine (HL)



21.33 (a) The ligand 1,4,7-triazacyclononane, L, forms the nickel complexes $[NiL_2]_2[S_2O_6]_3{\cdot}7H_2O$ and $[NiL_2][NO_3]Cl{\cdot}H_2O$. X-ray diffraction data for these complexes reveal that in the cation in $[NiL_2][NO_3]Cl{\cdot}H_2O$, the Ni–N bond lengths lie in the range 209–212 pm, while in $[NiL_2]_2[S_2O_6]_3{\cdot}7H_2O$, two Ni–N bonds (mutually *trans*) are of length 211 pm and the remaining Ni–N bonds are in the range 196–199 pm. Rationalize these data.

1,4,7-triazacyclononane

(b) Suggest why some reports of the properties of low-spin $[Fe(bpy)_3]^{2+}$ state that its salts possess very low magnetic moments.



(c) The ligand HL can be represented as follows:

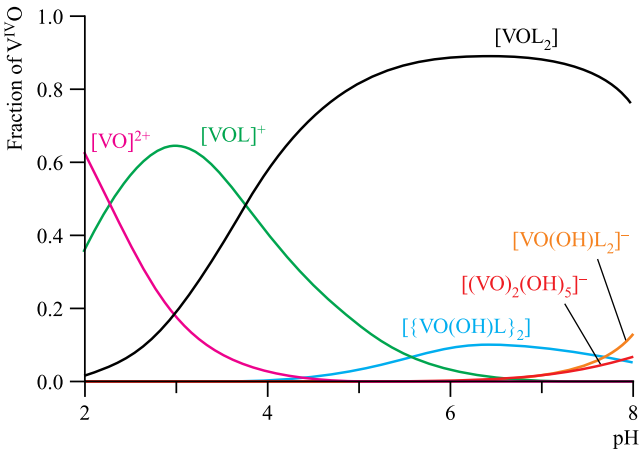
What is the term given to these forms of HL? The conjugate base of HL forms the complexes *mer*-$[VL_3]^-$ and $[V(Me_2NCH_2CH_2NMe_2)L_2]$. Draw the structure of *mer*-$[VL_3]^-$, and the structures of the possible isomers of $[V(Me_2NCH_2CH_2NMe_2)L_2]$.

INORGANIC CHEMISTRY MATTERS

21.34 Vanadium(IV) complexes act as mimics for insulin, a hormone secreted by the pancreas. Among the complexes being studied is $[VOL_2]$ in which HL is maltol:

maltol

Figure 21.45 (on p. 802) shows the pH dependence of the species in aqueous solution containing $[VO]^{2+}$ and HL in a 1 : 2 ratio. (a) Suggest a structure for $[VOL_2]$. (b) For which ion is $[VO]^{2+}$ an abbreviation? (c) Rationalize the shapes of the curves in Fig. 21.45 and suggest structures for the species present. (d) Why are studies such as that summarized in Fig. 21.45 important in the development of anti-diabetes drugs?



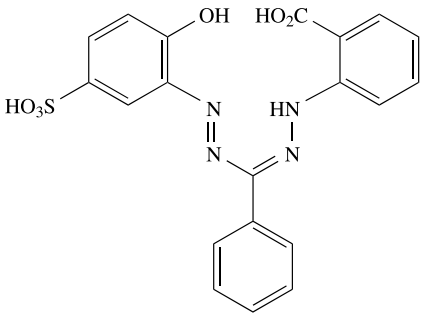


Fig. 21.45. Speciation curves for complexes formed in an aqueous solution of vanadium(IV) and maltol (HL) with a metal : ligand ratio of 1 : 2. [Redrawn with permission from T. Kiss *et al.* (2000) *J. Inorg. Biochem.*, vol. 80, p. 65, Elsevier.]

21.35 The tanning process in the manufacture of leather relies upon the interaction of Cr^{3+} with the fibrous protein collagen. Although glycine and L-proline are the most important amino acids (see Table 29.2) in collagen, glutamic acid ($pK_a = 3.8$) and aspartic acid ($pK_a = 4.2$) are also present. During tanning, the pH of an aqueous solution of $Cr(OH)SO_4$ is lowered from ≈2.8 to 3.8. (a) What chromium(III) ion is present in aqueous solution at very low pH and why is H^+ needed to stabilize this species? (b) In the absence of collagen, aqueous solutions of Cr^{3+} at pH 3.8 contain linear, tri- and tetranuclear species. Suggest structures for these species. (c) A study [A.D. Covington *et al.* (2001) *Polyhedron*, vol. 20, p. 461] of the interaction of chromium(III) with collagen states that, at pH 3.8, carboxylate groups should compete with hydroxido ligands for chromium. The study concludes that the predominant chromium-containing species bound to leather is a linear oligomer with nuclearity 2 or 3. Using this information, suggest how Cr^{3+} interacts with collagen and indicate how Cr^{3+} may be involved in cross-linking of collagen fibres. (d) A major concern in the tanning industry is to prevent toxic waste arising from the oxidation of Cr(III) to Cr(VI). Chromium(VI) may be present as $[Cr_2O_7]^{2-}$ and two other anions, depending upon the pH. Write equilibria to show how the three Cr(VI) species are interrelated, and suggest a method to remove them from waste water.

21.36 The compound shown below is a formazan dye usually referred to as 'zincon'. It is used to detect Zn^{2+} and Cu^{2+} ions:

(a) Suggest how the ligand binds to Zn^{2+} or Cu^{2+}, and comment on the role of pH in determining the overall charge of the complex. (b) Why does the ligand include a SO_3H substituent? (c) Zincon itself absorbs at 463 nm. Suggest how the absorption arises. (d) When zincon binds Cu^{2+}, the absorption at 463 nm is replaced by one at 600 nm. Why does this make zincon an easy method of detection for Cu^{2+} ions? (e) The copper(II) complex of zincon can be used as a sensor for $[CN]^-$ ions in aqueous solution. Addition of $[CN]^-$ results in the disappearance of the absorption at 600 nm and reappearance of the absorption at 463 nm. Outline the chemical changes occurring in solution.

	La	Hf	Ta	W	Re	Os	Ir	Pt	Au	Hg	
	Ac	Rf	Db	Sg	Bh	Hs	Mt	Ds	Rg	Cn	

22.1 Introduction

Chapter 21 dealt with descriptive chemistry of the first row *d*-block metals and, in this chapter, we focus on the second and third row metals (the *heavier metals*). Reasons for discussing the lighter and heavier metals separately were given in Section 21.1.

Lanthanum, La, is commonly classified with the lanthanoids (see Fig. 1.14) even though 'lanthanoid' means 'like lanthanum' and La is strictly a group 3 metal. Because of the chemical similarity of La to the elements Ce–Lu, they are considered together in Chapter 27. The only mention of La in this chapter is its occurrence.

22.2 Occurrence, extraction and uses

Figure 22.1 shows the relative abundances of the second and third row *d*-block metals. Compared with the first row metals (Fig. 21.1), the abundances of some of the heavier metals are very low, e.g. Os, 1×10^{-4} ppm and Ir, 6×10^{-6} ppm; Tc does not occur naturally. ***Yttrium*** and ***lanthanum*** are similar to the lanthanoids and occur with them in nature. The major yttrium and lanthanum ores are *monazite* (a mixed metal phosphate, (Ce,La,Nd,Pr,Th,Y...)PO_4) and *bastnäsite* ((Ce,La,Y...)CO_3F); their composition varies, e.g. an 'yttrium-rich' mineral might contain $\leq$1% Y, a 'lanthanum-rich' one up to 35% La. The extraction of yttrium involves conversion to YF_3 or YCl_3 followed by reduction with Ca or K respectively; the separation of lanthanoid metals is described in Section 27.5. The most important use of yttrium is in phosphors (high purity Y_2O_3 and YVO_4) for television and computer displays. Although traditional uses in TVs containing cathode-ray tubes have declined, phosphors remain in use in some flat screen displays, e.g. plasma TVs. Yttrium is also used in corrosion-resistant alloys, and in the formation of yttrium garnets for microwave filters and synthetic gemstones (yttrium aluminium garnets, YAG, $Al_5Y_3O_{12}$).

Zirconium is the next most abundant *d*-block metal in the Earth's crust after Fe, Ti and Mn, and is present to quite a large extent in lunar rock samples collected in the Apollo missions. Zirconium and ***hafnium*** occur naturally together and are hard to separate. Hf is rarer than Zr, 5.3 and 190 ppm, respectively, of the Earth's crust. The main ores are *baddeleyite* (ZrO_2), *zircon* ((Zr,Hf)SiO_4, <2% Hf) and *alvite* ((Zr,Hf)$SiO_4 \cdot xH_2O$, <2% Hf). Extraction of Zr involves reduction of ZrO_2 by Ca, or conversion of ZrO_2 to K_2ZrF_6 (by treatment with K_2SiF_6) followed by reduction. Both Zr and Hf can be produced from zircon by reaction sequence 22.1. The mixture of metals so obtained is used for strengthening steel.

$$MO_2 \xrightarrow{CCl_4,\ 770\ K} MCl_4 \xrightarrow{Mg\ under\ Ar,\ 1420\ K} M \quad (M = Zr \text{ or } Hf) \qquad (22.1)$$

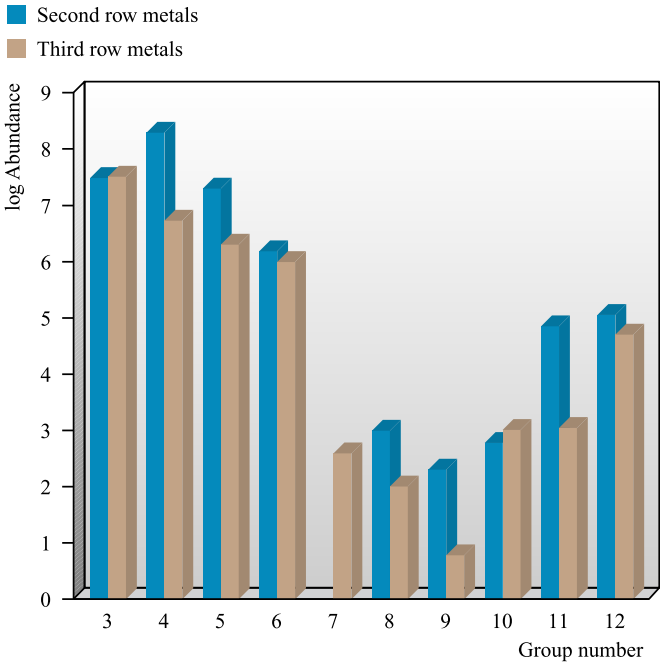

Fig. 22.1. Relative abundances of the second and third row *d*-block metals in the Earth's crust. The data are plotted on a logarithmic scale, and the units of abundance are parts per 10^9. Technetium (group 7) does not occur naturally.

Zirconium has a high corrosion resistance and low cross-section for neutron capture and is used for cladding fuel rods in water-cooled nuclear reactors. For this application, Zr must be free of Hf, which is a very good neutron absorber. The main use of pure Hf is in nuclear reactor control rods. Zirconium and hafnium compounds possess similar lattice energies and solubilities, and their complexes have similar stabilities. This means that separation techniques (e.g. ion exchange, solvent extraction) encounter the same problems as those of the lanthanoids. Very pure metals can be obtained by zone refining (see Box 6.3) or by thermal decomposition of the iodides on a hot metal filament. Zirconium compounds have a range of catalytic applications. Uses of ZrO_2 are described in Section 22.5. In Box 15.4, we highlighted applications of Hf and Zr nitrides.

Niobium (formerly called ***columbium***) and ***tantalum*** occur together in the mineral *columbite* $(Fe,Mn)(Nb,Ta)_2O_6$. When the mineral is Nb-rich, it is called *niobite* and when Ta-rich, *tantalite*. Fusion of the ore with alkali gives poly-niobates and -tantalates, and further treatment with dilute acid yields Nb_2O_5 and Ta_2O_5. One method of separation utilizes the more basic character of Ta: at a controlled concentration of HF and KF in aqueous solution, the oxides are converted to $K_2[NbOF_5]$ and $K_2[TaF_7]$. The former is more water-soluble than the latter. The modern separation technique is fractional extraction from aqueous HF solution into methyl isobutyl ketone. Niobium is used in the manufacture of tough steels and superalloys which are used in the aerospace industry, e.g. in frameworks designed for the Gemini space program (the forerunner to the Apollo moon missions). Superconducting magnets (e.g. in MRI equipment, see Box 4.3) contain NbTi metallic multicore conductors. Tantalum is very high melting (mp 3290 K) and extremely resistant to corrosion by air and water. It is used in corrosion-resistant alloys, e.g. for construction materials in the chemical industry. The inertness of the metal makes it suitable for use in surgical appliances including prostheses. Tantalum has wide application in the manufacture of electronic components, in particular, capacitors that are used in mobile phones and personal computers.

The German for tungsten is *wolfram*, hence the symbol W. Although ***molybdenum*** and ***tungsten*** compounds are usually isomorphous, the elements occur separately. The major Mo-containing ore is *molybdenite* (MoS_2) and the metal is extracted by reactions 22.2. Tungsten occurs in *wolframite* ($(Fe,Mn)WO_4$) and *scheelite* ($CaWO_4$) and scheme 22.3 shows typical extraction processes.

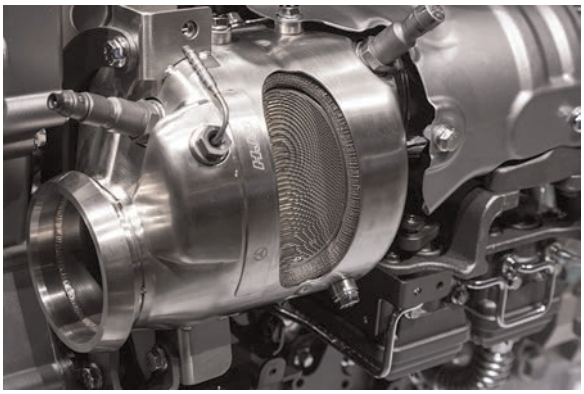
$$MoS_2 \xrightarrow{\Delta\ (870\ K)\ \text{in air}} MoO_3 \xrightarrow{H_2,\ 870\ K} Mo \qquad (22.2)$$

$$(Fe,Mn)WO_4 \xrightarrow{Na_2CO_3,\ \text{fusion}} \underset{\text{insoluble}}{(Fe,Mn)_2O_3} + \underset{\text{soluble}}{Na_2WO_4}$$

$$Na_2WO_4 \xrightarrow{HCl} WO_3 \xrightarrow{H_2,\ 870\ K} W \qquad (22.3)$$

Molybdenum is very hard and high melting (mp 2896 K), and tungsten has the highest melting point (3695 K) of all metals (Table 6.2). Both metals are used in the manufacture of toughened steels (for which wolframite can be reduced directly by Al). Tungsten carbides have extensive use in cutting tools and abrasives. A major use of W metal is in electric light bulb filaments including low-energy halogen lamps. Molybdenum has an essential role in biological systems (see Section 29.1).

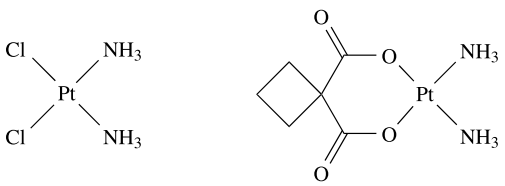
Technetium is an artificial element, available as ^{99}Tc (a β-particle emitter, $t_{\frac{1}{2}} = 2.13 \times 10^5$ yr) which is isolated from fission product wastes by oxidation to $[TcO_4]^-$. Separation employs solvent extraction and ion-exchange methods. The $[TcO_4]^-$ ion is the common precursor in technetium chemistry. Technetium metal can be obtained by H_2 reduction of $[NH_4][TcO_4]$ at high temperature. The principal use of Tc compounds is in nuclear medicine where they are important imaging agents (see Box 22.6). ***Rhenium*** is rare and occurs in small amounts in Mo ores. During roasting (first step in eq. 22.2), volatile Re_2O_7 forms and is deposited in flue dusts. It is dissolved in water and precipitated as $KReO_4$. The two major uses of Re are in petroleum-reforming catalysts and as a component of high-temperature superalloys. Such alloys are used in, for example, heating



ENVIRONMENT

Box 22.1 Environmental catalysts

The platinum-group metals Rh, Pd and Pt play a vital role in keeping the environment devoid of pollutants originating from vehicle exhausts. They are present in catalytic converters (which we discuss in detail in Section 25.8) where they catalyse the conversion of hydrocarbon wastes, CO and NO_x (see Box 15.7) to CO_2, H_2O and N_2. In 2008, the manufacture of catalytic converters used 81% of the rhodium, 47% of palladium and 44% of platinum consumed worldwide. The growth rate of environmental catalyst manufacture by companies such as Johnson Matthey in the UK is driven by legislative measures for the control of exhaust emissions. Regulations in force in the US and Europe have had a major impact on the levels of emissions and have improved the quality of urban air. Tighter control of vehicle emissions has now been introduced in most parts of Asia.



For more details of catalytic converters, see Section 25.8.

Catalytic converter showing interior design. Small particles (≈1600 pm diameter) of Pd, Pt or Rh are dispersed on a support such as γ-alumina which coats a metallic (metalith) or ceramic (monolith) honeycomb-like substrate. The combination of substrate and γ-aluminia 'washcoat' produces a very large surface area (see Section 25.8).

elements, thermocouples and filaments for photographic flash equipment and mass spectrometers.

The *platinum-group metals* (Ru, Os, Rh, Ir, Pd and Pt) are rare (Fig. 22.1) and expensive, and occur together either native or in sulfide ores of Cu and Ni. World production of platinum-group metals is dominated by South Africa (48% of world output in 2014) and Russia (30%), with mines in the US, Canada and Zimbabwe producing most of the remainder. The main source of ***ruthenium*** is from wastes from Ni refining, e.g. from *pentlandite*, (Fe, Ni)S. ***Osmium*** and ***iridium*** occur in *osmiridium*, a native alloy with variable composition: 15–40% osmium and 80–50% iridium. ***Rhodium*** occurs in *native platinum* and in *pyrrhotite* ores ($Fe_{1-n}S$, $n = 0$–0.2, often with ≤5% Ni). Native platinum is of variable composition but may contain as much as 86% Pt, other constituents being Fe, Ir, Os, Au, Rh, Pd and Cu. The ore is an important source of ***palladium*** which is also a side-product of Cu and Zn refining. Besides being obtained native, ***platinum*** is extracted from *sperrylite* ($PtAs_2$). Extraction and separation methods for the six metals are interlinked, solvent extraction and ion-exchange methods being used.[†] The metals are important heterogeneous catalysts, e.g. Pd for hydrogenation and dehydrogenation, Pt for NH_3 oxidation and hydrocarbon reforming, and Rh and Pt for catalytic converters (see Box 22.1). Uses of Ru and Rh include alloying with Pt and Pd to increase their hardness for use in, for example, the manufacture of electrical components (e.g. electrodes and thermocouples) and laboratory crucibles. Osmium and iridium have few commercial uses. They are employed to a limited extent as alloying agents; an IrOs alloy is used in pen-nibs. Palladium is widely used in the electronics industry (in printed circuits and multilayer ceramic capacitors). The ability of Pd to absorb large amounts of H_2 (see Section 10.7) leads to it being used in the industrial purification of H_2. Platinum is particularly inert: Pt electrodes have laboratory applications (e.g. in the standard hydrogen and pH electrodes) and medical applications of microelectrodes are becoming increasingly important.[‡] The metal is widely used in electrical wires, thermocouples and jewellery. Platinum-containing compounds such as *cisplatin* (**22.1**) and *carboplatin* (**22.2**) are antitumour drugs, and we discuss these further in Box 22.9.

(22.1) **(22.2)**

Silver and ***gold*** occur native, and in sulfide, arsenide and telluride ores, e.g. *argentite* (Ag_2S) and *sylvanite* ($(Ag,Au)Te_2$). Silver is usually worked from the residues of Cu, Ni or Pb refining and, like Au, can be extracted

[†] For further discussion, see: P.A. Tasker, P.G. Plieger and L.C. West (2004) in *Comprehensive Coordination Chemistry II*, eds J.A. McCleverty and T.J. Meyer, Elsevier, Oxford, vol. 9, p. 759 – 'Metal complexes for hydrometallurgy and extraction'.

[‡] For an overview, see: J.H. Lee, H. Kim, J.H. Kim and S.-H. Lee (2016) *Lab Chip*, vol. 16, p. 959.

from all its ores by reaction 22.4, the cyanido complex being reduced to the metal by Zn.

$$4M + 8[CN]^- + 2H_2O + O_2 \longrightarrow 4[M(CN)_2]^- + 4[OH]^- \quad (M = Ag, Au) \qquad (22.4)$$

Although the use of cyanide is currently the most important means of extracting gold from its ores, its toxicity is a clear disadvantage. Other methods of extraction are therefore being considered, for example the use of ligands such as thiourea, thiocyanate and thiosulfate, which form water-stable gold complexes. Native gold typically contains 85–95% Au with Ag as the second constituent. Silver is used in soldering alloys, high-capacity batteries, electrical equipment and printed circuits. Silver salts were used extensively in the photographic industry, but their importance has declined now that digital cameras dominate the market. Silver iodide (in the form of flares or ground-sited acetone–AgI generators) is used in cloud seeding to control rain patterns in certain regions. Gold has been worked since ancient civilization, not only in the usual yellow form, but as red, purple or blue *colloidal gold*. Modern uses of colloidal gold are in electron microscope imaging, staining of microscope slides and as colouring agents, e.g. reduction of Au(III) with $SnCl_2$ yields *purple of Cassius*, used in the manufacture of ruby glass. Uses of gold include coinage, the electronics industry and jewellery; *carat* indicates the gold content (24 carat = pure gold). Some gold compounds are used as anti-arthritic drugs. Recycling of Ag and Au (as with other precious metals) is an important way of conserving resources.

Cadmium occurs as the rare mineral *greenockite* (CdS), but the metal is isolated almost entirely from zinc ores, CdS occurring (<0.5%) in ZnS. Being more volatile than Zn, Cd can be collected in the first stage of the distillation of the metal. Cadmium has a relatively low melting point (594 K) and is used as an alloying agent in low-melting alloys. The main use of cadmium is in NiCd batteries (see eq. 21.5). Cadmium selenide and telluride are semiconductors and are employed in the electronics industry. CdTe has potential application in solar cells, although the market currently makes greatest use of Si-based cells. The Weston standard cell (cell 22.5) uses a Cd/Hg amalgam cathode, but use of this cell is declining. Cadmium is toxic and environmental legislation in the European Union and US in particular has led to a reduction in its use. Cadmium used in NiCd batteries can be recycled, but its use in other areas is expected to decrease.

$$Cd(Hg)\,|\,CdSO_4,\ H_2O\,\vdots\,Hg_2SO_4\,|\,Hg \qquad (22.5)$$

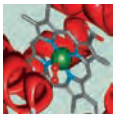
The symbol Hg is derived from *hydrargyrum* (Latin) meaning 'liquid silver'. The major source of ***mercury*** is cinnabar (HgS), from which the metal is extracted by roasting in air (eq. 22.6).

$$HgS + O_2 \longrightarrow Hg + SO_2 \qquad (22.6)$$

Mercury has many uses but is a cumulative poison (see Box 22.2).

22.3 Physical properties

Some physical properties of the heavier *d*-block metals have already been discussed or tabulated:



- trends in first ionization energies (Fig. 1.16);
- ionization energies (Appendix 8);
- metallic radii (Table 6.2 and Fig. 19.1);
- values of Δ_aH^o (Table 6.2);
- lattice types (Table 6.2);
- an introduction to electronic absorption and emission spectra, and magnetism (Chapter 20).

For convenience, selected physical properties are listed in Table 22.1.

The electronic configurations of the ground state M(g) atoms change rather irregularly with increasing atomic number, more so than for the first row metals (compare Tables 22.1 and 21.1). The *nd* and $(n + 1)s$ atomic orbitals are closer in energy for $n = 4$ or 5 than for $n = 3$. For ions of the first row metals, the electronic configuration is generally d^n and this brings a certain amount of order to discussions of the properties of M^{2+} and M^{3+} ions. Simple M^{n+} cations of the heavier metals are rare, and it is not possible to discuss their chemistry in terms of simple redox couples (e.g. M^{3+}/M^{2+}) as we did for most of the first row metals.

The atomic numbers of pairs of second and third row metals (except Y and La) differ by 32 units and there is an appreciable difference in electronic energy levels and, therefore, electronic spectra and ionization energies. Within a triad, the first ionization energy is generally higher for the third than for the first and second metals, but the reverse is often true for removal of subsequent electrons. Even where a pair of second and third row metal compounds are isostructural, there are often quite significant differences in stability with respect to oxidation and reduction.

Figure 22.2 shows that, with the exception of Hg (group 12), the heavier metals have higher values of Δ_aH^o than their first row congeners. This is a consequence of the greater spatial extent of *d* orbitals with an increase in principal quantum number, and greater orbital overlap: $5d$–$5d > 4d$–$4d > 3d$–$3d$. The trend corresponds to the fact that, compared with the first row metals, the heavier metals exhibit many more compounds containing M–M bonds. Figure 22.2 also shows that the highest values of

BIOLOGY AND MEDICINE

Box 22.2 Mercury: a highly toxic, liquid metal

The low melting point (234 K) of Hg results in its being a unique metal. Its high thermal expansion coefficient makes it a suitable liquid for use in thermometers, and it has widespread application in barometers, diffusion pumps and in Hg switches in electrical apparatus. The use of mercury cells in the chlor-alkali process is gradually being phased out (see Box 11.4). Some other metals dissolve in mercury to give *amalgams*; their uses are varied, for example:

- Cd/Hg amalgam is a component in the Weston cell (see **cell 22.5**);
- Na/Hg amalgam is a convenient source of Na as a reducing agent;
- silver amalgam (≈50% Hg, 35% Ag, 13% Sn, 2% Cu by weight) is used for silver fillings in dentistry.

Despite these uses, Hg poses a serious health risk, as do its compounds (e.g. Me_2Hg). Mercury has a low enthalpy of vaporization (59 kJ mol^{-1}), and even below its boiling point (630 K) its volatility is high. At 293 K, a drop of liquid Hg vaporizes at a rate of 5.8 μg h^{-1} cm^{-2}, and at its saturation point the surrounding air contains 13 mg m^{-3}, a level far in excess of safe limits. Similarly, amalgams are a source of Hg vapour, and those in tooth fillings release toxic vapour directly into the human body. Research has shown that brushing teeth and chewing increases the vaporization process. The toxicity is now well established, and steps have been taken in some countries to phase out the use of Hg in dental fillings.

Mercury enters the environment from both industrial and natural sources. A continuously degassing volcano such as Mount Etna emits significant quantities of Hg (for Mount Etna, the rate of Hg emission is about 27 Mg per year). Once inorganic mercury enters water-courses and sediments of lakes, bacteria which normally reduce sulfates convert the metal into the form of methyl mercury, $[MeHg]^+$. In this form, mercury(II) progresses along the food chain, eventually accumulating in fish. The accumulation occurs because the rate of uptake exceeds the rate of mercury excretion by animals, and species high up the food chain (large fish and fish-eating birds and mammals, including man) may accumulate potentially toxic levels of mercury. Methyl mercury is lipophilic and is able to cross the blood–brain barrier. Mercury vapour, Hg(0), that enters the body accumulates in the kidneys, brain and testicles. It is oxidized to Hg(II) and, along with methyl mercury, is readily coordinated by soft sulfur donors present in proteins. The end result of mercury poisoning is severe damage to the central nervous system. One of the reasons why the toxicity is so high is that its retention time in body tissue is especially long, ≈65 days in the kidneys. The effects of Hg poisoning were referred to by Lewis Carroll in *Alice in Wonderland* – the hat-making occupation of the Mad Hatter brought him into regular contact with $Hg(NO_3)_2$ which was used in the production of felt hats.

Mercury droplets.

§ Osmium and iridium are the densest elements known (22.59 and 22.56 g cm^{-3} respectively).

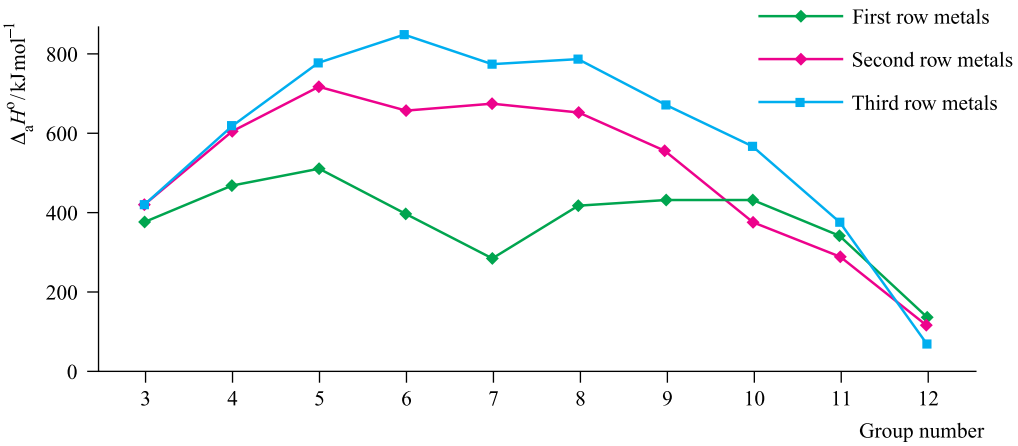

Fig. 22.2. Trends in the values of standard enthalpies of atomization (298 K) of the *d*-block metals; values are given in Tables 21.1 and 22.1.

$\Delta_a H^o$ occur for metals in the middle of a row. Among the heavier metals, there are numerous multimetal species with metal–metal bonding and these are discussed later in the chapter. Many low oxidation state *metal carbonyl clusters* also exist (see Chapter 24).

It is difficult to discuss satisfactorily the relative stabilities of oxidation states (Table 19.3).[†] The situation is complicated by the fact that low oxidation states for the heavier metals are stabilized in organometallic complexes, while in non-organometallic species, the stability of *higher* oxidation states tends to *increase* down a group. Consider group 6. Tungsten forms the stable WF_6 and WCl_6, while CrF_6 is not known. Although CrO_3 and chromate(VI) ions are powerful oxidizing agents, WO_3, tungstate(VI) species and molybdenum analogues are not readily reduced. In general, the stability of high oxidation states increases for a given triad in the sequence first row $\ll$ second row $<$ third row metals. Two factors appear important in the stabilization of third row high oxidation state compounds (e.g. AuF_5 and ReF_7) which have no second or first row counterparts:

- easier promotion of electrons for the 5*d* metals compared with 4*d* or 3*d* metals;
- better orbital overlap for 5*d* orbitals (or those with 5*d* character) than for 4*d* or 3*d* orbitals.

In comparing pairs of compounds such as MoF_6 and WF_6, or RuF_6 and OsF_6, the M–F bonds are stronger for the third than second row metal, and the symmetric stretching wavenumber and force constant are higher. Relativistic effects (see Box 13.3) are also important for the third row metals.

[†] See: S.H. Strauss (2001) *J. Chem. Ed.*, vol. 78, p. 1635 – 'In search of a deep understanding of the relative stabilities of transition metal halides'.

Effects of the lanthanoid contraction

Table 22.1 shows that pairs of metals in a triad (Zr and Hf, Nb and Ta etc.) are of similar radii. This is due to the *lanthanoid contraction*: the steady decrease in size along the series of lanthanoid metals Ce–Lu which lie between La and Hf in the third row of the *d*-block. The similarity extends to values of r_{ion} (where meaningful) and r_{cov} (e.g. the M–O distances in the high-temperature forms of ZrO_2 and HfO_2 differ by less than 1 pm) and to many pairs of second and third row compounds being isomorphous. Properties that depend mainly on atom or ion size (e.g. lattice energies, solvation energies, complex stability constants) are nearly the same for corresponding pairs of 4*d* and 5*d* metal compounds. Pairs of metals often occur naturally together (e.g. Zr and Hf, Nb and Ta) and are difficult to separate (Section 22.2).

Coordination numbers

Consistent with the increase in size in going from a first row to later metals in a triad, the heavier metals tend to show higher coordination numbers. The common range is 4 to 9 with the highest numbers being especially prevalent for metals in groups 3–5.

NMR active nuclei

Several of the metals have spin-active nuclei and this sometimes allows *direct* observation using NMR spectroscopy, e.g. ^{89}Y has a shift range >1000 ppm and ^{89}Y NMR spectroscopy is valuable for characterizing yttrium-containing compounds. In general, it is more convenient to make use of the coupling of metal nuclei to more easily observed nuclei such as ^{1}H, ^{13}C or ^{31}P. Some examples of nuclei with $I = \frac{1}{2}$ are ^{89}Y (100% abundant), ^{103}Rh (100%), ^{183}W (14.3%), ^{107}Ag (51.8%), ^{109}Ag (48.2%), ^{195}Pt (33.8%) and ^{187}Os (1.6%). Coupling to isotopes present

in <100% abundance gives rise to satellite peaks (see Section 4.8, Fig. 4.24 and Box 19.1).

22.4 Group 3: yttrium

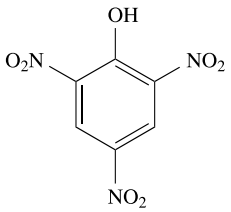
The metal

Bulk yttrium metal is passivated by an oxide layer and is quite stable in air. Metal turnings ignite if heated >670 K (eq. 22.7). Yttrium reacts with halogens (eq. 22.8) and combines with most other non-metals. The reaction between Y and H_2 under pressure was described in Section 10.7. Yttrium reacts slowly with cold water and dissolves in dilute acids (half-equation 22.9), liberating H_2.

$$4Y + 3O_2 \xrightarrow{\Delta} 2Y_2O_3 \qquad (22.7)$$

$$2Y + 3X_2 \xrightarrow{\Delta} 2YX_3 \quad (X = F, Cl, Br, I) \qquad (22.8)$$

$$Y^{3+} + 3e^- \rightleftharpoons Y \qquad E^\circ = -2.37\,V \qquad (22.9)$$



The chemistry of yttrium is that of the +3 oxidation state, the formation of lower hydrides being an exception.

Yttrium(III)

The halides YF_3, YCl_3, YBr_3 and YI_3 are white solids. The fluoride is water-insoluble, but YCl_3, YBr_3 and YI_3 are soluble. In solid YF_3, each Y atom is 9-coordinate (distorted tricapped trigonal prismatic), while both YCl_3 and YI_3 have layer structures (e.g. YI_3 adopts a BiI_3-structure) with 6-coordinate Y centres. Yttrium(III) chloride forms a hexahydrate, $YCl_3{\cdot}6H_2O$, which is correctly formulated as $[YCl_2(OH_2)_6]^+Cl^-$. Reaction of YCl_3 with KCl gives $K_3[YCl_6]$ containing the octahedral $[YCl_6]^{3-}$ ion. In contrast to ScF_3 which forms $[ScF_6]^{3-}$, YF_3 forms no complex ions of this type.

The white oxide Y_2O_3 is insoluble in water but dissolves in acids. It is used in ceramics, optical glasses and refractory materials (see also Section 22.2). The mixed metal oxide $YBa_2Cu_3O_7$ is a member of a family of materials that become superconducting upon cooling. These so-called *high-temperature superconductors* are discussed further in Section 28.4. Yttrium(III) hydroxide is a colourless solid, in which each Y^{3+} ion is in a tricapped trigonal prismatic YO_9 environment. The hydroxide is water-insoluble and exclusively basic.

In the coordination chemistry of Y^{3+}, coordination numbers of 6 to 9 are usual. Crystalline salts containing the aqua ions $[Y(OH_2)_8]^{3+}$ (dodecahedral, Fig. 19.10c) and $[Y(OH_2)_9]^{3+}$ (tricapped trigonal prismatic) have been structurally characterized. The Y^{3+} ion is 'hard' and in its complexes favours hard *N*- and *O*- donors, e.g. *trans*-$[YCl_4(THF)_2]^-$ (octahedral), *trans*-$[YCl_2(THF)_5]^+$ (pentagonal bipyramidal), $[Y(OH_2)_7(pic)]^{2+}$ (8-coordinate, Hpic = **22.3**), $[Y(NO_3\text{-}O,O')_3(OH_2)_3]$ (irregular 9-coordinate)

Hpic = picric acid

(22.3)

and $[Y(NO_3)_5]^{2-}$ (see end of Section 9.11). Reaction 22.10 yields a rare example of 3-coordinate Y(III). In the solid state, $[Y\{N(SiMe_3)_2\}_3]$ has a trigonal pyramidal rather than planar structure but this is probably caused by crystal packing effects (see Section 19.7).

$$YCl_3 + 3Na[N(SiMe_3)_2] \longrightarrow [Y\{N(SiMe_3)_2\}_3] + 3NaCl \qquad (22.10)$$

22.5 Group 4: zirconium and hafnium

The metals

In a finely divided form, Hf and Zr metals are pyrophoric, but the bulk metals are passivated. The high corrosion resistance of Zr is due to the formation of a dense layer of inert ZrO_2. The metals are not attacked by dilute acids (except HF) unless heated, and aqueous alkalis have no effect even when hot. At elevated temperatures, Hf and Zr combine with most non-metals (e.g. eq. 22.11).

$$MCl_4 \xleftarrow{Cl_2,\,\Delta} M \xrightarrow{O_2,\,\Delta} MO_2 \quad (M = Hf \text{ or } Zr) \qquad (22.11)$$

More is known about the chemistry of Zr than Hf, the former being more readily available (see Section 22.2).

Much of the chemistry concerns Zr(IV) and Hf(IV), the lower oxidation states being less stable with respect to oxidation than the first group member, Ti(III). In aqueous solutions, only M(IV) is stable although not as M^{4+}, even though tables of data may quote half-equation 22.12; solution species (see below) depend upon conditions.

$$M^{4+} + 4e^- \rightleftharpoons M \quad \begin{cases} M = Zr, & E^\circ = -1.70\,V \\ M = Hf, & E^\circ = -1.53\,V \end{cases} \qquad (22.12)$$

Stabilization of low oxidation states of Zr and Hf by π-acceptor ligands is discussed in Chapter 24.

Zirconium(IV) and hafnium(IV)

The halides MX_4 (M = Zr, Hf; X = F, Cl, Br, I; see Fig. 22.17), formed by direct combination of the elements, are white solids with the exception of orange-yellow ZrI_4

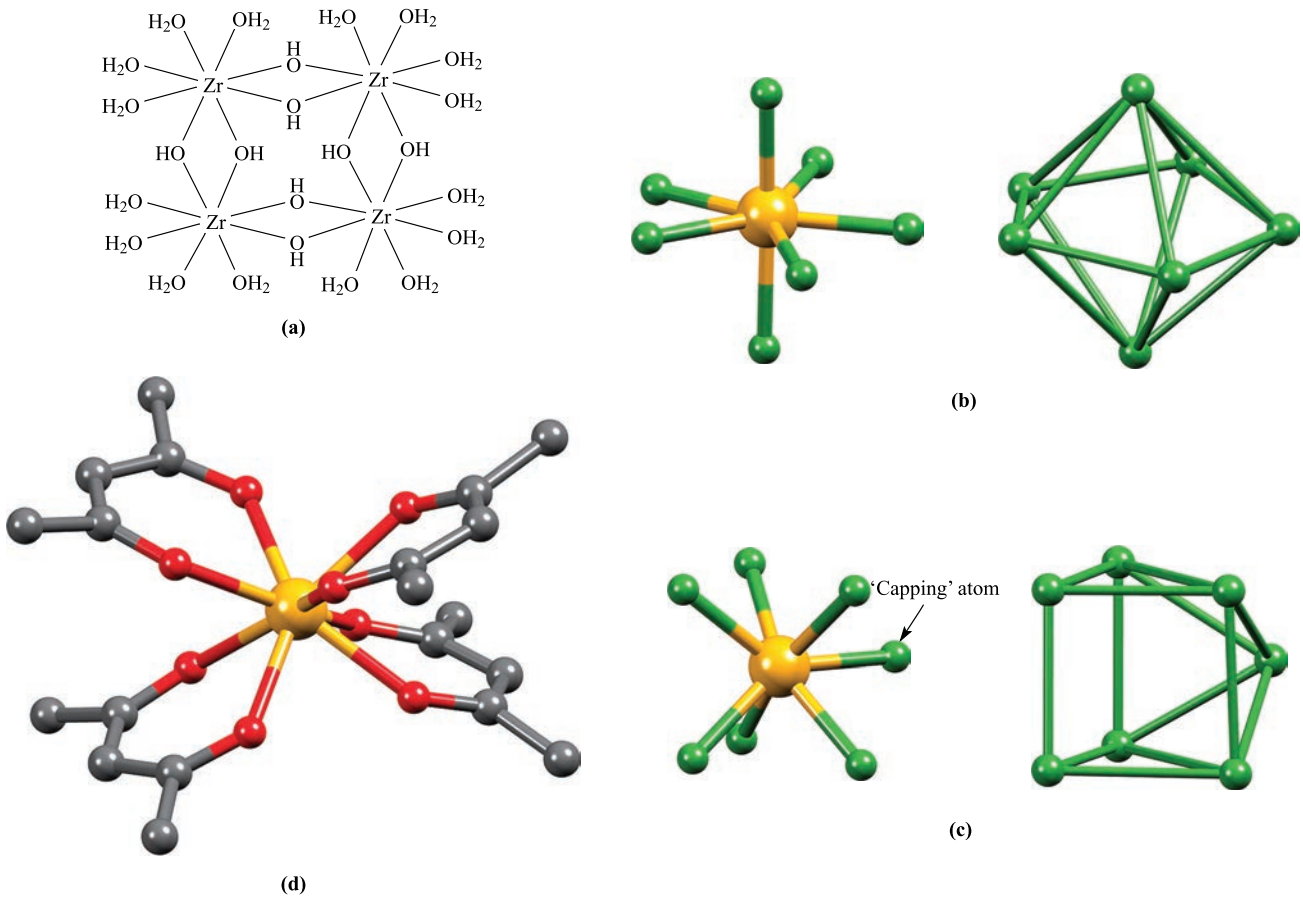


Fig. 22.3. (a) Representation of the structure of $[Zr_4(OH)_8(OH_2)_{16}]^{8+}$ in $[Zr_4(OH)_8(OH_2)_{16}]Cl_8{\cdot}12H_2O$, (b) the pentagonal bipyramidal structure (X-ray diffraction) of $[ZrF_7]^{3-}$ in $[H_3N(CH_2)_2NH_2(CH_2)_2NH_3][ZrF_7]$ [V.V. Tkachev *et al.* (1993) *Koord. Khim.*, vol. 19, p. 288], (c) the monocapped trigonal prismatic structure (X-ray diffraction) of $[ZrF_7]^{3-}$ in the guanidinium salt [A.V. Gerasimenko *et al.* (1985) *Koord. Khim.*, vol. 11, p. 566] and (d) the square antiprismatic structure (X-ray diffraction) of $[Zr(acac)_4]$ [W. Clegg (1987) *Acta Crystallogr., Sect. C*, vol. 43, p. 789]. Hydrogen atoms in (d) have been omitted; colour code: Zr, yellow; C, grey; O, red; F, green.

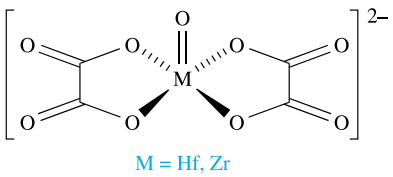
and HfI_4. The solids possess infinite structures ($ZrCl_4$, $ZrBr_4$, ZrI_4 and HfI_4 contain chains of edge-sharing octahedra) but the vapours contain tetrahedral molecules. Zirconium(IV) fluoride is dimorphic. The α-form consists of a network of F-bridged ZrF_8 square antiprisms and converts (>720 K) to β-ZrF_4 in which each Zr centre is dodecahedrally sited. Ultra-pure ZrF_4 for use in optical fibres and IR spectrometer parts is made by treatment of $[Zr(BH_4)_4]$ (see Section 13.5) with HF and F_2. The chlorides, bromides and iodides are water-soluble, but hydrolyse to MOX_2. Water reacts with ZrF_4 to give $[F_3(H_2O)_3Zr(\mu\text{-}F)_2Zr(OH_2)_3F_3]$. Both ZrF_4 and $ZrCl_4$ form highly electrically conducting materials with graphite, e.g. the reaction of ZrF_4, F_2 and graphite gives $C_nF(ZrF_4)_m$ ($n = 1$–100, $m = 0.0001$–0.15). The Lewis acidity of the halides is seen in the formation of complexes such as $HfCl_4{\cdot}2L$ ($L = NMe_3$, THF) and in the use of $ZrCl_4$ as a Lewis acid catalyst.

Oxides of Zr(IV) and Hf(IV) are produced by direct combination of the elements or by heating MCl_4 with H_2O followed by dehydration. The white oxides are isostructural and adopt extended structures in which Zr and Hf centres are 7-coordinate. Zirconium(IV) oxide is inert, and is used as an opacifier in ceramics and enamels and as an additive to synthetic apatites (see Section 15.2 and Box 15.11) used in dentistry. Pure ZrO_2 undergoes a phase change at 1370 K which results in cracking of the material, and for use in, for example, refractory materials, the higher temperature cubic phase is stabilized by adding MgO or CaO. Crystals of *cubic zirconia* (see Section 6.18) are commercially important as artificial diamonds. The addition of $[OH]^-$ to any water-soluble Zr(IV) compound produces the white amorphous $ZrO_2{\cdot}xH_2O$. There is no true Zr(IV) hydroxide.

In aqueous acidic solution, Zr(IV) compounds are present as partly hydrolysed species, e.g. $[Zr_3(OH)_4]^{8+}$ and $[Zr_4(OH)_8]^{8+}$. From solutions of $ZrCl_4$ in dilute HCl, '$ZrOCl_2{\cdot}8H_2O$' can be crystallized; this is tetrameric, $[Zr_4(OH)_8(OH_2)_{16}]Cl_8{\cdot}12H_2O$, and contains $[Zr_4(OH)_8(OH_2)_{16}]^{8+}$ (Fig. 22.3a) in which each Zr is dodecahedrally sited.

The high coordination numbers exhibited in some apparently simple compounds of Zr(IV) and Hf(IV) extend to

their complexes (e.g. see Fig. 19.11), hard fluorido and oxygen-donor ligands being favoured, e.g.:



- pentagonal bipyramidal: $[ZrF_7]^{3-}$ (Fig. 22.3b, e.g. Na^+, K^+ salts, structure is cation-dependent), $[HfF_7]^{3-}$, (e.g. K^+ salt, eq. 22.13), $[F_4(H_2O)Zr(\mu\text{-}F)_2Zr(OH_2)F_4]^{2-}$;
- capped trigonal prismatic: $[ZrF_7]^{3-}$ (Fig. 22.3c, e.g. $[NH_4]^+$ salt, structure is cation-dependent);
- dodecahedral: $[Zr(NO_3\text{-}O,O')_4]$ (eq. 22.14), $[Zr(ox)_4]^{4-}$;
- square antiprismatic: $[Zr(acac)_4]$ (Fig. 22.3d).

$$HfF_4 + 3KF \xrightarrow{\Delta \text{ in sealed Pt tube}} K_3[HfF_7] \qquad (22.13)$$

$$ZrCl_4 + 4N_2O_5 \xrightarrow{\text{anhydrous conditions}} [Zr(NO_3\text{-}O,O')_4] + 4NO_2Cl \qquad (22.14)$$

$$ZrCl_4 + 2CsCl \xrightarrow{1070\text{ K, in sealed } SiO_2 \text{ tube}} Cs_2[ZrCl_6] \qquad (22.15)$$

The $[ZrCl_6]^{2-}$ ion (eq. 22.15) is octahedral; colourless $Cs_2[ZrCl_6]$ adopts a $K_2[PtCl_6]$ structure (see Pt(IV) in Section 22.11) and is used as an image intensifier in X-ray imaging. A number of oxido complexes with square-based pyramidal structures are known, e.g. $[M(O)(ox)_2]^{2-}$ (M = Hf, Zr, **22.4**) and $[Zr(O)(bpy)_2]^{2+}$. Lower coordination numbers are stabilized by amido ligands, e.g. tetrahedral $[M(NPh_2)_4]$ and $[M\{N(SiMe_3)_2\}_3Cl]$ (M = Hf, Zr).

M = Hf, Zr

(22.4)

Lower oxidation states of zirconium and hafnium

The blue or black halides ZrX_3, ZrX_2 and ZrX (X = Cl, Br, I) are obtained by reduction of ZrX_4, e.g. heating Zr and $ZrCl_4$ in a sealed Ta tube gives ZrCl or $ZrCl_3$ depending on temperature. The corresponding hafnium chlorides are prepared similarly, e.g. eqs. 22.16 and 22.17.

$$Hf + HfCl_4 \xrightarrow{1070\text{ K, in sealed Ta tube}} HfCl \qquad (22.16)$$

$$Hf + HfCl_4 \xrightarrow{720\text{ K, in sealed Ta tube}} HfCl_3 \qquad (22.17)$$

The monohalides have layer structures consisting of sheets of metal and halogen atoms sequenced XMMX . . . XMMX . . . and are metallic conductors in a direction *parallel* to the layers. Compare this with the conductivity of graphite (see Section 14.4). The di- and trihalides disproportionate (eqs. 22.18 and 22.19).

$$2MCl_2 \longrightarrow M + MCl_4 \qquad (M = Hf, Zr) \qquad (22.18)$$

$$2MCl_3 \longrightarrow MCl_2 + MCl_4 \qquad (M = Hf, Zr) \qquad (22.19)$$

In general, there is no aqueous chemistry of M(I), M(II) and M(III), but exceptions are some hexazirconium clusters which are water-stable.[†]

Zirconium clusters

In this section, we introduce the first group of cluster compounds of the heavier *d*-block metals in which the external ligands are halides. Octahedral M_6 frameworks are present in most of these clusters, but, in contrast to similar group 5 and 6 species (Sections 22.6 and 22.7), most zirconium clusters are stabilized by an *interstitial atom*, e.g. Be, B, C or N.

Heating Zr powder, $ZrCl_4$ and carbon in a sealed Ta tube above 1000 K produces $Zr_6Cl_{14}C$. Under similar reaction conditions and with added alkali metal halides, clusters such as $Cs_3[Zr_6Br_{15}C]$, $K[Zr_6Br_{13}Be]$ and $K_2[Zr_6Br_{15}B]$ are formed. In the solid state, these octahedral Zr_6 clusters are connected by bridging halido ligands to generate extended structures. The formulae may be written to show the connectivity, e.g. writing $[Zr_6Br_{15}B]^{2-}$ as $[\{Zr_6(\mu\text{-}Br)_{12}B\}Br_{6/2}]^{2-}$ indicates that Zr_6 clusters are connected into a 3-dimensional network by six doubly-bridging Br atoms, three 'belonging' to each cluster.[‡] Some of these clusters can be 'cut-out' from the 3-dimensional network, for example, by working in ionic liquid media (see Fig. 9.9c and accompanying text) or, in some cases, by dissolving the solid state precursors in aqueous solution. Salts such as $[H_3O]_4[Zr_6Cl_{18}B]$ and $[H_3O]_5[Zr_6Cl_{18}Be]$ have been isolated under aqueous conditions, and are stabilized in the presence of acid.

In contrast to the high-temperature syntheses of Zr_6X clusters (X = B, C, N) described above, reduction of $ZrCl_4$ by Bu_3SnH followed by addition of PR_3 gives discrete clusters such as $[Zr_6Cl_{14}(P^nPr_3)_4]$ (Fig. 22.4a, Zr–Zr = 331–337 pm) and $[Zr_5Cl_{12}(\mu\text{-}H)_2(\mu_3\text{-}H)_2(PMe_3)_5]$ (Fig. 22.4b, Zr–Zr = 320–354 pm). Varying the reaction conditions leads to clusters such as $[Zr_6Cl_{14}(PMe_3)H_4]$, $[Zr_6Cl_{18}H_4]^{3-}$ and $[Zr_6Cl_{18}H_5]^{4-}$.*

22.6 Group 5: niobium and tantalum

The metals

The properties of Nb and Ta (and of corresponding pairs of their compounds) are similar. At high temperatures, both are

[†] X. Xie and T. Hughbanks (2000) *Inorg. Chem.*, vol. 39, p. 555 – 'Reduced zirconium halide clusters in aqueous solution'.

[‡] The nomenclature is actually more complicated, but more informative, e.g. R.P. Ziebarth and J.D. Corbett (1985) *J. Am. Chem. Soc.*, vol. 107, p. 4571.

* For a discussion of the location of H atoms in these and related Zr_6 cages, see: L. Chen, F.A. Cotton and W.A. Wojtczak (1997) *Inorg. Chem.*, vol. 36, p. 4047.

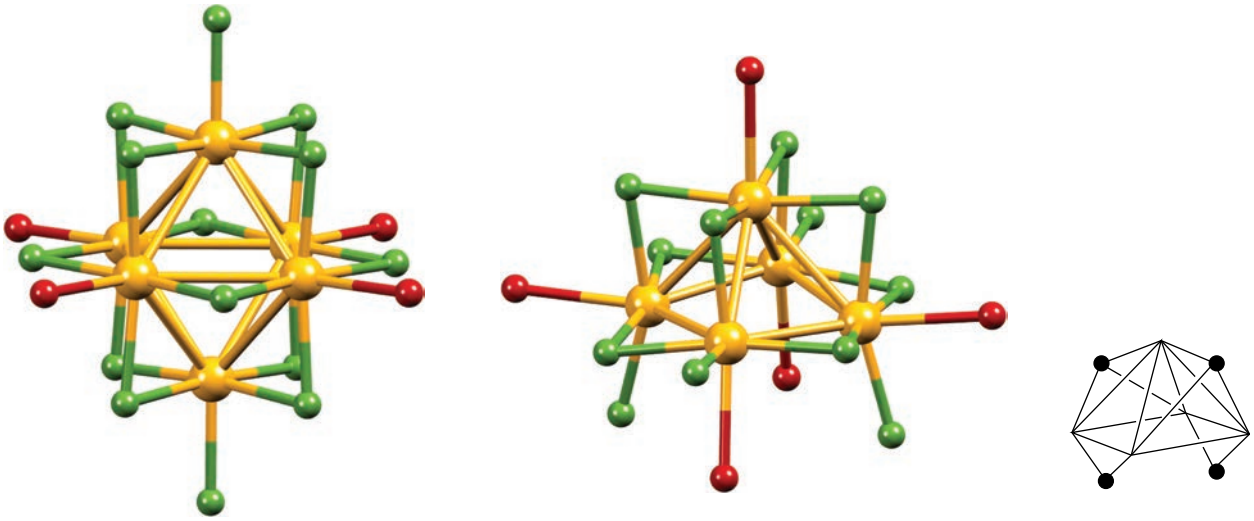


Fig. 22.4. The structures (determined by X-ray diffraction) of (a) $[Zr_6Cl_{14}(P^nPr_3)_4]$ [F.A. Cotton *et al.* (1992) *Angew. Chem. Int. Ed.*, vol. 31, p. 1050] and (b) $[Zr_5Cl_{12}(\mu\text{-}H)_2(\mu_3\text{-}H)_2(PMe_3)_5]$ [F.A. Cotton *et al.* (1994) *J. Am. Chem. Soc.*, vol. 116, p. 4364]. Colour code: Zr, yellow; Cl, green; P, red; Me and ^{n}Pr groups are omitted. The inset in (b) shows the μ-H and μ_3-H positions (black dots) with respect to the Zr_5 framework.

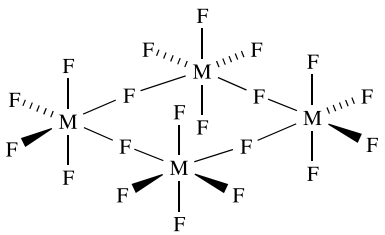
attacked by O_2 (eq. 22.20) and the halogens (eq. 22.21) and combine with most non-metals.

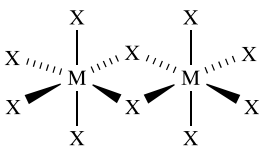
$$4M + 5O_2 \xrightarrow{\Delta} 2M_2O_5 \qquad (M = Nb, Ta) \qquad (22.20)$$



$$2M + 5X_2 \xrightarrow{\Delta} 2MX_5 \qquad (M = Nb, Ta; X = F, Cl, Br, I) \qquad (22.21)$$

The metals are passivated by the formation of oxide coatings, giving them high corrosion resistance. They are inert towards non-oxidizing acids, HF and HF/HNO_3 being two of the few reagents to attack them under ambient conditions. Fused alkalis react with Nb and Ta at high temperatures.

The chemistry of Nb and Ta is predominantly that of the +5 oxidation state. The heavier group 5 metals differ from V (see Section 21.6) in the relative instability of their lower oxidation states, their failure to form simple ionic compounds, and the inertness of the M(V) oxides. In contrast to V, it is not meaningful to assign ionic radii to Nb and Ta in their lower oxidation states since they tend to form hexanuclear clusters with metal–metal bonding (see later). For M(V), radii of 64 pm are usually tabulated for 'Nb^{5+}' and 'Ta^{5+}', but these are unreal quantities since Nb(V) and Ta(V) compounds are essentially covalent.



Niobium(V) and tantalum(V)

Niobium(V) and tantalum(V) halides (white MF_5, yellow MCl_5, yellow-red MBr_5 and yellow-brown MI_5) are volatile, air- and moisture-sensitive solids made by reaction 22.21. The chlorides and bromides are also made by halogenation of M_2O_5. NbI_5 is produced commercially by reaction of $NbCl_5$, I_2 and HI, and TaI_5 by treating $TaCl_5$ with BI_3. Each halide is monomeric (trigonal bipyramidal) in the gas phase, but the solid fluorides are tetrameric (**22.5**), while solid MCl_5, MBr_5 and MI_5 consist of dimers (**22.6**). The M−F−M bridges in tetramer **22.5** are linear and the $M-F_{bridge}$ bonds are longer (and weaker) than $M-F_{terminal}$ (206 *vs* 177 pm for M = Nb). Similarly, in dimer **22.6**, $M-X_{bridge} > M-X_{terminal}$.

M = Nb, Ta

(22.5)

M = Nb, Ta; X = Cl, Br, I

(22.6)

The halides NbF_5, TaF_5, $NbCl_5$ and $TaCl_5$ are useful starting materials in the chemistry of these metals. They are Friedel–Crafts catalysts and the Lewis acidity of NbF_5 and TaF_5 is

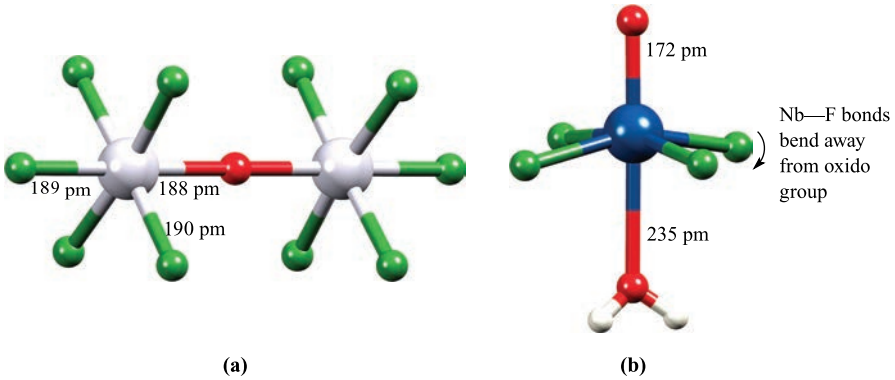


Fig. 22.5. The structures (determined by X-ray diffraction for the $[Et_4N]^+$ salts) of (a) $[Ta_2OF_{10}]^{2-}$ [J.C. Dewan *et al.* (1977) *J. Chem. Soc., Dalton Trans.*, p. 978] and (b) $[Nb(OH_2)(O)F_4]^-$ [N.G. Furmanova *et al.* (1992) *Kristallografiya*, vol. 37, p. 136]. Colour code: Ta, pale grey; Nb, blue; F, green; O, red; H, white.

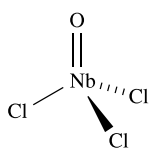
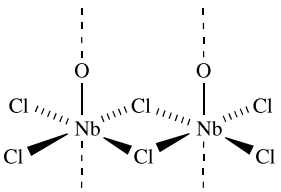


apparent in reaction 22.22 (which takes place in non-aqueous media, see Section 9.10), in the formation of related salts and other complexes (see later), and in the ability of a TaF_5/HF mixture to act as a superacid (see Section 9.9).

$$MF_5 + BrF_3 \longrightarrow [BrF_2]^+[MF_6]^- \quad (M = Nb, Ta) \qquad (22.22)$$

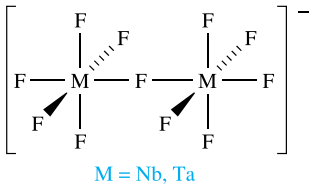


The compounds MOX_3 and MO_2X (M = Nb, Ta; X = F, Cl, Br, I) are prepared by halogenation of M_2O_5, or reaction of MX_5 with O_2 under controlled conditions. The halidooxidometal(V) compounds are monomeric in the vapour and polymeric in the solid: $NbOCl_3$ is representative with gas-phase monomer (**22.7**) and solid-phase polymer (**22.8**) which contains oxygen-bridged Nb_2Cl_6-units. Related anions include octahedral $[MOX_5]^{2-}$ (M = Nb, Ta; X = F, Cl), $[MOCl_4]^-$ (eq. 22.23), and $[Ta_2OX_{10}]^{2-}$ (X = F, Cl; Fig. 22.5a). The linearity of the bridge in $[Ta_2OX_{10}]^{2-}$ indicates multiple bond character (refer to Fig. 22.20).

$$MOCl_3 + ONCl \longrightarrow [NO]^+[MOCl_4]^- \quad (M = Nb, Ta) \qquad (22.23)$$

The structure of $[Nb(OH_2)(O)F_4]^-$ (Fig. 22.5b) shows how oxido and aqua ligand O atoms can be distinguished from the Nb−O bond lengths; it is not always possible to locate H atoms in X-ray diffraction studies (see Section 4.11).

(22.7)



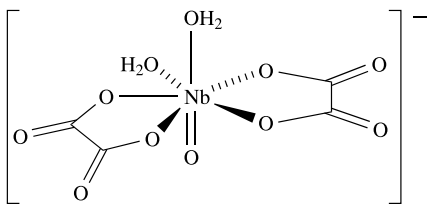
(22.8)

Hydrolysis of $TaCl_5$ with H_2O produces the hydrated oxide $Ta_2O_5{\cdot}xH_2O$. $Nb_2O_5{\cdot}xH_2O$ is best formed by boiling $NbCl_5$ in aqueous HCl. Heating the hydrates yields anhydrous Nb_2O_5 and Ta_2O_5 which are dense, inert white solids. Various polymorphs of Nb_2O_5 exist, with NbO_6 octahedra being the usual structural unit; the structures of both metal(V) oxides are complicated networks. Uses of Nb_2O_5 include those as a catalyst, in ceramics and in humidity sensors. Both Nb_2O_5 and Ta_2O_5 are insoluble in acids except concentrated HF, but dissolve in molten alkalis. If the resultant melts are dissolved in water, salts of niobates (precipitated below ≈pH 7) and tantalates (precipitated below ≈pH 10) can be isolated, e.g. $K_8[Nb_6O_{19}]{\cdot}16H_2O$ and $[Et_4N]_6[Nb_{10}O_{28}]{\cdot}6H_2O$. The $[Nb_6O_{19}]^{8-}$ ion consists of six MO_6 octahedral units with shared O atoms; it is isoelectronic and isostructural with $[Mo_6O_{19}]^{2-}$ and $[W_6O_{19}]^{2-}$ (see Fig. 22.9c). The $[Nb_{10}O_{28}]^{6-}$ ion is isostructural with $[V_{10}O_{28}]^{6-}$ (Fig. 21.9e) and contains octahedral building blocks as in $[Nb_6O_{19}]^{8-}$.

Heating Nb_2O_5 or Ta_2O_5 with group 1 or group 2 metal carbonates at high temperatures (e.g. Nb_2O_5 with Na_2CO_3 at 1650 K in a Pt crucible) yields mixed metal oxides such as $LiNbO_3$, $NaNbO_3$, $LiTaO_3$, $NaTaO_3$ and $CaNb_2O_6$. The $M'MO_3$ compounds crystallize with perovskite structures (Fig. 6.26), and exhibit ferroelectric and piezoelectric properties (see Section 14.9) which lead to uses in electro-optical and acoustic devices.

The coordination chemistry of Nb(V) and Ta(V) is well developed and there is a close similarity in the complexes formed by the two metals. Complexes with hard donors are favoured. Although 6-, 7- and 8-coordinate complexes are the most common, lower coordination numbers are observed, e.g. in $[Ta(NEt_2)_5]$ (trigonal bipyramidal), $[Nb(NMe_2)_5]$ and $[NbOCl_4]^-$ (square-based pyramidal). The Lewis acidity of the pentahalides, especially NbF_5 and TaF_5, leads to the formation of salts such as $Cs[NbF_6]$ and $K[TaF_6]$ (octahedral anions), $K_2[NbF_7]$ and $K_2[TaF_7]$ (capped trigonal prismatic anions), $Na_3[TaF_8]$ and $Na_3[NbF_8]$ (square antiprismatic anions) and $[^nBu_4N][M_2F_{11}]$ (eq. 22.24 and structure **22.9**).

$$MF_5 \xrightarrow{[^nBu_4N][BF_4]} [^nBu_4N][MF_6] \xrightarrow{MF_5} [^nBu_4N][M_2F_{11}] \quad (M = Nb, Ta) \qquad (22.24)$$



(22.9)

Other complexes include:

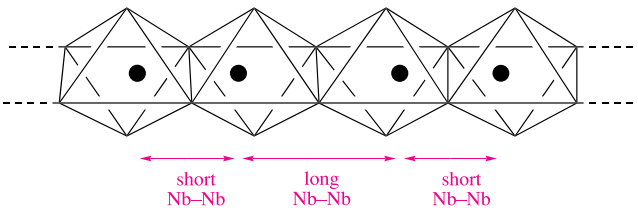
- octahedral: $[Nb(OH_2)(O)F_4]^-$ (Fig. 22.5b), $[Nb(NCS\text{-}N)_6]^-$, $[NbF_5(OEt_2)]$, *mer*-$[NbCl_3(O)(NCMe)_2]$;
- intermediate between octahedral and trigonal prismatic: $[Nb(SCH_2CH_2S)_3]^-$;
- pentagonal bipyramidal: $[Nb(OH_2)_2(O)(ox)_2]^-$ (**22.10**); $[Nb(O)(ox)_3]^{3-}$ (oxido ligand in an axial site);
- dodecahedral: $[M(\eta^2\text{-}O_2)_4]^{3-}$ (M = Nb, Ta), $[Nb(\eta^2\text{-}O_2)_2(ox)_2]^{3-}$;
- square antiprismatic: $[Ta(\eta^2\text{-}O_2)_2F_4]^{3-}$.

(For explanation of the η-nomenclature, see Box 23.1.)

(22.10)

Self-study exercises

1. The solution ^{19}F NMR spectrum of $[^nBu_4N][Ta_2F_{11}]$ at 173 K shows three signals: a doublet of quintets ($J = 165$ and 23 Hz, respectively), a doublet of doublets ($J = 23$ and 42 Hz) and a signal consisting of 17 lines with relative intensities close to 1:8:28:56:72:72:84:120:142:120:84:72:72:56:28:8:1. Rationalize these data.



[*Ans.* See S. Brownstein (1973) *Inorg. Chem.*, vol. 12, p. 584]

2. The anion $[NbOF_6]^{3-}$ has C_{3v} symmetry. Suggest a structure for this ion.

[*Ans.* See Fig. 19.9a; O atom in unique site]

Niobium(IV) and tantalum(IV)

With the exception of TaF_4, all halides of Nb(IV) and Ta(IV) are known. They are dark solids, prepared by reducing the respective MX_5 by heating with metal M or Al. Niobium(IV) fluoride is paramagnetic (d^1) and isostructural with SnF_4 (**14.15**). In contrast, MCl_4, MBr_4 and MI_4 are diamagnetic (or weakly paramagnetic) consistent with the pairing of metal atoms in the solid state. The structures of $NbCl_4$ and NbI_4 consist of edge-sharing distorted NbX_6 octahedra (**22.11**) with alternating Nb−Nb distances (303 and 379 pm in $NbCl_4$; 331 and 436 pm in NbI_4). The solid state structure of $TaCl_4$ is similar, with alternating Ta–Ta distances of 299 and 379 pm.

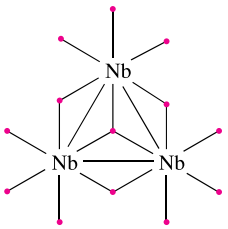
(22.11)

The tetrahalides are readily oxidized in air (e.g. NbF_4 to NbO_2F) and disproportionate on heating (reaction 22.25).

$$2TaCl_4 \xrightarrow{\Delta} TaCl_5 + TaCl_3 \qquad (22.25)$$

Blue-black NbO_2 is formed by reduction of Nb_2O_5 at 1070 K using H_2 or NH_3. It has a rutile structure (Fig. 6.24), distorted by pairing of Nb atoms (Nb−Nb = 280 pm). Heating Nb or Ta with elemental sulfur produces the metal(IV) sulfides (NbS_2 and TaS_2) which possess layer structures. Both compounds are polymorphic. The normal phase of NbS_2 comprises layers in which each Nb atom is in a trigonal prismatic environment. The layer structure of TaS_2 resembles that of CdI_2 (Fig. 6.25), but other phases of TaS_2 are known. TaS_2 is commercially available and exhibits lubricating properties similar to those of MoS_2 (see Box 22.5). One important property of the layered metal sulfides is their ability to form intercalation compounds by accommodating guest molecules or ions between the layers. For example, TaS_2 intercalates Li^+ ions and this is the basis for the use of TaS_2 and similar layered MS_2 solids as electrode materials in lithium ion-based batteries (see Section 28.2).

A range of Nb(IV) and Ta(IV) complexes are formed by reactions of MX_4 (X = Cl, Br, I) with Lewis bases containing *N*-, *P*-, *As*-, *O*- or *S*-donors, or by reduction of MX_5 in the presence of a ligand. Coordination numbers are typically 6, 7 or 8. For example, some structures confirmed for the *solid state* are:



- octahedral: *trans*-$[TaCl_4(PEt_3)_2]$, *cis*-$[TaCl_4(PMe_2Ph)_2]$;
- capped octahedral: $[TaCl_4(PMe_3)_3]$ (Fig. 19.9b);
- capped trigonal prismatic: $[NbF_7]^{3-}$ (eq. 22.26);

- dodecahedral: $[Nb(CN)_8]^{4-}$;
- square antiprismatic: $[Nb(ox)_4]^{4-}$.

$$4NbF_5 + Nb + 15KF \longrightarrow 5K_3[NbF_7] \qquad (22.26)$$

Lower oxidation state halides

Of the lower oxidation state compounds of Nb and Ta, we focus on halides. The compounds MX_3 (M = Nb, Ta and X = Cl, Br) are prepared by reduction of MX_5 and are quite inert solids. NbF_3 and TaF_3 crystallize with the ReO_3 structure (see Fig. 21.5).

(22.12)

A range of halides with M_3 or M_6 frameworks exist, but all have extended structures with the metal cluster units connected by bridging halides. The structure of Nb_3Cl_8 is represented in **22.12**, but of the nine outer Cl atoms shown, six are shared between two adjacent units, and three between three (see worked example 22.1). Alternatively, the structure can be considered in terms of an hcp array of Cl atoms with three-quarters of the octahedral holes occupied by Nb atoms such that they form Nb_3 triangles. Reduction of Nb_3I_8 (structurally analogous to Nb_3Cl_8) with Nb in a sealed tube at 1200 K yields Nb_6I_{11}. The formula can be written as $[Nb_6I_8]I_{6/2}$ indicating that $[Nb_6I_8]^{3+}$ units are connected by iodides shared between two clusters. (The ionic formulation is purely a formalism.) The $[Nb_6I_8]^{3+}$ cluster consists of an octahedral Nb_6-core, each face of which is iodido-capped (Fig. 22.6a). The clusters are connected into a network by bridges (Fig. 22.6c). Two other families of halides are M_6X_{14} (e.g. Nb_6Cl_{14}, Ta_6Cl_{14}, Ta_6I_{14}) and M_6X_{15} (e.g. Nb_6F_{15}, Ta_6Cl_{15}, Ta_6Br_{15}). Their formulae can be written as $[M_6X_{12}]X_{4/2}$ or $[M_6X_{12}]X_{6/2}$ showing that they contain cluster units $[M_6X_{12}]^{2+}$ and $[M_6X_{12}]^{3+}$ respectively (Fig. 22.6b). The clusters are

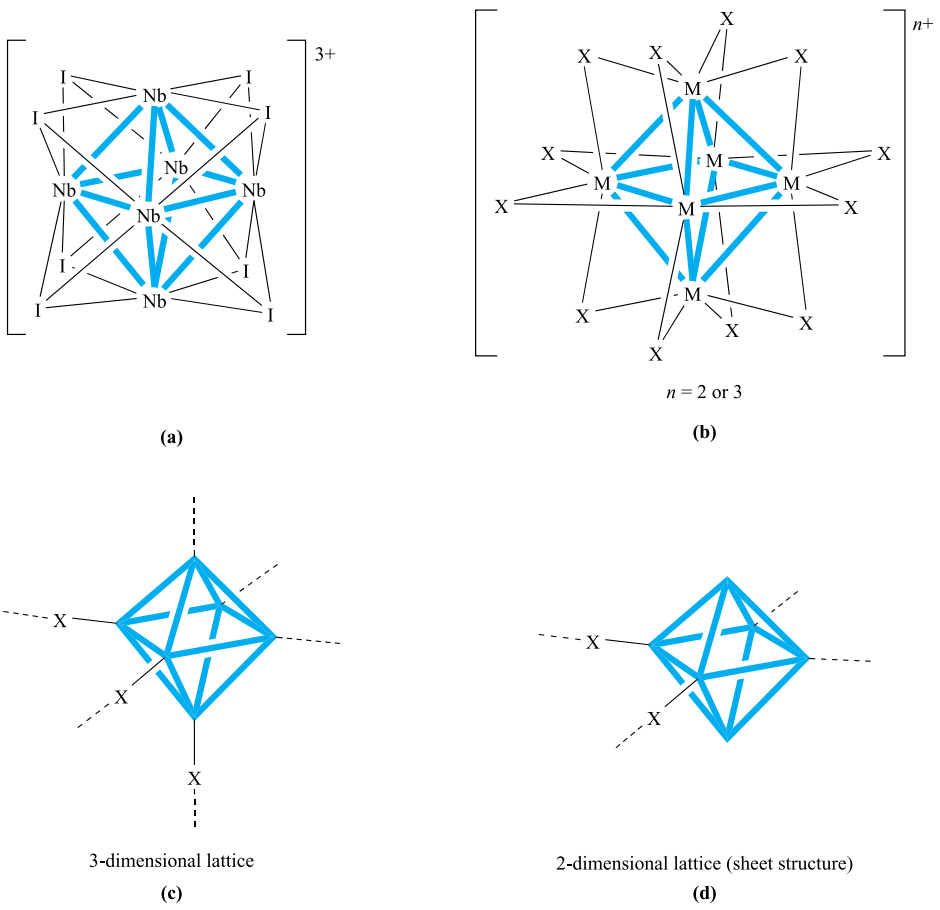


Fig. 22.6. Representations of the structures of (a) the $[Nb_6I_8]^{3+}$ unit found in Nb_6I_{11} and (b) the $[M_6X_{12}]^{n+}$ ($n = 2$ or 3) unit found in compounds of type M_6X_{14} and M_6X_{15} for M = Nb or Ta, X = halide. The cluster units are connected into (c) a 3-dimensional network or (d) a 2-dimensional sheet by bridging halides (see text).

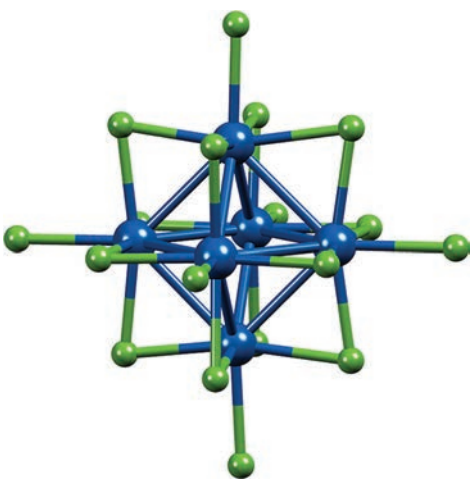
connected into either a 3-dimensional network (M_6X_{15}, Fig. 22.6c) or 2-dimensional sheet (M_6X_{14}, Fig. 22.6d).

Magnetic data show that the subhalides exhibit metal–metal bonding. The magnetic moment of Nb_3Cl_8 is 1.86 μ_B per Nb_3-unit (298 K) indicating one unpaired electron. This can be rationalized as follows:

- 3 Nb atoms provide 15 electrons (Nb s^2d^3);
- 8 Cl atoms provide 8 electrons (this is irrespective of the Cl bonding mode because bridge formation invokes coordinate bonds using Cl lone pairs);
- the total number of valence electrons is 23;
- 22 electrons are used in 8 Nb−Cl and 3 Nb−Nb single bonds;
- 1 electron is left over.

Compounds of the type M_6X_{14} are diamagnetic, while M_6X_{15} compounds have magnetic moments corresponding to one unpaired electron per M_6-cluster. If we consider M_6X_{14} to contain an $[M_6X_{12}]^{2+}$ unit, there are eight pairs of valence electrons remaining after allocation of 12 M−X bonds, giving a bond order of two-thirds per M−M edge (12 edges). In M_6X_{15}, after allocating electrons to 12 M−X single bonds, the $[M_6X_{12}]^{3+}$ unit has 15 valence electrons for M−M bonding. The observed paramagnetism indicates that one unpaired electron remains unused. The magnetic moment (per hexametal unit) of Ta_6Br_{15}, for example, is temperature-dependent: $\mu_{eff} = 2.17\,\mu_B$ at 623 K, 1.73 μ_B at 222 K and 1.34 μ_B at 77 K.

There is also a family of discrete clusters $[M_6X_{18}]^{n-}$ (M = Nb, Ta; X = Cl, Br, I). For example, the reaction of Nb_6Cl_{14} with KCl at 920 K produces $K_4[Nb_6Cl_{18}]$. The $[Nb_6Cl_{18}]^{4-}$ ion is oxidized by I_2 to $[Nb_6Cl_{18}]^{3-}$ or by Cl_2 to $[Nb_6Cl_{18}]^{2-}$. The $[M_6X_{18}]^{n-}$ ions are structurally similar (Fig. 22.7) and relationships between the structure of this discrete ion, that of the $[M_6Cl_{12}]^{n+}$ ion (Fig. 22.6b) and of the Zr_6 clusters (e.g. Fig. 22.4a) are clear.



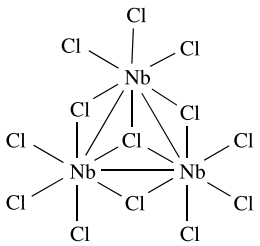


Fig. 22.7. The structure (X-ray diffraction) of $[Nb_6Cl_{18}]^{3-}$ in the $[Me_4N]^+$ salt [F.W. Koknat *et al.* (1974) *Inorg. Chem.*, vol. 13, p. 295]. Colour code: Nb, blue; Cl, green.

Worked example 22.1 Structures of halides of Nb

Part of the solid state structure of Nb_3Cl_8 is shown below. Explain how this structure is consistent with the stoichiometry of the compound.

The diagram above represents part of an extended structure. The 'terminal' Cl atoms are shared between units: 6 are shared between 2 units, and 3 are shared between 3 units.

Per Nb_3 unit, the number of Cl atoms

$$= 4 + (6 \times \tfrac{1}{2}) + (3 \times \tfrac{1}{3}) = 8$$

Thus, the stoichiometry of the compound = Nb_3Cl_8.

Self-study exercises

The answers to these questions can be found by reading the last subsection.

1. The solid state structure of NbI_4 consists of edge-shared octahedra. Explain how this description is consistent with the stoichiometry of the compound.
2. The formula of Nb_3I_{11} can be written as $[Nb_3I_8]I_{6/2}$. Explain how this can be translated into a description of the solid state structure of the compound.

22.7 Group 6: molybdenum and tungsten

The metals

The properties of Mo and W are similar. Both have very high melting points and enthalpies of atomization (Table 6.2 and Fig. 22.2). The metals are not attacked in air at 298 K, but react with O_2 at high temperatures to give MO_3, and are readily oxidized by the halogens (see later). Even at 298 K, oxidation to M(VI) occurs with F_2

(eq. 22.27, see Fig. 22.17). Sulfur reacts with Mo or W (e.g. eq. 22.28). Other sulfide phases of Mo are produced under different conditions.

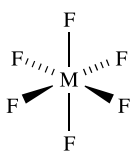
$$M + 3F_2 \longrightarrow MF_6 \qquad (M = Mo, W) \qquad (22.27)$$

$$M + 2S \xrightarrow{\Delta} MS_2 \qquad (M = Mo, W) \qquad (22.28)$$

The metals are inert towards most acids but are rapidly attacked by fused alkalis in the presence of oxidizing agents.

Molybdenum and tungsten exhibit a range of oxidation states (Table 19.3) although simple mononuclear species are not known for all states. The extensive chemistry of Cr(II) and Cr(III) (see Section 21.7) has no counterpart in the chemistries of the heavier group 6 metals, and, in contrast to Cr(VI), Mo(VI) and W(VI) are poor oxidizing agents. Since $W^{3+}(aq)$ is not known, no reduction potential for the W(VI)/W(III) couple can be given. Equations 22.29 and 22.30 compare the Cr and Mo systems at pH 0.

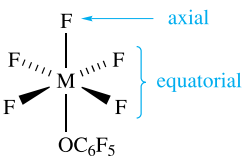
$$[Cr_2O_7]^{2-} + 14H^+ + 6e^- \rightleftharpoons 2Cr^{3+} + 7H_2O \quad E^o = +1.33\,V \qquad (22.29)$$



$$H_2MoO_4 + 6H^+ + 3e^- \rightleftharpoons Mo^{3+} + 4H_2O \quad E^o = +0.1\,V \qquad (22.30)$$

Molybdenum and tungsten compounds are usually isomorphous and essentially isodimensional.

Molybdenum(VI) and tungsten(VI)



The hexafluorides are formed by reaction 22.27, or by reactions of MoO_3 with SF_4 (sealed vessel, 620 K) and WCl_6 with HF or SbF_3. Both MoF_6 (colourless liquid, bp 307 K) and WF_6 (pale yellow, volatile liquid, bp 290 K) have molecular structures (**22.13**) and are readily hydrolysed. The only other hexahalides that are well established are the dark blue WCl_6 and WBr_6. The former is made by heating W or WO_3 with Cl_2 and has an octahedral molecular structure. WBr_6 (also molecular) is best made by reaction 22.31. Both WCl_6 and WBr_6 readily hydrolyse. Reactions of WF_6 with Me_3SiCl, or WCl_6 with F_2, yield mixed halides, e.g. *cis*- and *trans*-WCl_2F_4 and *mer*- and *fac*-WCl_3F_3.

$$W(CO)_6 + 3Br_2 \longrightarrow WBr_6 + 6CO \qquad (22.31)$$

M = Mo, W

(22.13)

M = Mo, W

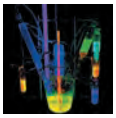
(22.14)

While MoF_6 and WF_6 are octahedral, the isoelectronic molecules $MoMe_6$ and WMe_6 adopt distorted trigonal prismatic structures (Box 20.3). Theoretical studies at the DFT level (see Section 4.13) show that there is only a low energy barrier to interconversion of octahedral and trigonal prismatic structures for MoF_6 and WF_6. Since the F atoms in an MF_6 molecule are equivalent, it is difficult to prove whether interconversion occurs in practice. However, the solution ^{19}F NMR spectra of $MF_5(OC_6F_5)$ (**22.14**) are temperature dependent, consistent with stereochemically non-rigid molecules. Moreover, in $WF_5(OC_6F_5)$, the retention of coupling between ^{19}F and ^{183}W nuclei between the low and high-temperature limiting spectra confirms that the fluxional process occurs without W–F bond cleavage.[†]

Self-study exercise

WF_6 reacts with PMe_3 or PMe_2Ph to form the 7-coordinate complex $WF_6(PMe_3)$ or $WF_6(PMe_2Ph)$. In the solid state, these possess capped trigonal prismatic and capped octahedral structures, respectively. Each of the solution ^{31}P and ^{19}F NMR spectra of $WF_6(PMe_3)$ exhibits one signal (J_{PF} = 74 Hz), as does each of the ^{31}P and ^{19}F NMR spectra of $WF_6(PMe_2Ph)$. What conclusions can you draw from these data?

[*Ans.* S. El-Kurdi *et al.* (2010) *Chem. Eur. J.*, vol. 16, p. 595.]



The compounds MOX_4 (M = Mo, X = F, Cl; M = W, X = F, Cl, Br) and MO_2X_2 (M = Mo, W; X = F, Cl, Br) can be made by a variety of routes, e.g. eq. 22.32. Reactions of MO_3 with CCl_4 yield MO_2Cl_2; WO_2Cl_2 decomposes on heating (eq. 22.33). These halidooxidometal(VI) compounds readily hydrolyse.

$$\left.\begin{array}{l} M + O_2 + F_2 \\ MOCl_4 + HF \\ MO_3 + F_2 \end{array}\right\} \longrightarrow MOF_4 \quad (M = Mo, W) \qquad (22.32)$$

$$2WO_2Cl_2 \xrightarrow{450-550\,K} WO_3 + WOCl_4 \qquad (22.33)$$

The solids do not contain monomeric units, e.g. $MoOF_4$ contains chains of $MoOF_5$ octahedra linked by Mo−F−Mo bridges (Fig. 22.8a). In WOF_4, W−O−W bridges are present within tetrameric units (Fig. 22.8b). The layer structure of WO_2Cl_2 is related to that of SnF_4 (**14.15**); each layer comprises bridged WO_4Cl_2

[†] For further details, see: G.S. Quiñones, G. Hägele and K. Seppelt (2004) *Chem. Eur. J.*, vol. 10, p. 4755 – 'MoF_6 and WF_6: non-rigid molecules?'

APPLICATIONS

Box 22.3 Electrochromic 'smart' windows

Walls of windows are commonplace in modern office blocks: use of electrochromic glass improves energy efficiency and working environment.

An electrochromic material is one which changes colour when an electrical potential difference is applied across the material. Turning off the external voltage supply reverses the colour change. Applications of electrochromic films include the manufacture of 'smart' windows, i.e. windows that can be reversibly made darker by applying a voltage stimulus. Such windows are able to modify the amount of daylight entering a building, and can be used to regulate solar heat transmission. Electrochromic devices are also used in vehicle mirrors and sunroof panels. The use of flexible polymers in place of glass substrates for the electrochromic films increases the range of applications.

Metal oxides containing redox active metals (e.g. WO_3, MoO_3, Ta_2O_5, Nb_2O_5, IrO_2) are the key inorganic materials applied to the production of electrochromic films, and of these oxides, WO_3 (either crystalline or amorphous) is the most important. A film of pure WO_3 is transparent and a colour change to blue arises from the reversible formation of a lithium tungsten bronze (see eq. 22.42 and associated text). A typical electrochemical film design is shown below. It consists of two outer layers of electrically conducting glass (usually SnO_2:F or In_2O_3:Sn, see Section 28.3). Between these are the active electrode (WO_3) and the counter electrode (e.g. $Li_xV_2O_5$), and sandwiched between them is a solid (polymer) electrolyte which conducts Li^+ ions. The counter electrode acts as a store for Li^+ ions. When a small potential (≈ 1.5 V) is applied across the cell, Li^+ ions migrate from the counter electrode, through the electrolyte to the active electrode. The uptake of Li^+ ions by WO_3 under a potential bias is represented by the equation:

$$\underset{\text{colourless}}{WO_3} + xLi^+ + xe^- \rightleftharpoons \underset{\text{blue}}{Li_xWO_3}$$

The reaction is fully reversible. For each Li^+ ion incorporated into Li_xWO_3, one W^{VI} centre is reduced to W^V. The above equation therefore becomes:

$$\underset{\text{colourless}}{W^{VI}O_3} + xLi^+ + xe^- \rightleftharpoons \underset{\text{blue}}{Li_xW^{VI}_{1-x}W^V_xO_3}$$

As the equilibria above show, WO_3 is a *cathodic* electrochromic material, i.e. the darkening of the electrochromic film occurs at the cathode in the cell. In contrast, IrO_2 is an *anodic* electrochromic material, and the reversible colour change of the electrochromic device depends on proton rather than lithium ion migration:

$$\underset{\text{colourless}}{H_xIrO_2} \rightleftharpoons \underset{\text{dark blue}}{IrO_2} + xH^+ + xe^-$$

The two oxidation states of iridium are Ir(IV) and Ir(III):

$$\underset{\text{colourless}}{H_xIr^{IV}_{1-x}Ir^{III}_xO_2} \rightleftharpoons \underset{\text{dark blue}}{Ir^{IV}O_2} + xH^+ + xe^-$$

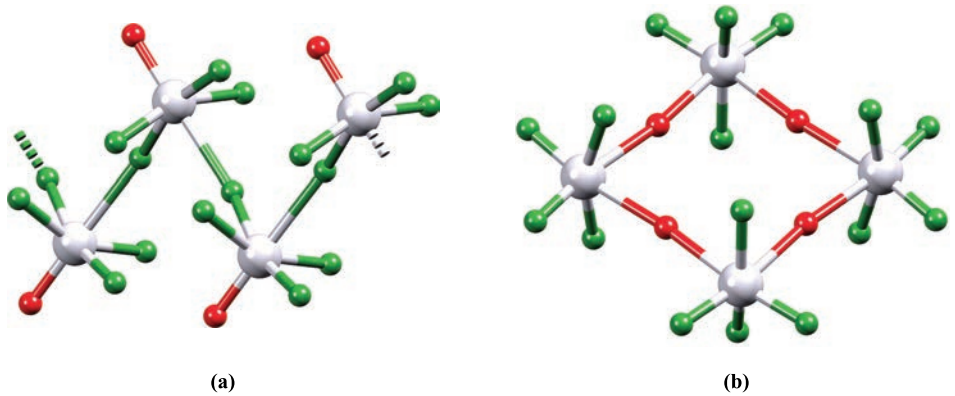

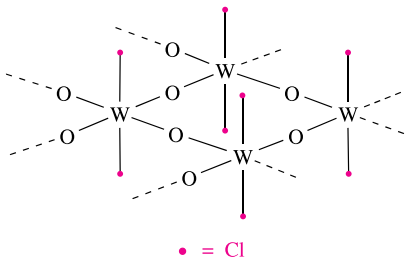

Fig. 22.8. (a) Part of one of the infinite chains that constitute the solid state structure of $MoOF_4$, and (b) one of the tetrameric units present in crystalline WOF_4. Colour code: Mo or W, pale grey; O, red; F, green.

units (**22.15**) and the lattice is able to act as an intercalation host.

(22.15)

The most important compounds of Mo(VI) and W(VI) are the oxides and the molybdate and tungstate anions. White MoO_3 (mp 1073 K) is usually made by reaction 22.34, and yellow WO_3 (mp 1473 K) by dehydration of tungstic acid (see below). Both oxides are commercially available.

$$MoS_2 \xrightarrow{\text{roast in air}} MoO_3 \qquad (22.34)$$

The structure of MoO_3 consists of layers of linked MoO_6 octahedra. The arrangement of the MoO_6 units is complex and results in a unique 3-dimensional network. Several polymorphs of WO_3 exist, all based on the ReO_3 structure (Fig. 21.5). Thin films of WO_3 are used in electrochromic windows (Box 22.3). Neither MoO_3 nor WO_3 reacts with acids, but in aqueous alkali, $[MO_4]^{2-}$ or polyoxometallate ions are produced. The chemistry of molybdates and tungstates is complicated and the uses of the homo- and heteropolyanions are extremely varied.[†] The simplest molybdate(VI) and tungstate(VI) ions are $[MoO_4]^{2-}$ and $[WO_4]^{2-}$, many salts of which are known. Alkali metal salts such as Na_2MoO_4 and Na_2WO_4 (commercially available as the dihydrates and useful starting materials in this area of chemistry) are made by dissolving MO_3 (M = Mo, W) in aqueous alkali metal hydroxide. From *strongly acidic* solutions of these molybdates and tungstates, it is possible to isolate yellow 'molybdic acid' and 'tungstic acid'. Crystalline molybdic and tungstic acids are formulated as $MoO_3{\cdot}2H_2O$ and $WO_3{\cdot}2H_2O$, and possess layer structures consisting of corner-sharing $MO_5(OH_2)$ octahedra with additional H_2O molecules residing between the layers. In crystalline salts, the $[MO_4]^{2-}$ ions are discrete and tetrahedral. In acidic media and dependent on the pH, condensation occurs to give polyanions, e.g. reaction 22.35.

$$7[MoO_4]^{2-} + 8H^+ \longrightarrow [Mo_7O_{24}]^{6-} + 4H_2O \qquad pH \approx 5 \qquad (22.35)$$

Structural features of $[Mo_7O_{24}]^{6-}$ (Fig. 22.9a), which are in common with other polynuclear molybdates and tungstates, are that:

- the cage is supported by oxygen bridges and there is no metal–metal bonding;
- the cage is constructed from octahedral MO_6-units connected by shared oxygen atoms.

As a consequence of this last point, the structures may be represented in terms of linked octahedra, in much the same way that silicate structures are depicted by linked tetrahedra (see structure **14.22** and Fig. 14.23). Figure 22.9b shows such a representation for $[Mo_7O_{24}]^{6-}$; each vertex corresponds to an O atom in Fig. 22.9a. By controlling the pH or working in non-aqueous media, salts of other molybdates and tungstates can be isolated. One of the simplest is $[M_6O_{19}]^{2-}$ (M = Mo, W) which is isostructural with $[M_6O_{19}]^{8-}$ (M = Nb, Ta) and possesses the *Lindqvist structure* (Fig. 22.9c). For tungsten, the solution system is more

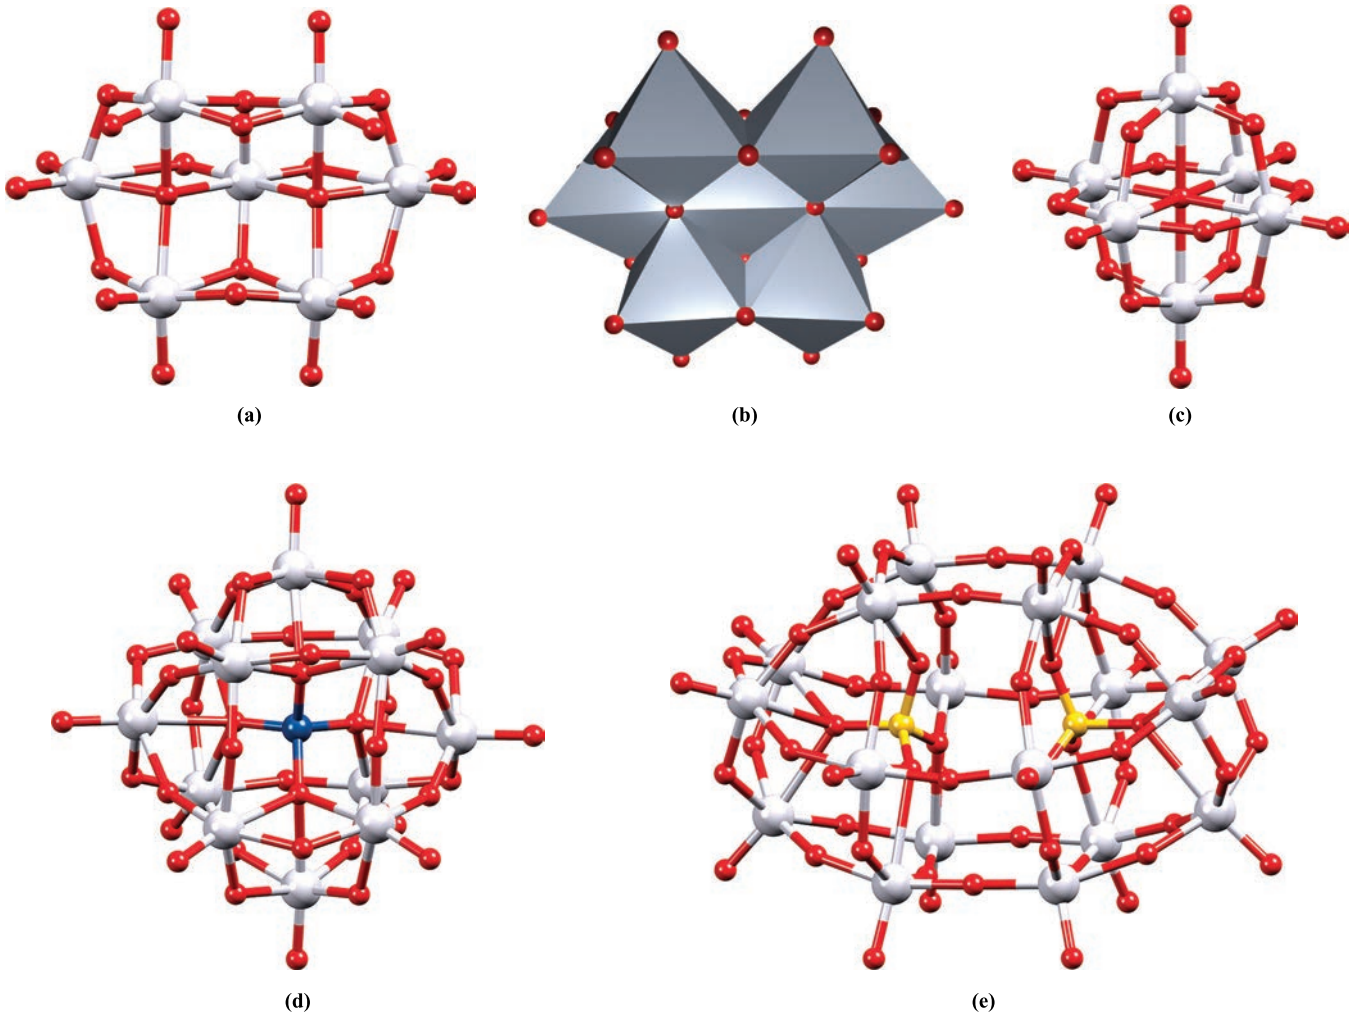

Fig. 22.9. (a) The structure of $[Mo_7O_{24}]^{6-}$ in the $[H_3N(CH_2)_2NH_2(CH_2)_2NH_3]^{3+}$ salt [P. Roman *et al.* (1992) *Polyhedron*, vol. 11, p. 2027]; (b) the $[Mo_7O_{24}]^{6-}$ ion represented in terms of seven octahedral building blocks (these can be generated in diagram (a) by connecting the O atoms); (c) the structure of $[W_6O_{19}]^{2-}$ determined for the $[W(CN^tBu)_7]^{2+}$ salt [W.A. LaRue *et al.* (1980) *Inorg. Chem.*, vol. 19, p. 315]; (d) the structure of the α-Keggin ion $[SiMo_{12}O_{40}]^{4-}$ in the guanidinium salt (the Si atom is shown in dark blue) [H. Ichida *et al.* (1980) *Acta Crystallogr., Sect. B*, vol. 36, p. 1382]; (e) the structure of $[H_3S_2Mo_{18}O_{62}]^{5-}$ (in the $[^nBu_4N]^+$ salt) formed by reducing the α-Dawson anion $[S_2Mo_{18}O_{62}]^{4-}$ (H atoms are omitted) [R. Neier *et al.* (1995) *J. Chem. Soc., Dalton Trans.*, p. 2521]. Colour code: Mo and W, pale grey; O, red; Si, blue; S, yellow.

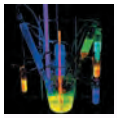
complicated than for molybdenum, and involves equilibria with W_7, W_{10}, W_{11} and W_{12} species. The lowest nuclearity anion, $[W_7O_{24}]^{6-}$, is isostructural with $[Mo_7O_{24}]^{6-}$. Salts can be isolated by careful control of pH, and under non-aqueous conditions salts of polytungstates unknown in aqueous solution can be crystallized.

Heteropolyanions have been well studied and have many applications, e.g. as catalysts. Two families are especially important:



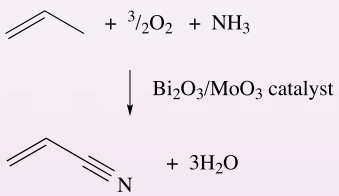
- the α-Keggin anions,[†] $[XM_{12}O_{40}]^{n-}$ (M = Mo, W; e.g. X = P or As, $n = 3$; X = Si, $n = 4$; X = B, $n = 5$);
- the α-Dawson anions, $[X_2M_{18}O_{62}]^{n-}$ (M = Mo, W; e.g. X = P or As, $n = 6$).

Equations 22.36 and 22.37 show typical syntheses of α-Keggin ions. All ions are structurally similar (Fig. 22.9d) with the hetero-atom tetrahedrally sited in the centre of the polyoxometallate cage. The construction of the cage from oxygen-linked, octahedral MO_6-units is apparent by studying Fig. 22.9d.

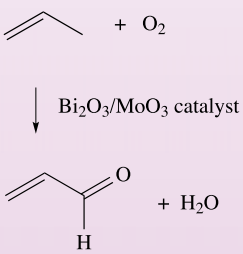
$$[HPO_4]^{2-} + 12[WO_4]^{2-} + 23H^+ \longrightarrow [PW_{12}O_{40}]^{3-} + 12H_2O \quad (22.36)$$

$$[SiO_3]^{2-} + 12[WO_4]^{2-} + 22H^+ \longrightarrow [SiW_{12}O_{40}]^{4-} + 11H_2O \quad (22.37)$$

[†] The prefix α distinguishes the structural type discussed here from other isomers; the first example, $[PMo_{12}O_{40}]^{3-}$, was reported in 1826 by Berzelius, and was structurally elucidated using X-ray diffraction in 1933 by J.F. Keggin.



APPLICATIONS



Box 22.4 Catalytic applications of MoO_3 and molybdates

Molybdenum-based catalysts are used to facilitate a range of organic transformations including benzene to cyclohexane, ethylbenzene to styrene, and propene to acetone.

Acrylonitrile (used in the manufacture of acrylic fibres, resins and rubbers) is produced commercially on a large scale by the reaction:

Propene is also the precursor to acrolein (acrylaldehyde):

The two manufacturing processes are together known as the SOHIO (Standard Oil of Ohio Company) process. The bismuth–molybdate catalyst functions by providing intimately associated Bi−O and Mo=O sites. The Bi−O sites are involved in abstracting α-hydrogen (see structure **24.47**) while the Mo=O sites interact with the incoming alkene, and are involved in activation of NH_3 and in C−N bond formation.

In Box 12.2, we described methods of desulfurizing emission gases. A combination of MoO_3 and CoO supported on activated alumina acts as an effective catalyst for the desulfurization of petroleum and coal-based products. This catalyst system has wide application in a process that contributes significantly to reducing SO_2 emissions.

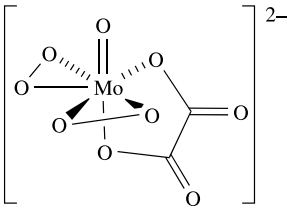
α-Dawson anions of Mo are formed spontaneously in solutions containing $[MoO_4]^{2-}$ and phosphates or arsenates at appropriate pH, but formation of corresponding tungstate species is slower and requires an excess of phosphate or arsenate. The α-Dawson cage structure can be viewed as the condensation of two α-Keggin ions with loss of six MO_3-units (compare Figs. 22.9d and 22.9e). The structure shown in Fig. 22.9e is that of $[H_3S_2Mo_{18}O_{62}]^{5-}$, a protonated product of the 4-electron reduction of the α-Dawson ion $[S_2Mo_{18}O_{62}]^{4-}$. Apart from bond length changes, the cage remains unaltered by the addition of electrons. Similarly, reduction of α-Keggin ions occurs without gross structural changes. Reduction converts some of the M(VI) to M(V) centres and is accompanied by a change in colour to intense blue. Hence, reduced Keggin and Dawson anions are called *heteropoly blues*.



Heteropolyanions with incomplete cages, *lacunary* anions, may be made under controlled pH conditions, e.g. at pH ≈ 1, $[PW_{12}O_{40}]^{3-}$ can be prepared (eq. 22.36) while at pH ≈ 2, $[PW_{11}O_{39}]^{7-}$ is formed. Lacunary ions act as ligands by coordination through terminal *O*-atoms. Complexes include $[PMo_{11}VO_{40}]^{4-}$, $[(PW_{11}O_{39})Ti(\eta^5\text{-}C_5H_5)]^{4-}$ and $[(PW_{11}O_{39})Rh_2(O_2CMe)_2(DMSO)_2]^{5-}$.

The formation of mononuclear complexes by Mo(VI) and W(VI) is limited. Simple complexes include octahedral $[WOF_5]^-$ and *cis*-$[MoF_4O_2]^{2-}$. Salts of $[MoF_7]^-$ (eq. 22.38) and $[MoF_8]^{2-}$ (eq. 22.39) have been isolated.

$$MoF_6 + [Me_4N]F \xrightarrow{MeCN} [Me_4N][MoF_7] \qquad (22.38)$$

$$MoF_6 + 2KF \xrightarrow{\text{in } IF_5} K_2[MoF_8] \qquad (22.39)$$

The peroxido ligand, $[O_2]^{2-}$, forms a range of complexes with Mo(VI) and W(VI), e.g. $[M(O_2)_2(O)(ox)]^{2-}$ (M = Mo, W) is pentagonal bipyramidal (**22.16**) and $[Mo(O_2)_4]^{2-}$ is dodecahedral. Some peroxido complexes of Mo(VI) catalyse the epoxidation of alkenes.

(22.16)

Molybdenum(V) and tungsten(V)

The known pentahalides are yellow MoF_5, yellow WF_5, black $MoCl_5$, dark green WCl_5 and black WBr_5, all solids at 298 K. The pentafluorides are made by heating MoF_6 with Mo (or WF_6 with W, eq. 22.40), but both disproportionate on heating (eq. 22.41).

$$5WF_6 + W \xrightarrow{\Delta} 6WF_5 \qquad (22.40)$$

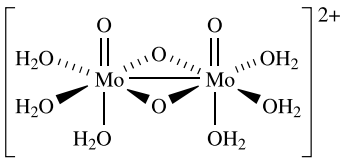
$$2MF_5 \xrightarrow{\Delta,\ T\ K} MF_6 + MF_4 \qquad (22.41)$$

$M = Mo,\ T > 440\ K;\ M = W,\ T > 320\ K$

Direct combination of the elements under controlled conditions gives $MoCl_5$ and WCl_5. The pentafluorides MoF_5 and WF_5 are tetrameric in the solid, isostructural with NbF_5 and TaF_5 (**22.5**). $MoCl_5$ and WCl_5 are dimeric and structurally similar to $NbCl_5$ and $TaCl_5$ (**22.6**). Each pentahalide is paramagnetic, indicating little or no metal–metal interaction.

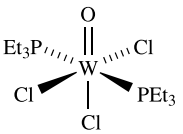
Tungsten bronzes contain M(V) and M(VI) (see Box 22.3) and are formed by vapour-phase reduction of WO_3 by alkali metals, reduction of Na_2WO_4 by H_2 at 800–1000 K, or by reaction 22.42.

$$\frac{x}{2}Na_2WO_4 + \frac{3-2x}{3}WO_3 + \frac{x}{6}W \xrightarrow{1120\ K} Na_xWO_3 \qquad (22.42)$$



Tungsten bronzes are inert materials M_xWO_3 $(0 < x < 1)$ with defect perovskite structures (Fig. 6.26). Their colour depends on x: golden for $x \approx 0.9$, red for $x \approx 0.6$, violet for $x \approx 0.3$. Bronzes with $x > 0.25$ exhibit metallic conductivity owing to a band-like structure associated with W(V) and W(VI) centres in the lattice. Those with $x < 0.25$ are semiconductors (see Section 6.8). Similar compounds are formed by Mo, Ti and V.[†]

Our discussion of complexes of Mo(V) and W(V) is restricted to selected mononuclear species. Octahedral coordination is common, for example $[MoF_6]^-$ (eq. 22.43), $[WF_6]^-$ and $[MoCl_6]^-$. 8-Coordinate W(V) is found in $[WF_8]^{3-}$ (eq. 22.44).



$$MoF_6\ (\text{in excess}) \xrightarrow{KI\ \text{in liquid}\ SO_2} K[MoF_6] \qquad (22.43)$$

$$W(CO)_6 \xrightarrow{KI\ \text{in}\ IF_5} K_3[WF_8] \qquad (22.44)$$

Treatment of WCl_5 with concentrated HCl leads to $[WOCl_5]^{2-}$, and $[WOBr_5]^{2-}$ forms when $[W(O)_2(ox)_2]^{3-}$ reacts with aqueous HBr. Dissolution of $[MoOCl_5]^{2-}$ in aqueous acid produces yellow $[Mo_2O_4(OH_2)_6]^{2+}$ (**22.17**) which is diamagnetic, consistent with a Mo–Mo single bond. A number of complexes $[MOCl_3L_2]$ are known, e.g. $WOCl_3(THF)_2$ (a useful starting material since the THF ligands are labile), $[WOCl_3(PEt_3)_2]$ (**22.18**) and $[MoOCl_3(bpy)]$. High coordination numbers are observed in $[Mo(CN)_8]^{3-}$ and $[W(CN)_8]^{3-}$, formed by oxidation of $[M(CN)_8]^{4-}$ using Ce^{4+} or $[MnO_4]^-$. The coordination geometries are cation-dependent, illustrating the small energy difference between dodecahedral and square antiprismatic structures.

(22.17)

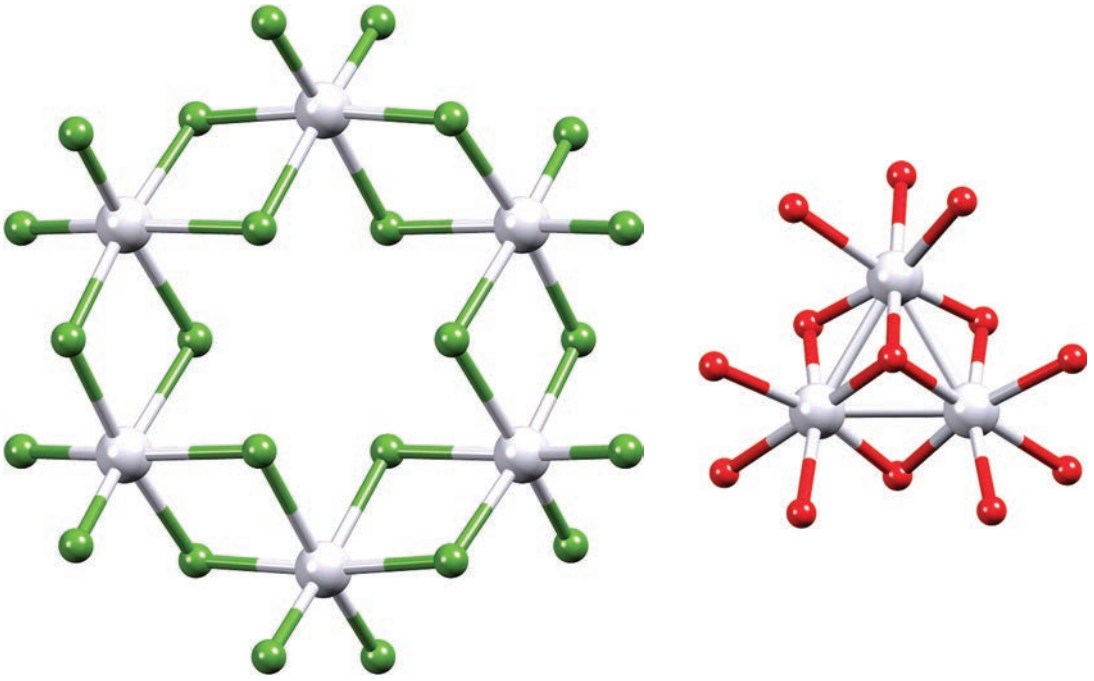
(22.18)

Molybdenum(IV) and tungsten(IV)

Binary halides MX_4 are established for M = Mo, W and X = F, Cl and Br; WI_4 exists but is not well characterized. Equations 22.45 and 22.46 show representative syntheses.

$$MoO_3 \xrightarrow{H_2,\ 720\ K} MoO_2 \xrightarrow{CCl_4,\ 520\ K} MoCl_4 \qquad (22.45)$$

$$WCl_6 \xrightarrow{W(CO)_6,\ \text{reflux in chlorobenzene}} WCl_4 \qquad (22.46)$$



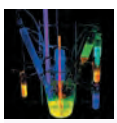
Tungsten(IV) fluoride is polymeric, and a polymeric structure for MoF_4 is consistent with Raman spectroscopic data. Three polymorphs of $MoCl_4$ exist: α-$MoCl_4$ has the $NbCl_4$ structure (**22.11**) and, at 520 K, transforms to the β-form containing cyclic Mo_6Cl_{24} units (Fig. 22.10a). The structure of the third polymorph is unknown. Tungsten(IV) chloride (structurally like α-$MoCl_4$) is a useful starting material in W(IV) and lower oxidation state chemistry. All the tetrahalides are air- and moisture-sensitive.

Reduction of MO_3 (M = Mo, W) by H_2 yields MoO_2 and WO_2 which adopt rutile structures (Fig. 6.24), distorted (as in NbO_2) by pairing of metal centres; in MoO_2, Mo–Mo distances are 251 and 311 pm. The oxides do not dissolve in non-oxidizing acids. Molybdenum(IV) sulfide (eq. 22.28) has a layer structure and is used as a lubricant (Box 22.5).

Molybdenum(IV) is stabilized in acidic solution as red $[Mo_3(\mu_3\text{-}O)(\mu\text{-}O)_3(OH_2)_9]^{4+}$ (Fig. 22.10b) which is formed by reduction of $Na_2[MoO_4]$ or oxidation of $[Mo_2(OH_2)_8]^{4+}$.

The halido complexes $[MX_6]^{2-}$ (M = Mo, W; X = F, Cl, Br) are known although $[WF_6]^{2-}$ has been little studied. By adjusting the conditions of reaction 22.43 (i.e. taking a 1:2

[†] See for example: C.X. Zhou, Y.X. Wang, L.Q. Yang and J.H. Lin (2001) *Inorg. Chem.*, vol. 40, p. 1521 – 'Syntheses of hydrated molybdenum bronzes by reduction of MoO_3 with $NaBH_4$'; X.K. Hu *et al.* (2008) *Chem. Mater.*, vol. 20, p. 1527 – 'Comparative study on MoO_3 and H_xMoO_3 nanobelts: structure and electric transport'.

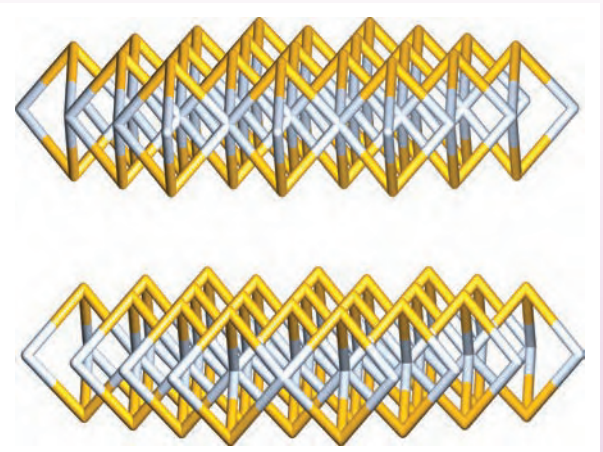


(a) (b)

Fig. 22.10. (a) The β-form of $MoCl_4$ consists of cyclic Mo_6Cl_{24} units. The structure was determined by X-ray diffraction [U. Müller (1981) *Angew. Chem.*, vol. 93, p. 697]. Colour code: Mo, pale grey; Cl, green. (b) The structure of $[Mo_3(\mu_3\text{-}O)(\mu\text{-}O)_3(OH_2)_9]^{4+}$ determined by X-ray diffraction for the hydrated $[4\text{-}MeC_6H_4SO_3]^-$ salt; H atoms are omitted from the terminally bound H_2O ligands. Mo–Mo distances are in the range 247–249 pm. [D.T. Richens *et al.* (1989) *Inorg. Chem.*, vol. 28, p. 1394]. Colour code: Mo, pale grey; O, red.

molar ratio $MoF_6:I^-$, and removing I_2 as it is formed), $K_2[MoF_6]$ can be isolated. Salts of $[MoCl_6]^{2-}$ can be made starting from $MoCl_5$, e.g. $[NH_4]_2[MoCl_6]$ by heating $MoCl_5$ with NH_4Cl. Many salts of $[WCl_6]^{2-}$ are known (e.g. reaction 22.47) but the ion decomposes on contact with water.

$$2M[WCl_6] \xrightarrow{550\,K} M_2[WCl_6] + WCl_6 \quad (M = \text{group 1 metal}) \qquad (22.47)$$



Reduction of H_2WO_4 using Sn in HCl in the presence of K_2CO_3 leads to $K_4[W_2(\mu\text{-}O)Cl_{10}]$; the anion is structurally like $[Ta_2(\mu\text{-}O)F_{10}]^{2-}$ (Fig. 22.5a).

APPLICATIONS

Box 22.5 MoS_2: a solid lubricant

After purification and conversion into appropriate grade powders, the mineral *molybdenite*, MoS_2, has widespread commercial applications as a solid lubricant. It is applied to reduce wear and friction, and is able to withstand high-temperature working conditions. The lubricating properties are a consequence of the solid state layer structure (compare with graphite). Within each layer, each Mo centre is in a trigonal prismatic environment and each S atom bridges three Mo centres (in the figure, the colour code is Mo, pale grey, and S, yellow). The upper and lower surfaces of each layer consist entirely of S atoms, and there are only weak van der Waals forces operating between S–Mo–S slabs. Applications of MoS_2 lubricants range from engine oils and greases (used in engineering equipment) to coatings on sliding fitments.

Octahedral geometries are common for complexes of Mo(IV) and W(IV), syntheses of which often involve ligand-mediated reduction of the metal centre, e.g. reactions 22.48 and 22.49.

$$WOCl_4 + 3Ph_3P \longrightarrow \textit{trans}\text{-}[WCl_4(PPh_3)_2] + Ph_3PO \qquad (22.48)$$

$$MoCl_5 \xrightarrow{\text{excess py or bpy}} \begin{cases} MoCl_4(py)_2 \\ MoCl_4(bpy) \end{cases} \qquad (22.49)$$

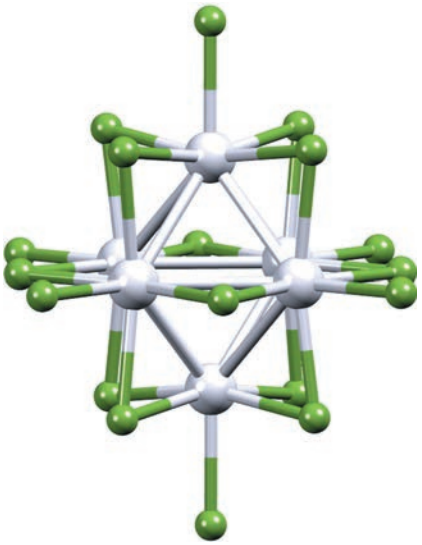
The salt $K_4[Mo(CN)_8]\cdot 2H_2O$ was the first example (in 1939) of an 8-coordinate (dodecahedral) complex. However, studies on a range of salts of $[Mo(CN)_8]^{4-}$ and $[W(CN)_8]^{4-}$ reveal cation dependence, both dodecahedral and square antiprismatic anions being found. The $K_4[M(CN)_8]$ salts are formed by reactions of K_2MO_4, KCN and KBH_4 in the presence of acetic acid. The $[M(CN)_8]^{4-}$ ions are kinetically inert with respect to ligand substitution (see Section 26.2), but can be oxidized to $[M(CN)_8]^{3-}$ as described earlier.

Molybdenum(III) and tungsten(III)

All the binary halides of Mo(III) and W(III) are known except for WF_3. The Mo(III) halides are made by reducing a halide of a higher oxidation state. Reduction of $MoCl_5$ with H_2 at 670 K gives $MoCl_3$ which has a layer structure similar to $CrCl_3$ but distorted and rendered diamagnetic by pairing of metal atoms (Mo−Mo = 276 pm). The 'W(III) halides' contain M_6 clusters and are prepared by controlled halogenation of a lower halide (see eqs. 22.55 and 22.56). W_6Cl_{18} (Fig. 22.11) has also been made by reducing WCl_4 using graphite in a silica tube at 870 K.

In contrast to Cr(III) (see Section 21.7), mononuclear complexes of Mo(III) and W(III) (especially the latter) are rare, there being an increased tendency for M−M bonding for the M(III) state. Electrolytic reduction of MoO_3 in concentrated HCl yields $[MoCl_5(OH_2)]^{2-}$ and $[MoCl_6]^{3-}$, the red K^+ salts of which are stable in dry air but are readily hydrolysed to $[Mo(OH_2)_6]^{3+}$, one of the few simple aqua ions of the heavier metals. By changing the reaction conditions, $[Mo_2Cl_9]^{3-}$ is formed in place of $[MoCl_6]^{3-}$, but reduction of WO_3 in concentrated HCl always gives $[W_2Cl_9]^{3-}$; $[WX_6]^{3-}$ has not been isolated. Both $[MoF_6]^{3-}$ and $[MoCl_6]^{3-}$ are paramagnetic with magnetic moments close to 3.8 μ_B ($\approx \mu$(spin-only) for d^3). The $[M_2X_9]^{3-}$ ions adopt structure **22.19**; magnetic data and M−M distances (from crystalline salts) are consistent with metal–metal bonding. The $[W_2Cl_9]^{3-}$ ion is diamagnetic, indicating a W≡W triple bond consistent with the short bond length of 242 pm. Oxidation (eq. 22.50) to $[W_2Cl_9]^{2-}$ causes the W−W bond to lengthen to 254 pm consistent with a lower bond order of 2.5.

$$2[W_2Cl_9]^{3-} + Cl_2 \longrightarrow 2[W_2Cl_9]^{2-} + 2Cl^- \qquad (22.50)$$



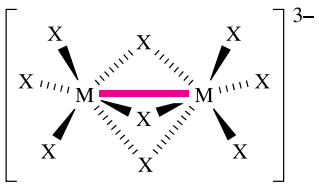


Fig. 22.11. The structure of W_6Cl_{18}, determined by X-ray diffraction [S. Dill *et al.* (2004) *Z. Anorg. Allg. Chem.*, vol. 630, p. 987]. The W–W bond distances are all close to 290 pm. Colour code: W, pale grey; Cl, green.

M = Mo, W; X = Cl, Br (see text)

(22.19)

In $Cs_3[Mo_2X_9]$, the Mo−Mo bond lengths are 266 pm (X = Cl) and 282 pm (X = Br). These data and magnetic moments at 298 K of 0.6 μ_B (X = Cl) and 0.8 μ_B (X = Br) per Mo, indicate significant Mo−Mo interaction but with a bond order <3. Contrast this with $[Cr_2X_9]^{3-}$, in which there is no Cr−Cr bonding (Section 21.7).

In Mo(III) and W(III) chemistry, Mo≡Mo and W≡W triple bonds ($\sigma^2\pi^4$, see Fig. 21.17) are common, and derivatives with amido and alkoxy ligands have received much attention, e.g. as precursors for solid state materials. Reaction of $MoCl_3$ (or $MoCl_5$) or WCl_4 with $LiNMe_2$ gives $Mo_2(NMe_2)_6$ or $W_2(NMe_2)_6$ respectively. Both possess staggered structures (Fig. 22.12a) with M−M bond lengths of 221 (Mo) and 229 pm (W) typical of triple bonds. The orientations of the NMe_2 groups in the solid state suggest that the M−N bonds contain metal *d*–nitrogen *p* π-contributions. A staggered conformation, short Mo−Mo bond and shortened Mo−N bonds are also observed in $Mo_2Cl_2(NMe_2)_4$ (Fig. 22.12b); this and the W analogue are made by reacting $M_2(NMe_2)_6$ with Me_3SiCl. The air- and moisture-sensitive $M_2(NMe_2)_6$ and $M_2Cl_2(NMe_2)_4$ (M = Mo, W) are precursors for many derivatives including alkoxy compounds (eq. 22.51 and

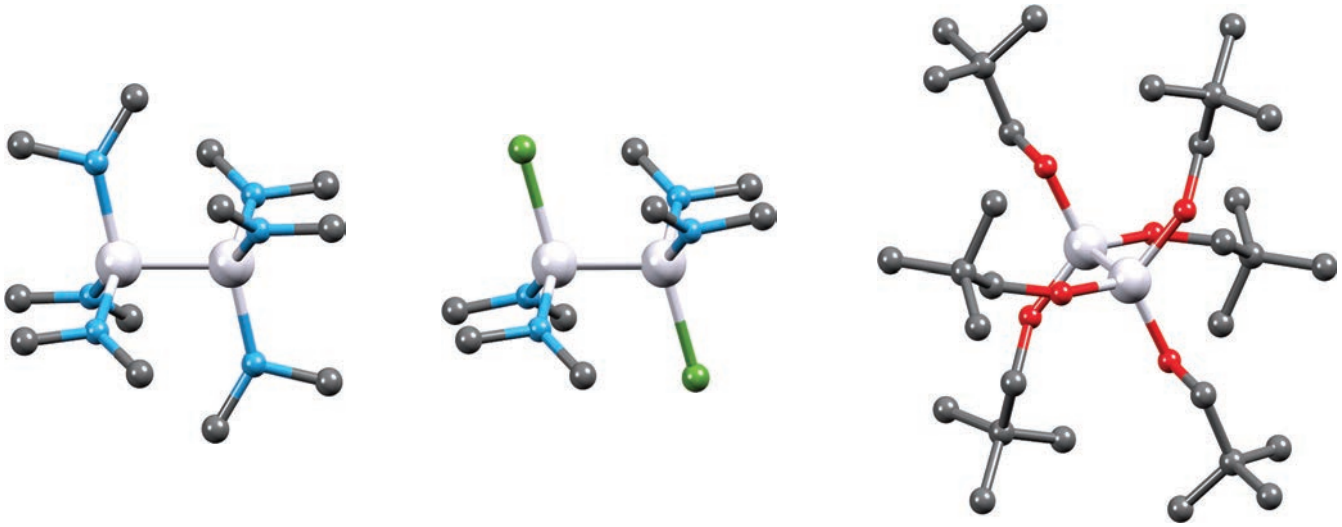

Fig. 22.12. The staggered structures (X-ray diffraction) of (a) $Mo_2(NMe_2)_6$ [M.H. Chisholm *et al.* (1976) *J. Am. Chem. Soc.*, vol. 98, p. 4469], (b) $Mo_2Cl_2(NMe_2)_4$ [M. Akiyama *et al.* (1977) *Inorg. Chem.*, vol. 16, p. 2407] and (c) $Mo_2(OCH_2{}^tBu)_6$ [M.H. Chisholm *et al.* (1977) *Inorg. Chem.*, vol. 16, p. 1801]. Hydrogen atoms are omitted for clarity; colour code: Mo, pale grey; N, blue; O, red; C, grey; Cl, green.

Fig. 22.12c); $[W_2(OR)_6]$ compounds are less stable than their Mo analogues. An extensive chemistry of alkoxy derivatives has been developed.†

$$Mo_2(NMe_2)_6 \xrightarrow{ROH} Mo_2(OR)_6 \qquad (22.51)$$

(R must be bulky, e.g. ^tBu, ^iPr, $CH_2{}^tBu$)

Molybdenum(II) and tungsten(II)

With the exception of organometallic and cyanido complexes, few mononuclear species are known for Mo(II) and W(II). The pentagonal bipyramidal $[Mo(CN)_7]^{5-}$ ion is formed by reducing $[MoO_4]^{2-}$ using H_2S in the presence of $[CN]^-$. In the capped trigonal prismatic $[MoBr(CN^tBu)_6]^+$ (eq. 22.52), the Br^- ligand occupies the capping site.

$$[MoBr_2(CO)_4] + 6\,{}^tBuNC \longrightarrow [MoBr(CN^tBu)_6]Br + 4CO \qquad (22.52)$$

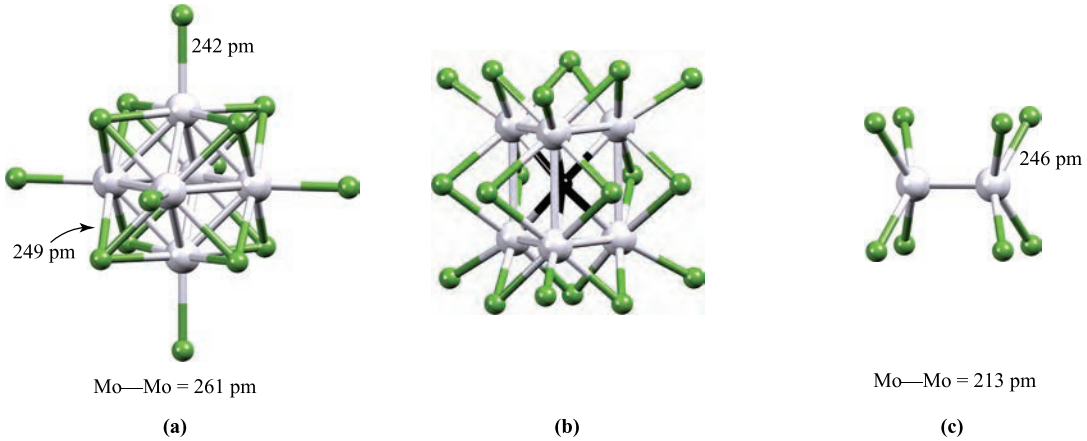
The binary M(II) (M = Mo, W) halides are made from the higher halides, e.g. WCl_2 by disproportionation of WCl_4 at ≈700 K or from reduction of WCl_6 by H_2 at ≈700 K, and $MoCl_2$ by fusion of Mo with $MoCl_3$, $MoCl_4$ or $MoCl_5$. The structures of the dihalides consist of $[M_6X_8]^{4+}$ clusters (structurally like $[Nb_6I_8]^{3+}$, Fig. 22.6a) with each M atom bonded to an additional X atom. The clusters are connected into a 2-dimensional layer structure by M−X−M bridges, i.e. $[M_6X_8]X_2X_{4/2}$. Reactions such as 22.53 and 22.54 produce salts containing discrete $[M_6X_{14}]^{2-}$ ions (Fig. 22.13a). The diamagnetism of $[M_6X_{14}]^{2-}$ is consistent with M−M bonding, and M−M single bonds can be allocated by following a similar electron-counting procedure as for $[Nb_6X_{12}]^{2+}$ and $[Ta_6X_{12}]^{2+}$ (see Section 22.6). Octahedral $Mo_6(\mu_3\text{-}X)_8$ (usually X = S, Se, Te) cluster units are the building blocks in so-called *Chevrel phases*, $M_xMo_6X_8$ (M = group 1 or 2 metal, or *p*-, *d*- or *f*-block metal). These materials exhibit interesting electronic (in particular, superconducting) properties and are discussed further in Section 28.4.

$$MoCl_2 \xrightarrow{Et_4NCl \text{ in dil. HCl, EtOH}} [Et_4N]_2[Mo_6Cl_{14}] \qquad (22.53)$$

$$MoBr_2 \xrightarrow{CsBr,\ IBr,\ 325\ K} Cs_2[Mo_6Br_{14}] \qquad (22.54)$$

While the Mo(II) halides are not readily oxidized, WCl_2 and WBr_2 (eqs. 22.55 and 22.56) are oxidized to give products containing $[W_6(\mu\text{-}Cl)_{12}]^{6+}$ or $[W_6(\mu_3\text{-}Br)_8]^{6+}$ clusters, terminal halides and bridging $[Br_4]^{2-}$ units. The formulae of the products in the equations below indicate whether the clusters are discrete or linked.

Rev.*, vol. 105, p. 2949; M.H. Chisholm and Z. Zhou (2004) *J. Mater. Chem.*, vol. 14, p. 3081; M.H. Chisholm (2014) *J. Organomet. Chem.*, vol. 751, p. 55.



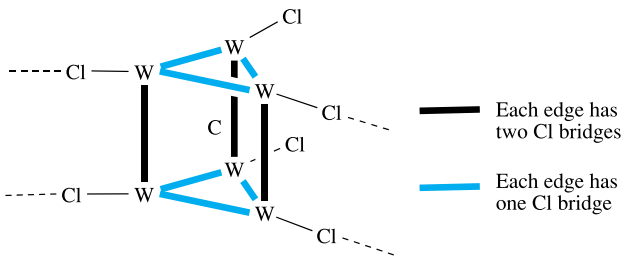


Fig. 22.13. The structures (X-ray diffraction) of (a) $[Mo_6Cl_{14}]^{2-}$ in the $[Ph_4P]^+$ salt [M.A. White *et al.* (1994) *Acta Crystallogr., Sect. C*, vol. 50, p. 1087], (b) $W_6Cl_{18}C$ [Y.-Q. Zheng *et al.* (2003) *Z. Anorg. Allg. Chem.*, vol. 629, p. 1256] and (c) $[Mo_2Cl_8]^{4-}$ in the compound $[H_3NCH_2CH_2NH_3]_2[Mo_2Cl_8]\cdot 2H_2O$ [J.V. Brenic *et al.* (1969) *Inorg. Chem.*, vol. 8, p. 2698]. Colour code: Mo or W, pale grey; Cl, green; C, black.

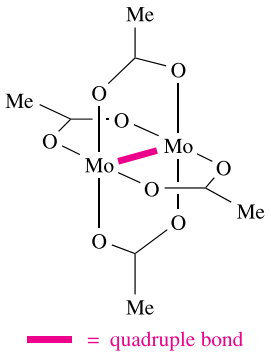
$$[W_6Cl_8]Cl_2Cl_{4/2} \xrightarrow{Cl_2,\ 373\ K} [W_6Cl_{12}]Cl_6 \qquad (22.55)$$

$$[W_6Br_8]Br_2Br_{4/2} \xrightarrow{Br_2,\ T<420\ K} \begin{cases} [W_6Br_8]Br_6 \\ [W_6Br_8]Br_4(Br_4)_{2/2} \\ [W_6Br_8]Br_2(Br_4)_{4/2} \end{cases} \qquad (22.56)$$

When WBr_2 (i.e. $[W_6Br_8]Br_2Br_{4/2}$) is heated with AgBr *in vacuo* with a temperature gradient of 925/915 K, the products are yellow-green $Ag_2[W_6Br_{14}]$ and black-brown $Ag[W_6Br_{14}]$. Both silver salts contain discrete anions, structurally similar to $[Mo_6Cl_{14}]^{2-}$ (Fig. 22.13a). The difference in colour of the compounds is characteristic of W in different oxidation states: $[W_6Br_{14}]^{2-}$ contains W in oxidation state +2, whereas $[W_6Br_{14}]^-$ is formulated as $[W^{II}{}_5W^{III}Br_{14}]^-$.

In contrast to the more usual octahedral tungsten halide clusters, $W_6Cl_{16}C$ (formed in the reaction of W, WCl_5 and CCl_4 *in vacuo* with a temperature gradient of 1030/870 K) contains an example of a carbon-centred trigonal prismatic cluster unit. The cluster units are connected into a 2-dimensional sheet (**22.20**) and a formulation of $[W_6Cl_{12}C]Cl_2Cl_{4/2}$ is appropriate. The related compound $W_6Cl_{18}C$ can also be isolated and consists of discrete trigonal prismatic, carbon-centred clusters (Fig. 22.13b). When WCl_6 is reduced by Bi at 670 K in the presence of CCl_4, a black solid is produced (proposed to be $W_6Cl_{16}C$) from which discrete $[W_6Cl_{18}C]^{2-}$ clusters can be isolated by the addition of $[Bu_4N]Cl$. Reduction of WCl_6 by Bi at 770 K in the presence of NaN_3 leads to the formation of $Na[W_6Cl_{18}N]$. The $[W_6Cl_{18}C]^{2-}$ and $[W_6Cl_{18}N]^-$ anions contain interstitial C and N, respectively, and are structurally analogous to $W_6Cl_{18}C$ (Fig. 22.13b).



(22.20)

Compounds containing an $\{Mo{\equiv}Mo\}^{4+}$ unit are well exemplified in Mo(II) chemistry. In contrast, the chemistry of the $\{W{\equiv}W\}^{4+}$ unit is less extensive. Two reasons for this observation are that complexes containing a $\{W_2\}^{4+}$ core are more prone to oxidation than those based on $\{Mo_2\}^{4+}$, and that suitable precursors to $\{Mo_2\}^{4+}$-containing complexes are more abundant than those to analogous tungsten-containing compounds. A description of Mo≡Mo and W≡W quadruple bonds in terms of σ, π and δ components is analogous to that of a Cr≡Cr bond (see Section 21.7 and Fig. 21.17), and the effect of the δ component in forcing the ligands to be eclipsed is illustrated by the structure of $[Mo_2Cl_8]^{4-}$ (Fig. 22.13c).[†] This is made in the reaction sequence 22.57, the intermediate acetate $Mo_2(\mu\text{-}O_2CMe)_4$ (**22.21**) being a useful synthon in this area of chemistry, e.g. reaction 22.58. Replacement of the Cl^- ligands in $[Mo_2Cl_8]^{4-}$ yields a range of derivatives. Equation 22.59 gives examples, one of which involves concomitant oxidation of the $\{Mo{\equiv}Mo\}^{4+}$ core. Derivatives containing $[MeSO_3]^-$ or $[CF_3SO_3]^-$ bridges are

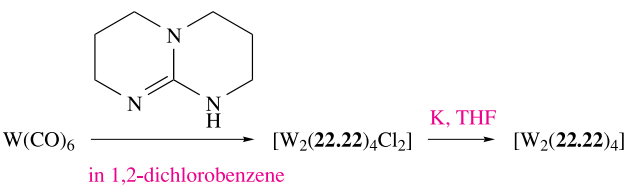
[†] For a review of the development of the δ-bond, see: L.R. Falvello, B.M. Foxman and C.A. Murillo (2014) *Inorg. Chem.*, vol. 53, p. 9441 – 'Fitting the pieces of the puzzle: The δ bond'.

useful precursors and can be used to prepare the highly reactive $[Mo_2(NCMe)_8]^{4+}$ (eq. 22.60).

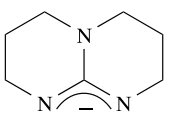
(22.21)

$$Mo(CO)_6 \xrightarrow{MeCO_2H} Mo_2(\mu\text{-}O_2CMe)_4 \xrightarrow{KCl\text{ in HCl}} [Mo_2Cl_8]^{4-} \quad (22.57)$$

$$Mo_2(\mu\text{-}O_2CMe)_4 \xrightarrow{LiMe\text{ in }Et_2O} Li_4[Mo_2Me_8]\cdot 4Et_2O \quad (22.58)$$



$$[Mo_2Cl_8]^{4-} \xrightarrow[\text{in presence of } O_2]{[HPO_4]^{2-}} [Mo_2(\mu\text{-}HPO_4)_4]^{2-} \quad (22.59)$$



$$[Mo_2Cl_8]^{4-} \xrightarrow{[SO_4]^{2-}} [Mo_2(\mu\text{-}SO_4)_4]^{4-}$$

$$[Mo_2(\mu\text{-}O_3SCF_3)_2(OH_2)_4]^{2+} \xrightarrow{MeCN} [Mo_2(NCMe)_8]^{4+} \quad (22.60)$$

Each Mo centre in these Mo_2 derivatives possesses a vacant orbital (as in structure **21.20**), but forming Lewis base adducts is not facile; '$[Mo_2(\mu\text{-}O_2CMe)_4(OH_2)_2]$' has not been isolated, although the oxidized species $[Mo_2(\mu\text{-}SO_4)_4(OH_2)_2]^{3-}$ and $[Mo_2(\mu\text{-}HPO_4)_4(OH_2)_2]^{2-}$ are known. An unstable adduct $[Mo_2(\mu\text{-}O_2CMe)_4(py)_2]$ results from addition of pyridine to $[Mo_2(\mu\text{-}O_2CMe)_4]$, and a more stable one can be made by using $[Mo_2(\mu\text{-}O_2CCF_3)_4]$.

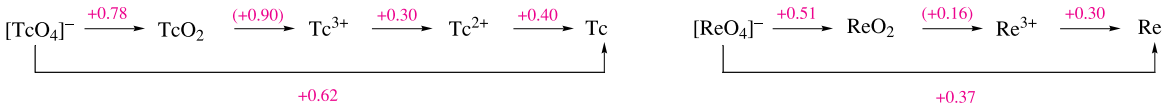
Not all the derivatives mentioned above contain Mo≡Mo bonds, e.g. oxidation occurs in reaction 22.59 in the formation of $[Mo_2(\mu\text{-}HPO_4)_4]^{2-}$. Table 22.2 lists the Mo–Mo bond lengths in selected compounds, and the bond orders follow from the energy level diagram in Fig. 21.17b; e.g. $[Mo_2Cl_8]^{4-}$ has a $\sigma^2\pi^4\delta^2$ configuration (Mo≡Mo), but $[Mo_2(HPO_4)_4]^{2-}$ and $[Mo_2(HPO_4)_4(OH_2)_2]^{2-}$ are $\sigma^2\pi^4$ (Mo≡Mo). Oxidation of the $[M_2]^{4+}$ (M = Mo or W) core is most facile when the bridging ligand is **22.22**. Dissolution of $[Mo_2(\mathbf{22.22})_4]$ in CH_2Cl_2 results in a 1-electron oxidation of the $[Mo_2]^{4+}$ core and formation of $[Mo_2(\mathbf{22.22})_4Cl]$. In contrast, when $[W_2(\mathbf{22.22})_4]$ dissolves in a chloroalkane solvent, it is oxidized directly to $[W_2(\mathbf{22.22})_4Cl_2]$, i.e. $[W_2]^{6+}$. Gas-phase photoelectron spectroscopic data (see Section 4.12) show that initial ionization of $[W_2(\mathbf{22.22})_4]$ requires only 339 kJ mol^{-1}. Just how low this value is can be appreciated by comparing it with a value of IE_1 = 375.7 kJ mol^{-1} for Cs, the element with the lowest first ionization energy (see Fig. 1.16). $[W_2(\mathbf{22.22})_4]$ can be prepared in a convenient 2-step procedure, starting from the readily available and air-stable $W(CO)_6$:

(22.22)

Table 22.2 Mo–Mo bond lengths and orders in selected dimolybdenum species.

Compound or ion†	Mo–Mo bond distance / pm	Mo–Mo bond order	Notes
$Mo_2(\mu\text{-}O_2CMe)_4$	209	4.0	Structure **22.21**
$Mo_2(\mu\text{-}O_2CCF_3)_4$	209	4.0	Analogous to **22.21**
$[Mo_2Cl_8]^{4-}$	214	4.0	Fig. 22.13c
$[Mo_2(\mu\text{-}SO_4)_4]^{4-}$	211	4.0	Analogous to **22.21**
$[Mo_2(\mu\text{-}SO_4)_4(OH_2)_2]^{3-}$	217	3.5	Contains axial H_2O ligands
$[Mo_2(\mu\text{-}HPO_4)_4(OH_2)_2]^{2-}$	223	3.0	Contains axial H_2O ligands

† Data for anions refer to K^+ salts; contrast Fig. 22.13c where the $[Mo_2Cl_8]^{4-}$ parameters refer to the $[H_3NCH_2CH_2NH_3]^{2+}$ salt. For an overview of Mo≡Mo bond lengths, see: F.A. Cotton, L.M. Daniels, E.A. Hillard and C.A. Murillo (2002) *Inorg. Chem.*, vol. 41, p. 2466.



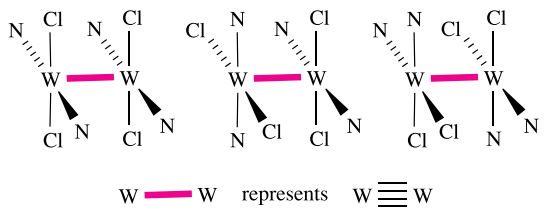


Fig. 22.14. Potential diagrams for technetium and rhenium in aqueous solution at pH 0; compare with the diagram for manganese in Fig. 8.2.

Self-study exercises

1. Rationalize why the Mo–Mo bond length increases (≈7 pm) when $[Mo_2(\mu\text{-}O_2CR)_4]$ ($R = 2,4,6\text{-}{}^{i}Pr_3C_6H_2$) undergoes a 1-electron oxidation.
   [*Ans.* See: F.A. Cotton *et al.* (2002) *Inorg. Chem.*, vol. 41, p. 1639]
2. Rationalize why the two $MoCl_4$-units in $[Mo_2Cl_8]^{4-}$ are eclipsed. [*Ans.* See Fig. 21.16 and discussion]
3. Confirm that $W_2Cl_4(NH_2Cy)_4$ (Cy = cyclohexyl) possesses a ditungsten quadruple bond. The $W_2Cl_4N_4$ core in $W_2Cl_4(NH_2Cy)_4$ is non-centrosymmetric. Which of the following is the structure of this core?

22.8 Group 7: technetium and rhenium

The metals

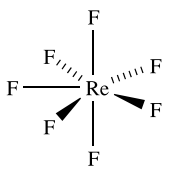
The heavier group 7 metals, Tc and Re, are less reactive than Mn. Technetium does not occur naturally (see Section 22.2). The bulk metals tarnish slowly in air, but more finely divided Tc and Re burn in O_2 (eq. 22.61) and react with the halogens (see below). Reactions with sulfur give TcS_2 and ReS_2.

$$4M + 7O_2 \xrightarrow{650\ K} 2M_2O_7 \qquad (M = Tc, Re) \qquad (22.61)$$

The metals dissolve in oxidizing acids (e.g. conc HNO_3) to give $HTcO_4$ (pertechnetic acid) and $HReO_4$ (perrhenic acid), but are insoluble in HF or HCl.

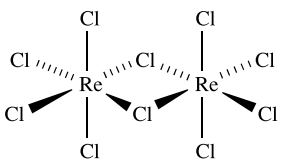
Technetium and rhenium exhibit oxidation states from 0 to +7 (Table 19.3), although M(II) and lower states are stabilized by π-acceptor ligands such as CO (see Box 22.6) and will not be considered further in this section. The chemistry of Re is better developed than that of Tc, but interest in the latter has expanded with the current use of its compounds in nuclear medicine. There are significant differences between the chemistries of Mn and the heavier group 7 metals:

- a comparison of the potential diagrams in Fig. 22.14 with that for Mn (Fig. 8.2) shows that $[TcO_4]^-$ and $[ReO_4]^-$ are significantly more stable with respect to reduction than $[MnO_4]^-$;
- the heavier metals have less cationic chemistry than manganese;
- a tendency for M–M bond formation leads to higher nuclearity species being important for the heavier metals.



High oxidation states of technetium and rhenium: M(VII), M(VI) and M(V)

Rhenium reacts with F_2 to give yellow ReF_6 and ReF_7 (see Fig. 22.17) depending on conditions, and ReF_5 is made by reaction 22.62. Direct combination of Tc and F_2 leads to TcF_6 and TcF_5; TcF_7 is not known.[†]



$$ReF_6 \xrightarrow{\text{over W wire, 870 K}} ReF_5 \qquad (22.62)$$

For the later halogens, combination of the elements at appropriate temperatures affords $TcCl_6$, $ReCl_6$, $ReCl_5$ and $ReBr_5$. The high oxidation state halides are volatile solids which are hydrolysed by water to $[MO_4]^-$ and MO_2 (e.g. eq. 22.63).

$$3ReF_6 + 10H_2O \longrightarrow 2HReO_4 + ReO_2 + 18HF \qquad (22.63)$$

(22.23)

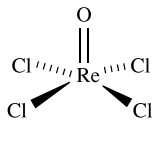
(22.24)

The fluorides ReF_7, ReF_6 and TcF_6 are molecular with pentagonal bipyramidal, **22.23**, and octahedral structures. $ReCl_6$ is probably a molecular monomer, but $ReCl_5$ (a useful precursor in Re chemistry) is a dimer (**22.24**).

Halidooxidometal compounds are well represented:

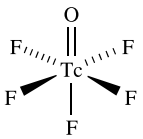
- M(VII): $TcOF_5$, $ReOF_5$, TcO_2F_3, ReO_2F_3, ReO_2Cl_3, ReO_3F, TcO_3F, TcO_3Cl, TcO_3Br, TcO_3I, ReO_3Cl, ReO_3Br;
- M(VI): $TcOF_4$, $ReOF_4$, ReO_2F_2, $TcOCl_4$, $ReOCl_4$, $ReOBr_4$;
- M(V): $ReOF_3$, $TcOCl_3$.

[†] Calculations suggest TcF_7 might be prepared: S. Riedel, M. Renz and M. Kaupp (2007) *Inorg. Chem.*, vol. 46, p. 5734 – 'High-valent technetium fluorides. Does TcF_7 exist?'.



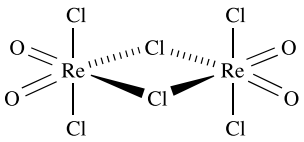
They are prepared by reacting oxides with halogens, or halides with O_2, or by reactions such as 22.64 and 22.65. ReO_2Cl_3 is prepared by treating Re_2O_7 with an excess of BCl_3. Whereas $ReOF_5$ can be prepared by the high-temperature reaction between ReO_2 and F_2, the Tc analogue must be made by reaction 22.66 because the reaction of F_2 and TcO_2 gives TcO_3F.

$$ReCl_5 + 3Cl_2O \longrightarrow ReO_3Cl + 5Cl_2 \quad (22.64)$$



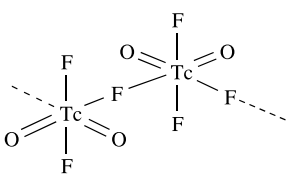
$$\left.\begin{aligned} Tc_2O_7 + 4HF &\longrightarrow 2TcO_3F + [H_3O]^+ + [HF_2]^- \\ TcO_3F + XeF_6 &\longrightarrow TcO_2F_3 + XeOF_4 \end{aligned}\right\} \quad (22.65)$$

$$2TcO_2F_3 + 2KrF_2 \xrightarrow{\text{in anhydrous HF}} 2TcOF_5 + 2Kr + O_2 \quad (22.66)$$

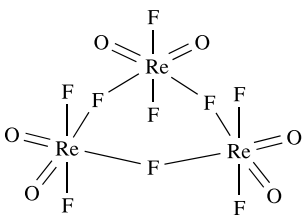


Few high oxidation state halidooxidotechnetium or -rhenium compounds have been structurally characterized in the solid state. $ReOCl_4$ (**22.25**) and $TcOF_5$ (**22.26**) are molecular. ReO_2Cl_3 is dimeric with each Re atom in a distorted octahedral environment (**22.27**), while TcO_2F_3 is polymeric with oxido groups *trans* to bridging F atoms (**22.28**). X-ray diffraction data for $K[Re_2O_4F_7]\cdot 2ReO_2F_3$ show that ReO_2F_3 adopts a polymeric structure analogous to TcO_2F_3. $TcOF_4$ and $ReOF_4$ also have polymeric structures with O atoms *trans* to M–F–M bridges. In SO_2ClF solution, ReO_2F_3 exists as an equilibrium mixture of a cyclic trimer (**22.29**) and tetramer; the Tc analogue is present only as the trimer.

(22.25)



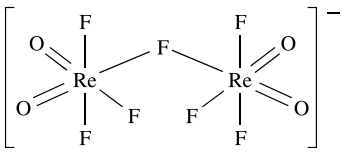
(22.26)



$Re{-}Cl_{term}$ = 227 pm $Re{-}Cl_{bridge}$ = 259 pm

(22.27)

(22.28)



(22.29)

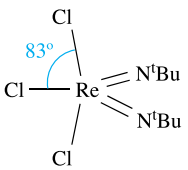
Self-study exercises

1. Rationalize why the ^{19}F NMR spectrum of a solution of $TcOF_5$ in SO_2ClF at 163 K exhibits a doublet and a quintet (J = 75 Hz). What will be the relative integrals of these signals? [*Hint*: See structure **22.26**]

2. The reaction of $TcOF_5$ with SbF_5 gives $[Tc_2O_2F_9]^+[Sb_2F_{11}]^-$. Suggest a structure for the cation. [*Ans.* See N. LeBlond *et al.* (2000) *Inorg. Chem.*, vol. 39, p. 4494]

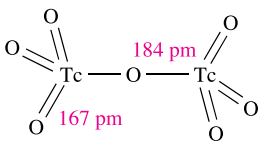
3. Assuming a static structure, predict what you would expect to see in the solution ^{19}F NMR spectrum of the following anion:

[*Ans.* See W.J. Casteel, Jr *et al.* (1999) *Inorg. Chem.*, vol. 38, p. 2340]



4. To obtain pure TcO_3F, the equilibrium:

$$[TcO_4]^- + 3HF \rightleftharpoons TcO_3F + [H_3O]^+ + 2F^-$$



is driven to the right-hand side by adding BiF_5. Suggest how this works.

[*Ans.* See J. Supel *et al.* (2007) *Inorg. Chem.*, vol. 46, p. 5591]

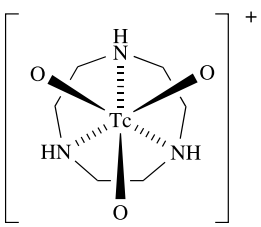
A number of imido analogues of halidooxidometal compounds ($[RN]^{2-}$ is isoelectronic with O^{2-}) have been structurally characterized and include tetrahedral $Re(N^tBu)_3Cl$ and trigonal bipyramidal $Re(N^tBu)_2Cl_3$ (**22.30**). Reduction of $Tc(NAr)_3I$ using Na leads to the dimer $[(ArN)_2Tc(\mu\text{-}NAr)_2Tc(NAr)_2]$ when Ar = 2,6-$Me_2C_6H_3$, but when Ar is the bulkier 2,6-$^iPr_2C_6H_3$, the product is $Tc_2(NAr)_6$ with an ethane-like configuration. Each dimer contains a Tc–Tc single bond.

(22.30)

(22.31)

The yellow, volatile oxides M_2O_7 (M = Tc, Re) form when the metals burn in O_2. The volatility of Re_2O_7 is used in manufacturing Re (see Section 22.2). In the solid and vapour states, Tc_2O_7 is molecular with a linear Tc–O–Tc bridge (**22.31**). In the vapour, Re_2O_7 has a similar structure but the solid adopts a complex layer

structure. The oxides are the anhydrides of $HTcO_4$ and $HReO_4$ and dissolve in water (eq. 22.67) to give solutions containing $[TcO_4]^-$ (pertechnetate) and $[ReO_4]^-$ (perrhenate). Pertechnetate and perrhenate salts are the commonest starting materials in Tc and Re chemistries.



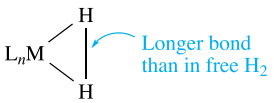
$$M_2O_7 + H_2O \longrightarrow 2HMO_4 \qquad (M = Tc, Re) \qquad (22.67)$$

Pertechnetic and perrhenic acids are strong acids. Crystalline $HReO_4$ (yellow), $HReO_4{\cdot}H_2O$ and $HTcO_4$ (dark red) have been isolated; crystalline $HReO_4{\cdot}H_2O$ consists of a hydrogen-bonded network of $[H_3O]^+$ and $[ReO_4]^-$ ions. The acids react with H_2S to precipitate M_2S_7 (eq. 22.68) in striking contrast to the reduction of $[MnO_4]^-$ to Mn^{2+} by H_2S.

$$2HMO_4 + 7H_2S \longrightarrow M_2S_7 + 8H_2O \qquad (M = Tc, Re) \qquad (22.68)$$

The $[TcO_4]^-$ and $[ReO_4]^-$ ions are tetrahedral (see Fig. 22.15) and isostructural with $[MnO_4]^-$. Whereas $[MnO_4]^-$ is intense purple due to a ligand-to-metal charge transfer absorption in the visible region, $[ReO_4]^-$ and $[TcO_4]^-$ are colourless because the corresponding LMCT band is in the UV region (see Section 20.7).

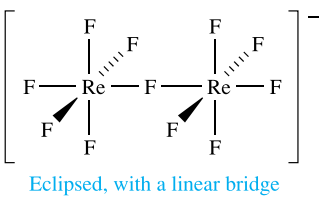
Solvated or complexed $[TcO_3]^+$ and $[ReO_3]^+$ are both known, e.g. cation **22.32**. The closest example of a free $[TcO_3]^+$ ion is found in the fluorosulfonate salt. The solid state structure of $[TcO_3][SO_3F]$ contains trigonal pyramidal $[TcO_3]^+$ (Tc–O = 168 pm), but there are three short $O_3Tc^+ \cdots OSO_2F^-$ contacts (Tc$\cdots$O = 224–228 pm) placing the Tc atom in a distorted octahedral environment.



(22.32)

Rhenium(VI) oxide, ReO_3, is made by reducing Re_2O_7 with CO. TcO_3 has not been isolated. Red ReO_3 crystallizes with a cubic structure (Fig. 21.5) which is a prototype structure. ReO_3 is a metallic-like electrical conductor owing to delocalization of the d^1 electrons. No reaction between ReO_3 and H_2O, dilute acids or alkalis occurs, but reaction 22.69 occurs with concentrated alkalis.

$$3ReO_3 + 2[OH]^- \xrightarrow[\text{conc}]{\Delta} 2[ReO_4]^- + ReO_2 + H_2O \qquad (22.69)$$

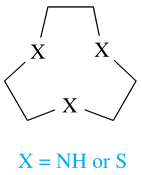


For the +5 oxidation state, the only oxide or halidooxidometal compound is the blue Re_2O_5 but it is unstable with respect to disproportionation.

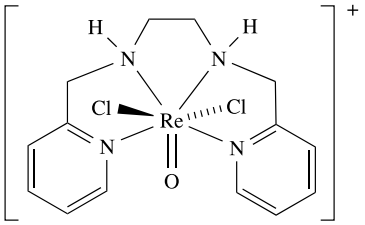
Technetium(VII) and rhenium(VII) form a series of hydride complexes (neutron diffraction data are essential for accurate H location) including the tricapped trigonal prismatic $[TcH_9]^{2-}$, $[ReH_9]^{2-}$ (see Section 10.7) and $[ReH_7(Ph_2PCH_2CH_2PPh_2\text{-}P,P')]$. Some hydrido complexes contain coordinated η^2-H_2 (**22.33**) with a 'stretched' H–H bond, e.g. in $[ReH_5(\eta^2\text{-}H_2)\{P(4\text{-}C_6H_4Me)_3\}_2]$ two H atoms are separated by 136 pm, the next shortest H$\cdots$H separation being 175 pm.

(22.33)

A few halido complexes are known for M(VI) and M(V): square antiprismatic $[ReF_8]^{2-}$ (formed from KF and ReF_6), $[ReF_6]^-$ (from reduction of ReF_6 with KI in liquid SO_2), $[TcF_6]^-$ (from TcF_6 and CsCl in IF_5), $[ReCl_6]^-$ (in the salt $[PCl_4]_3[Re^VCl_6][Re^{IV}Cl_6]$ formed from the reaction of $ReCl_5$ and PCl_5) and $[Re_2F_{11}]^-$ (**22.34**, formed as the $[Re(CO)_6]^+$ salt when an excess of ReF_6 reacts with $Re_2(CO)_{10}$ in anhydrous HF).



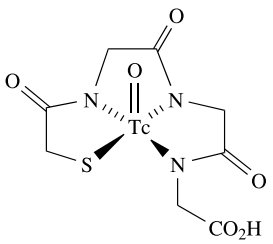
Eclipsed, with a linear bridge



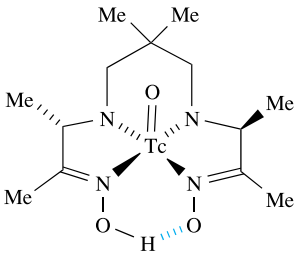
(22.34)

Complexes of M(VII), M(VI) and M(V) (M = Tc, Re) are dominated by oxido and nitrido species, with octahedral and square-based pyramidal (oxido or nitrido ligand in the apical site) structures being common. Complexes of M(V) outnumber those of the higher oxidation states, with square-based pyramidal structures usually favoured. Examples include:

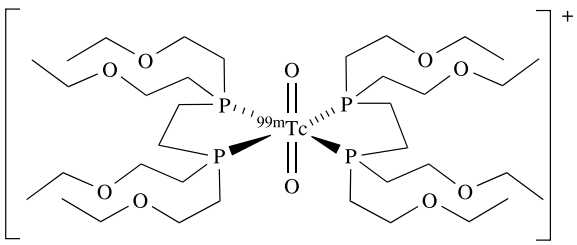
- octahedral M(VII): *fac*-$[ReO_3L]^+$ (L = **22.35**, see structure **22.32**), *fac*-$[ReO_3Cl(phen)]$, $[TcNCl(\eta^2\text{-}O_2)_2]^-$;
- octahedral M(VI): $[ReOCl_5]^-$, *trans*-$[TcN(OH_2)Br_4]^-$, *mer*-$[TcNCl_3(bpy)]$;
- square-based pyramidal M(VI): $[TcNCl_4]^-$, $[TcNBr_4]^-$;
- octahedral M(V): $[ReOCl_5]^{2-}$, $[ReOCl_4(py)]^-$, *trans*-$[TcO_2(en)_2]^+$, *trans*-$[TcO_2(py)_4]^+$, *cis*-$[TcNBr(bpy)_2]^+$;
- square-based pyramidal M(V): $[ReOCl_4]^-$, $[TcOCl_4]^-$, $[TcO(ox)_2]^-$;
- pentagonal bipyramidal, rare for Re(V): complex **22.36**;
- square antiprismatic Re(V): $[Re(CN)_8]^{3-}$.



(22.35)



(22.36)



The development of technetium agents for imaging the brain, heart and kidneys has prompted the study of a range of Tc(V) oxido complexes, many of which are square-based pyramidal and contain a tetradentate ligand, often a mixed *S*- and *N*-donor. The oxido ligand occupies the apical site. Complexes **22.37** and **22.38** (in their ^{99m}Tc forms, see Box 22.6) are examples of radiopharmaceuticals used as kidney and brain imaging agents respectively. Complex **22.39** (containing the metastable radioisotope ^{99m}Tc) is marketed as the heart imaging agent Myoview. The ethoxyethyl substituents render the complex lipophilic, a requirement for biodistribution (uptake into the heart and clearance from the blood and liver).[†]

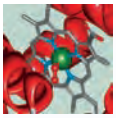
Technetium(IV) and rhenium(IV)

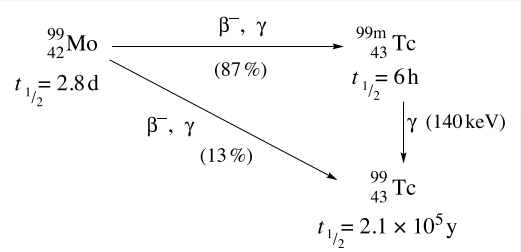
The reaction of Tc_2O_7 with CCl_4 at 670 K (or heating Tc and Cl_2) gives $TcCl_4$ as a moisture-sensitive, red solid. The halides ReX_4 (X = F, Cl, Br, I) are all known. Blue ReF_4 forms when ReF_5 is reduced by H_2 over a Pt gauze, and black $ReCl_4$ is made by heating $ReCl_5$ and Re_3Cl_9. Solid $TcCl_4$ and $ReCl_4$ are polymeric but not isostructural. $TcCl_4$ adopts chain structure **22.40** and has a magnetic moment of 3.14 μ_B (298 K) per Tc(IV) centre. In $ReCl_4$, dimers are linked into zigzag chains by chlorido-bridges (**22.41**) and the short Re−Re distance is consistent with metal–metal bonding (compare **22.41** with **22.19**). The salt $[PCl_4]^+[Re_2Cl_9]^-$ is formed by reducing $ReCl_5$ using PCl_3 at 373–473 K under a stream of N_2. The salt contains discrete ions. $[Re_2Cl_9]^-$ adopts a structure analogous to **22.19**, and the Re−Re distance of 272 pm is consistent with a single bond. When PCl_5 is heated with $ReCl_4$ at 570 K under vacuum, the product is $[PCl_4]_2[Re_2Cl_{10}]$. The structure of the $[Re_2Cl_{10}]^{2-}$ ion is similar to the $ReCl_5$ dimer (**22.24**); neither has a direct Re−Re bond.



(22.40)

(22.41)

The oxides TcO_2 and ReO_2 are made by thermal decomposition of $[NH_4][MO_4]$ or reduction of M_2O_7 by M or H_2. Both adopt rutile structures (Fig. 6.24), distorted by pairing of metal centres as in MoO_2. With O_2, TcO_2 is oxidized to Tc_2O_7, and with H_2 at 770 K, reduction of TcO_2 to the metal occurs.



Reduction of $KReO_4$ using I^- in concentrated HCl produces $K_4[Re_2(\mu\text{-}O)Cl_{10}]$. The $[Re_2(\mu\text{-}O)Cl_{10}]^{4-}$ anion has a linear Re−O−Re bridge with Re−O π-character (Re−O = 186 pm) and is structurally related to $[W_2(\mu\text{-}O)Cl_{10}]^{4-}$ and $[Ru_2(\mu\text{-}O)Cl_{10}]^{4-}$ (see Fig. 22.18). The octahedral complexes $[MX_6]^{2-}$ (M = Tc, Re; X = F, Cl, Br, I) are all known and are probably the most important M(IV) complexes. Salts of $[TcF_6]^{2-}$ are most conveniently prepared by reducing $[TcO_4]^-$ with $Na_2S_2O_4$, followed by addition of an alkali metal fluoride or Me_4NF (Fig. 22.15). The ions $[MX_6]^{2-}$ (X = Cl, Br, I) are formed by reducing $[MO_4]^-$ (e.g. by I^-) in concentrated HX. Reactions of $[MBr_6]^{2-}$ with HF yield $[MF_6]^{2-}$. The chlorido complexes (e.g. as K^+ or $[Bu_4N]^+$ salts) are useful starting materials in Tc and Re chemistries, but both are readily hydrolysed

BIOLOGY AND MEDICINE

Box 22.6 Technetium-99m labelling using $[Tc(OH_2)_3(CO)_3]^+$

Most radioisotopes used in nuclear medicine are artificial. They are produced in nuclear reactors (e.g. ^{89}Sr, ^{57}Co), cyclotrons (e.g. ^{11}C, ^{18}F) or specialized generators such as a molybdenum-technetium generator. The metastable radioisotope ^{99m}Tc has a half-life of 6 hours and is important for medical imaging. It is a decay product of ^{99}Mo ($t_{1/2}$ = 2.8 days), which is itself man-made, being produced in a nuclear reactor. The radioactive decay of ^{99}Mo to ^{99m}Tc and the much longer lived ^{99}Tc is summarized below:

For medical use, ^{99}Mo is used in the form of $[^{99}MoO_4]^{2-}$ adsorbed on alumina in a 'cold kit' generator. The commercial assembly of the latter is shown in the photograph opposite. Decay of $[^{99}MoO_4]^{2-}$ gives $[^{99m}TcO_4]^-$ which is selectively eluted from the generator and combined with an appropriate ligand to give a complex suitable for injection into a patient. The ^{99m}Tc-containing complexes are designed to target tumour cells. As ^{99m}Tc decays to ^{99}Tc, γ-radiation of energy 140 keV is emitted. This energy falls within the range (≈100–200 keV) compatible with modern γ-detectors. The emitted γ-radiation can be recorded in the form of a γ-camera scan or *scintigram*. These 2-dimensional images are used to evaluate both primary tumours and metastases. (Metastasis is the growth of a secondary malignant tumour from a primary cancer.) Three-dimensional images are obtained by using *single photon emission computed tomography* (SPECT). This technique enables a radiographer to obtain an image by using only micromolar or nanomolar concentrations of the ^{99m}Tc tracer. ^{99m}Tc is invaluable for diagnostic imaging, and with the development of a suite of technetium-containing complexes, it is now possible to image the heart, liver, kidneys, brain and bone.

In developing new techniques of tumour imaging with radioisotopes, one goal is to label single-chain antibody fragments which may efficiently target tumours. The complex $[^{99m}Tc(OH_2)_3(CO)_3]^+$:

Clean-room assembly of technetium-99m generators. $[^{99}MoO_4]^{2-}$ is adsorbed on alumina in a 'cold kit' generator, and radioactive decay produces $[^{99m}TcO_4]^-$.

can be used to label single-chain antibody fragments which carry *C*-terminal histidine tags. High activities are achieved (90 mCi mg^{-1}) and, *in vivo*, the technetium-labelled fragments are very stable. This technique appears to have a high potential for application in clinical medicine. The original method of preparing $[^{99m}Tc(OH_2)_3(CO)_3]^+$ involved the reaction between $[^{99m}TcO_4]^-$ and CO at 1 bar pressure in aqueous NaCl at pH 11. For commercial radiopharmaceutical kits, use of gaseous CO is inconvenient and solid, air-stable sources of CO are desirable. Potassium boranocarbonate, $K_2[H_3BCO_2]$ (made from $H_3B{\cdot}THF$/CO and ethanolic KOH), is ideal: it acts as both a source of CO and a reducing agent, and reacts with $[^{99m}TcO_4]^-$ under buffered, aqueous conditions to give $[^{99m}Tc(OH_2)_3(CO)_3]^+$.

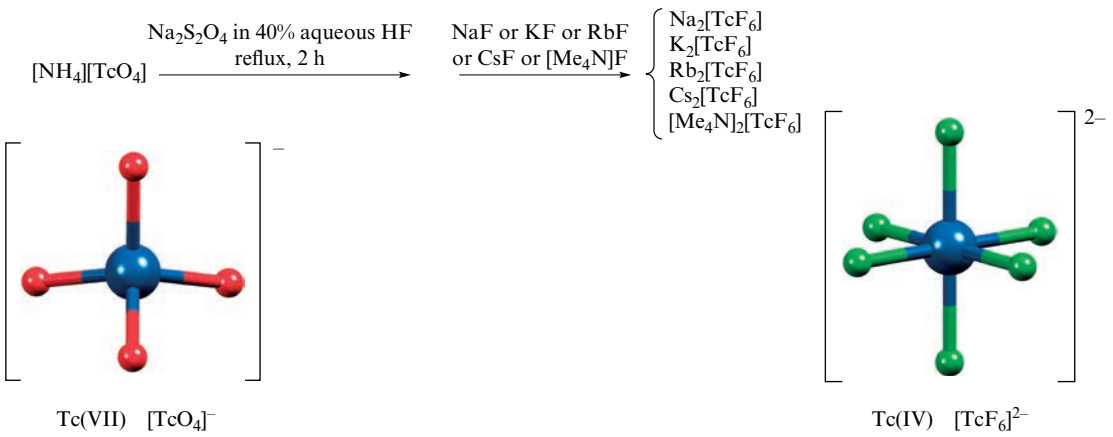

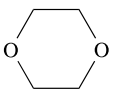

Fig. 22.15. Synthetic route to salts of $[TcF_6]^{2-}$; sodium dithionite ($Na_2S_2O_4$) is the reducing agent. (See: S.M. Balasekaran *et al.* (2013) *Inorg. Chem.*, vol. 52, p. 7094.)

in water. In aqueous solution, $[TcCl_6]^{2-}$ is in equilibrium with $[TcCl_5(OH_2)]^-$, and complete hydrolysis gives TcO_2. Halide exchange between $[ReI_6]^{2-}$ and HCl leads to *fac*-$[ReCl_3I_3]^{2-}$, *cis*- and *trans*-$[ReCl_4I_2]^{2-}$ and $[ReCl_5I]^{2-}$. In most complexes, octahedral coordination for Re(IV) and Tc(IV) is usual, e.g. *cis*-$[TcCl_2(acac)_2]$, *trans*-$[TcCl_4(PMe_3)_2]$, $[Tc(NCS\text{-}N)_6]^{2-}$, $[Tc(ox)_3]^{2-}$, *trans*-$[ReCl_4(PPh_3)_2]$, $[ReCl_5(OH_2)]^-$, $[ReCl_5(PEt_3)]^-$, $[ReCl_4(bpy)]$ and *cis*-$[ReCl_4(THF)_2]$. A notable exception is the pentagonal bipyramidal $[Re(CN)_7]^{3-}$ ion which is made as the $[Bu_4N]^+$ salt by heating $[Bu_4N]_2[ReCl_6]$ with $[Bu_4N][CN]$ in DMF.

Self-study exercise

The hydrolysis of $TcCl_4$ immediately gives TcO_2. However, *cis*-$[TcCl_4(OH_2)_2]$ can be isolated as the solvate $[TcCl_4(OH_2)_2]\cdot 2C_4H_8O_2$ from a solution of $TcCl_4$ in dioxane ($C_4H_8O_2$) containing trace amounts of water. Suggest what intermolecular interactions are responsible for stabilizing $[TcCl_4(OH_2)_2]$, and indicate how *cis*-$[TcCl_4(OH_2)_2]\cdot 2C_4H_8O_2$ can adopt a chain-like structure in the solid state.

dioxane

Technetium(III) and rhenium(III)

For the +3 oxidation state, metal–metal bonding becomes important. Rhenium(III) halides (X = Cl, Br, I) are trimeric, M_3X_9. No Tc(III) halide or ReF_3 is known. Rhenium(III) chloride is an important precursor in Re(III) chemistry and is made by heating $ReCl_5$. Its structure (Fig. 22.16a) consists of an Re_3 triangle (Re–Re = 248 pm), each edge being chlorido-bridged; the terminal Cl atoms lie above and below the metal framework. In the solid, two-thirds of the terminal Cl atoms are involved in weak bridging

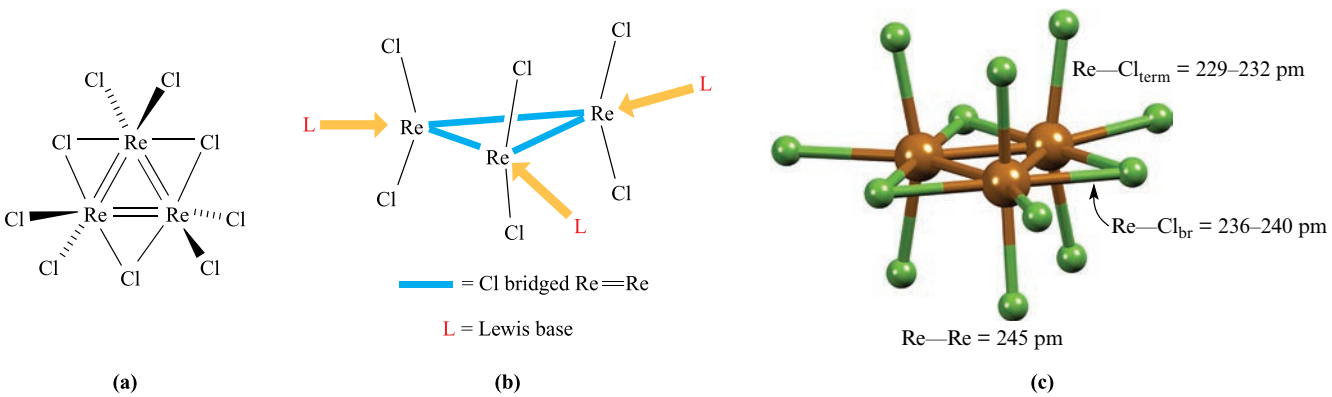

Fig. 22.16. Schematic representations of (a) the structure of Re_3Cl_9 (interactions between units occur in the solid, see text) and (b) the sites of addition of Lewis bases to Re_3Cl_9. (c) The structure (X-ray diffraction) of $[Re_3Cl_{12}]^{3-}$ in the $[Me_3NH]^+$ salt [M. Irmler *et al.* (1991) *Z. Anorg. Allg. Chem.*, vol. 604, p. 17]; colour code: Re, brown; Cl, green.

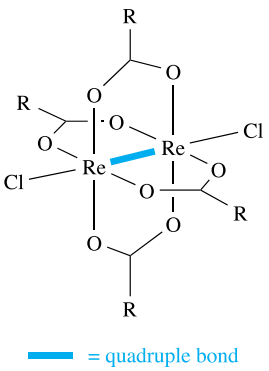
interactions to Re atoms of adjacent molecules. Rhenium(III) chloride is diamagnetic, and Re=Re double bonds are allocated to the metal framework, i.e. the (formally) $\{Re_3\}^{9+}$ core contains 12 valence electrons (Re, s^2d^5) which are used for metal–metal bonding. Lewis bases react with Re_3Cl_9 (or $Re_3Cl_9(OH_2)_3$) to give complexes of type $Re_3Cl_9L_3$ (Fig. 22.16b). $Re_3Cl_9(OH_2)_3$ can be isolated from aqueous solutions of the chloride at 273 K. Scheme 22.70 shows further examples of Lewis base additions.

$$Re_3Cl_9(py)_3 \xleftarrow{py} Re_3Cl_9 \xrightarrow{PR_3} Re_3Cl_9(PR_3)_3 \qquad (22.70)$$

The reaction of MCl with Re_3Cl_9 gives $M[Re_3Cl_{10}]$, $M_2[Re_3Cl_{11}]$ or $M_3[Re_3Cl_{12}]$ depending upon the conditions, for example reactions 22.71 and 22.72. Figure 22.16c shows the structure of the $[Re_3Cl_{12}]^{3-}$ ion.



$$Re_3Cl_9 \xrightarrow{\text{excess CsCl, conc HCl}} Cs_3[Re_3Cl_{12}] \qquad (22.71)$$

$$Re_3Cl_9 \xrightarrow{[Ph_4As]Cl,\ \text{dil HCl}} [Ph_4As]_2[Re_3Cl_{11}] \qquad (22.72)$$

The diamagnetic $[Re_2Cl_8]^{2-}$ was the first example of a species containing a metal–metal quadruple bond. It is made by reducing $[ReO_4]^-$ using H_2 or $[HPO_2]^{2-}$ and is isostructural with $[Mo_2Cl_8]^{4-}$ (Fig. 22.13c) with a Re−Re distance of 224 pm. Salts of $[Re_2Cl_8]^{2-}$ are blue ($\lambda_{max} = 700$ nm) arising from a $\sigma^2\pi^4\delta^1\delta^{*1} \leftarrow \sigma^2\pi^4\delta^2$ transition (Fig. 21.17). Reactions of $[Re_2Cl_8]^{2-}$ include ligand displacements and redox processes. With Cl_2, $[Re_2Cl_9]^-$ is formed (i.e. oxidation and Cl^- addition). Reaction 22.73 shows the reaction of carboxylates with $[Re_2Cl_8]^{2-}$; the reaction can be reversed by treatment with HCl.

$$[Re_2Cl_8]^{2-} + 4[RCO_2]^- \longrightarrow [Re_2(\mu\text{-}O_2CR)_4Cl_2] + 6Cl^- \qquad (22.73)$$

(22.42)

(22.42)

When $[Re_2Cl_8]^{2-}$ reacts with bidentate phosphanes (e.g. reaction 22.74), the $\{Re_2\}^{6+}$ core with a $\sigma^2\pi^4\delta^2$ configuration (Re≡Re) is reduced to an $\{Re_2\}^{4+}$ unit ($\sigma^2\pi^4\delta^2\delta^{*2}$, Re≡Re). The change might be expected to lead to an increase in the Re−Re bond length, but in fact it stays the same (224 pm). The introduction of the bridging ligands counters the decrease in bond order by 'clamping' the Re atoms together.

$$[Re_2Cl_8]^{2-} + 2Ph_2PCH_2CH_2PPh_2 \xrightarrow{-Cl^-} [Re_2Cl_4(\mu\text{-}Ph_2PCH_2CH_2PPh_2)_2] \qquad (22.74)$$

reduction

The $[Tc_2Cl_8]^{2-}$ ion is also known but is less stable than $[Re_2Cl_8]^{2-}$. The paramagnetic $[Tc_2Cl_8]^{3-}$ ($\sigma^2\pi^4\delta^2\delta^{*1}$, Tc−Tc = 211 pm, eclipsed ligands) is easier to isolate than $[Tc_2Cl_8]^{2-}$ ($\sigma^2\pi^4\delta^2$, Tc−Tc = 215 pm, eclipsed ligands). The *increase* in Tc−Tc distance of 4 pm in going from $[Tc_2Cl_8]^{3-}$ to $[Tc_2Cl_8]^{2-}$ is not readily rationalized. Reduction of the $\{Tc_2\}^{6+}$ core occurs when $[Tc_2Cl_8]^{2-}$ undergoes reaction 22.75. The product (also made from $Tc^{II}{}_2Cl_4(PR_3)_4$ and $HBF_4{\cdot}OEt_2$) is expected to have a staggered arrangement of ligands consistent with the change from $\sigma^2\pi^4\delta^2$ to $\sigma^2\pi^4\delta^2\delta^{*2}$, and this has been confirmed for the related $[Tc_2(NCMe)_8(OSO_2CF_3)_2]^{2+}$.

$$[Tc_2Cl_8]^{2-} \xrightarrow{HBF_4{\cdot}OEt_2,\ \text{in MeCN}} [Tc_2(NCMe)_{10}]^{4+} \qquad (22.75)$$

Mononuclear complexes of Re(III) and Tc(III) are quite well exemplified (often with π-acceptor ligands stabilizing the +3 oxidation state) and octahedral coordination is usual, e.g. $[Tc(acac)_2(NCMe)_2]^+$, $[Tc(acac)_3]$, $[Tc(NCS\text{-}N)_6]^{3-}$, *mer*-$[Tc(Ph_2PCH_2CH_2CO_2)_3]$, *mer*,*trans*-$[ReCl_3(NCMe)(PPh_3)_2]$. 7-Coordination has been observed in $[ReBr_3(CO)_2(bpy)]$ and $[ReBr_3(CO)_2(PMe_2Ph)_2]$. Simple aqua ions such as $[Tc(OH_2)_6]^{3+}$ are not known, although, stabilized by CO, it is possible to prepare the Tc(I) species $[Tc(OH_2)_3(CO)_3]^+$ (see Box 22.6).

Technetium(I) and rhenium(I)

The chemistry of Tc(I) and Re(I) complexes has increased in importance with their application as, or models for, diagnostic imaging agents (see Box 22.6). The M(I) centre is stabilized by using π-acceptor ligands, e.g. CO, RNC or η^6-arene ligands.† Reduction of $[TcO_4]^-$ by $[S_2O_4]^{2-}$ in alkaline aqueous EtOH in the presence of an isocyanide, RNC, gives octahedral $[Tc(CNR)_6]^+$. With R = CH_2CMe_2OMe, this species is lipophilic and the ^{99m}Tc complex is marketed under the trade name of Cardiolite as a heart imaging agent. Since $[S_2O_4]^{2-}$ is not a strong enough reducing agent to convert $[ReO_4]^-$ to $[Re(CNR)_6]^+$ in the presence of RNC, these rhenium(I) complexes are made by treating $[ReOCl_3(PPh_3)_2]$ with an excess of RNC.

† For bis(arene) complexes of Tc(I), see: M. Benz, H. Braband, P. Schmutz, J. Halter and R. Alberto (2015) *Chem. Sci.*, vol. 6, p. 165.

Another group of important Tc(I) and Re(I) complexes are those containing the *fac*-$M(CO)_3^+$ unit. A convenient synthesis of *fac*-$[M(CO)_3X_3]$ involves treatment of $[MO_4]^-$ or $[MOCl_4]^-$ (M = Tc or Re) with BH_3·THF/CO (see Box 22.6). The CO ligands exhibit a strong *trans*-effect (see Section 26.3) and labilize the Cl^- ligands in *fac*-$[M(CO)_3Cl_3]^{2-}$. Consequently, solvent molecules, including H_2O, readily exchange with Cl^- to give *fac*-$[M(CO)_3(solv)_3]^+$. While the *fac*-$M(CO)_3^+$ unit is inert with respect to ligand substitution, solvent molecules exchange with a variety of ligands. *fac*-$[Tc(CO)_3(OH_2)_3]^+$ is of increasing significance in radiopharmaceutical applications.

Self-study exercises

1. Show that *fac*-$[Tc(CO)_3(CN)_3]^{2-}$ belongs to the C_{3v} point group.
2. A sample of *fac*-$[Tc(CO)_3(CN)_3]^{2-}$ was made using $K^{13}CN$, and was labelled to an extent of ≈70%. Rationalize why the ^{99}Tc NMR spectrum of this complex shows a quartet (J 186 Hz), superimposed on a less intense triplet. Are any other signals expected in the spectrum?

[*Ans.* See P. Kurz *et al.* (2004) *Inorg. Chem.*, vol. 43, p. 3789]

22.9 Group 8: ruthenium and osmium

The metals

Like all platinum-group metals, Ru and Os are relatively noble. Osmium powder reacts slowly with O_2 at 298 K to give the volatile OsO_4 (the bulk metal requires heating to 670 K). Ruthenium metal is passivated by a coating of non-volatile RuO_2 and reacts further with O_2 only at temperatures above 870 K. Both metals react with F_2 and Cl_2 when heated (see below), and are attacked by mixtures of HCl and oxidizing agents, and by molten alkalis.

Table 19.3 shows the range of oxidation states exhibited by the group 8 metals. In this section we consider oxidation states from +2 to +8. The lower states are stabilized by π-acceptor ligands and are covered in Chapter 24. Consistent with trends seen for earlier second and third row metals, Ru and Os form some compounds with metal–metal multiple bonds.

High oxidation states of ruthenium and osmium: M(VIII), M(VII) and M(VI)

Despite the fact that the maximum oxidation state of Ru and Os is +8 (e.g. in RuO_4 and OsO_4), the only binary halides formed for the high oxidation states are RuF_6 (eq. 22.76) and OsF_6 (eq. 22.77). The formation of OsF_7 has been claimed but not proven (Fig. 22.17).

$$2RuF_5 + F_2 \xrightarrow{500\,K,\,50\,bar} 2RuF_6 \qquad (22.76)$$

$$Os + 3F_2 \xrightarrow{500\,K,\,1\,bar} OsF_6 \qquad (22.77)$$

Ruthenium(VI) fluoride is an unstable brown solid. OsF_6 is a volatile yellow solid with a molecular (octahedral) structure. Neutron powder diffraction data for OsF_6 reveal that the four equatorial Os–F bonds are slightly shorter than the apical bonds, providing evidence for a small Jahn–Teller effect, consistent with the t_{2g}^2 ground state electronic configuration for Os(VI). Metal carbonyl cations (see Section 24.5) are rare but in superacid media, OsF_6 reacts with CO to give the osmium(II) complex $[Os(CO)_6]^{2+}$ (eq. 22.78).

$$OsF_6 + 4SbF_5 + 8CO \xrightarrow{300\,K,\,1.5\,bar\,CO\ in\ HF/SbF_5} [Os(CO)_6][Sb_2F_{11}]_2 + 2COF_2 \qquad (22.78)$$

Several fluoridooxido compounds of Os(VIII), Os(VII) and Os(VI) are known, but $RuOF_4$ is the only example for Ru. All are very moisture-sensitive. Yellow-green $RuOF_4$ can be prepared from RuO_2 and argon-diluted F_2 at 720 K. This form of $RuOF_4$ is polymeric, with octahedral units **22.43** linked into helical chains (see Fig. 22.18a). If the synthesis is carried out with neat F_2 at 570 K, a yellow form of $RuOF_4$ is produced. Crystallographic data for this polymorph confirm the presence of loosely held dimers **22.44** (Ru···F = 234 pm compared with Ru–F = 184 to 192 pm).

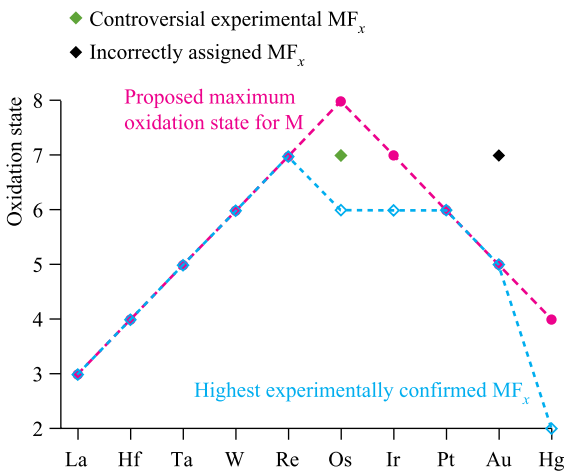


Fig. 22.17. Highest oxidation state 5*d* metal fluorides showing confirmed experimental data, erroneous or unconfirmed data, and the possible maximum oxidation state that could be attained by the metal. [Adapted from: S. Riedel and M. Kaupp (2006) *Inorg. Chem.*, vol. 45, p. 10497.]

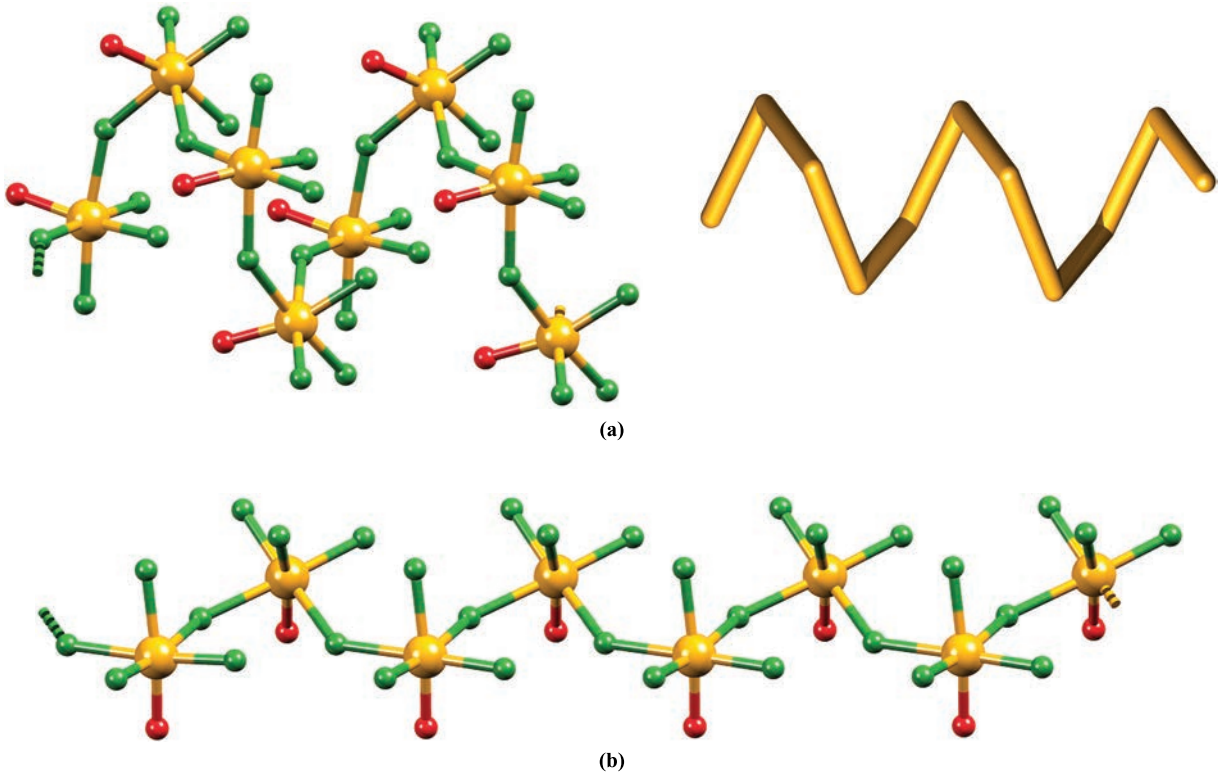

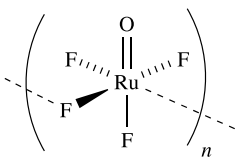

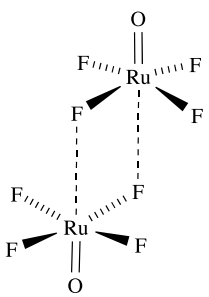

Fig. 22.18. Structures (X-ray diffraction) of the two polymorphs of $OsOF_4$. (a) Form I consists of helical polymer chains, and the structure of the polymeric form of $RuOF_4$ is analogous. (b) In form II of $OsOF_4$, each chain has a flattened, zigzag backbone. Colour code: Os, yellow; O, red; F, green. [Data: structural data were provided by Konrad Seppelt; from H. Shorafa *et al.* (2007) *Z. Anorg. Allg. Chem.*, vol. 633, p. 543.]

yellow-green form of $RuOF_4$

(22.43)

yellow form of $RuOF_4$

(22.44)

Deep blue $OsOF_4$ is best prepared[†] by lengthy heating of OsO_4 with OsF_6. Like $RuOF_4$, $OsOF_4$ crystallizes in two modifications: a helical polymer (Fig. 22.18a) and a closely related polymeric structure in which the chain is flattened (Fig. 22.18b). $OsOCl_4$ can be prepared from OsO_4 and BCl_3 but is very unstable. Crystalline $OsOCl_4$ consists of loosely bound dimers like those of yellow $RuOF_4$ (**22.44**).

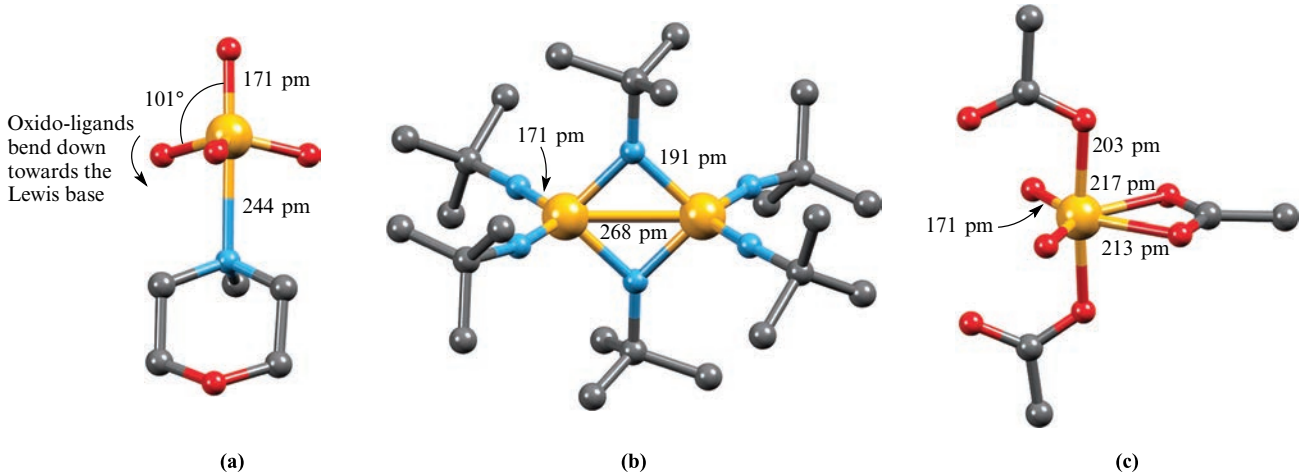
The only fluoridooxidoosmium compound that contains Os(VII) is green $OsOF_5$. This may be made by heating OsF_6 and OsO_4 at ≈ 500 K, and crystalline $OsOF_5$ consists of monomeric molecules. The compound 'OsO_2F_3' does not contain Os(VII), but is the mixed oxidation state species $OsO_3F_2{\cdot}OsOF_4$.[‡]

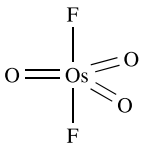
Red *cis*-OsO_2F_4 forms when OsO_4 reacts with HF and KrF_2 at 77 K. Yellow OsO_3F_2 (made from F_2 and OsO_4) is also molecular in the gas phase (**22.45**) but is polymeric in the solid with Os−F−Os bridges connecting *fac*-octahedral units. Scheme 22.79 illustrates the ability of OsO_3F_2 to act as a fluoride acceptor.

$$\mathrm{OsO_3F_2} \xrightarrow[\text{warm to 213 K}]{\text{NOF, 195 K}} \mathrm{[NO]^+[\mathit{fac}\text{-}OsO_3F_3]^-}$$
$$\Big\downarrow \text{[Me}_4\text{N]F in anhydrous HF}$$
$$\mathrm{[Me_4N]^+[\mathit{fac}\text{-}OsO_3F_3]^-} \qquad (22.79)$$

[†] For discussion of problems associated with literature reports of $OsOF_4$, see: H. Shorafa and K. Seppelt (2007) *Z. Anorg. Allg. Chem.*, vol. 633, p. 543.

[‡] For detailed discussion, see: H. Shorafa and K. Seppelt (2006) *Inorg. Chem.*, vol. 45, p. 7929.





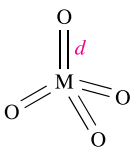


Fig. 22.19. The structures (X-ray diffraction) of (a) the adduct formed between *N*-methylmorpholine and OsO_4 [A.J. Bailey *et al.* (1997) *J. Chem. Soc.*, *Dalton Trans.*, p. 3245], (b) $[Os_2(N^tBu)_4(\mu\text{-}N^tBu)_2]^{2+}$ in the $[BF_4]^-$ salt [A.A. Danopoulos *et al.* (1991) *J. Chem. Soc.*, *Dalton Trans.*, p. 269] and (c) $[OsO_2(O_2CMe)_3]^-$ in the solvated K^+ salt [T. Behling *et al.* (1982) *Polyhedron*, vol. 1, p. 840]. Colour code: Os, yellow; O, red; C, grey; N, blue.

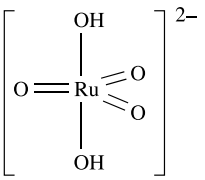
(22.45)

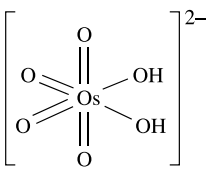
M = Ru, Os; *d* = 171 pm (gas phase)

(22.46)



Both Ru and Os form toxic, volatile, yellow oxides MO_4 (RuO_4 mp 298 K, bp 403 K; OsO_4 mp 313 K, bp 403 K)† but RuO_4 is more readily reduced than OsO_4. Osmium(VIII) oxide ('osmic acid') is made from Os and O_2 (see above), but the formation of RuO_4 requires acidified $[IO_4]^-$ or $[MnO_4]^-$ oxidation of RuO_2 or $RuCl_3$. Both tetraoxides have penetrating ozone-like odours; they are sparingly soluble in water but soluble in CCl_4. The oxides are isostructural (molecular structure **22.46**). Ruthenium(VIII) oxide is thermodynamically unstable with respect to RuO_2 and O_2 (eq. 22.80) and is liable to explode. It is a very powerful oxidant, reacting violently with organic compounds. Osmium(VIII) oxide is used as an oxidizing agent in organic synthesis (e.g. converting alkenes to 1,2-diols) and as a biological stain, but its ease of reduction and its volatility make it dangerous to the eyes. For M = Os, reaction 22.80 occurs only on heating.

$$MO_4 \longrightarrow MO_2 + O_2 \qquad (M = Ru, Os) \qquad (22.80)$$



Osmium(VIII) oxide forms adducts with Lewis bases such as Cl^-, 4-phenylpyridine and *N*-morpholine. The adducts are distorted trigonal bipyramidal with the oxido ligands in the equatorial and one axial site (Fig. 22.19a). OsO_4 acts as a fluoride acceptor, reacting with $[Me_4N]F$ at 298 K to give $[Me_4N][OsO_4F]$, and with two equivalents of $[Me_4N]F$ at 253 K to yield $[Me_4N]_2[cis\text{-}OsO_4F_2]$.

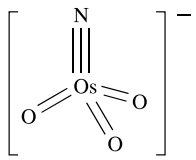
When RuO_4 dissolves in aqueous alkali, O_2 is evolved and $[RuO_4]^-$ forms; in concentrated alkali, reduction proceeds to $[RuO_4]^{2-}$ (eq. 22.81). K_2RuO_4 can also be made by fusing Ru with KNO_3 and KOH.

$$4[RuO_4]^- + 4[OH]^- \longrightarrow 4[RuO_4]^{2-} + 2H_2O + O_2 \qquad (22.81)$$

(22.47)

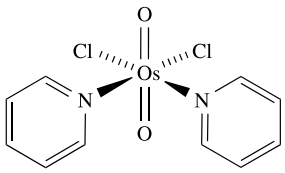
(22.48)

Both $[RuO_4]^-$ and $[RuO_4]^{2-}$ are powerful oxidants but can be stabilized in solution by pH control under non-reducing conditions. In solid state salts, $[RuO_4]^-(d^1)$ has a flattened tetrahedral structure (Ru–O = 179 pm), but crystals of '$K_2[RuO_4]\cdot H_2O$' are actually $K_2[RuO_3(OH)_2]$ containing anion **22.47**. In contrast to its action on RuO_4, alkali reacts with OsO_4 to give *cis*-$[OsO_4(OH)_2]^{2-}$ (**22.48**) which is reduced to *trans*-$[OsO_2(OH)_4]^{2-}$ by EtOH. Anion **22.48** has been isolated in crystalline $Na_2[OsO_4(OH)_2]\cdot 2H_2O$. Reaction 22.82 gives $K[Os(N)O_3]$ which contains tetrahedral $[Os(N)O_3]^-$ (**22.49**), isoelectronic and isostructural with OsO_4. The IR spectrum of $[Os(N)O_3]^-(C_{3v})$ contains bands at 871 and 897 cm^{-1}



† The literature contains differing values for OsO_4: see Y. Koda (1986) *J. Chem. Soc.*, *Chem. Commun.*, p. 1347.

(asymmetric and symmetric $\nu_{Os=O}$, respectively) and 1021 cm^{-1} ($\nu_{Os\equiv N}$); this compares with absorptions at 954 and 965 cm^{-1} for OsO_4 (T_d, see Fig. 3.16).



$$OsO_4 + NH_3 + KOH \longrightarrow K[Os(N)O_3] + 2H_2O \quad (22.82)$$

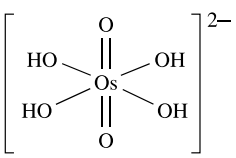
$$OsO_4 \xrightarrow{(Me_3Si)NH^tBu} Os(N^tBu)_4 \quad (22.83)$$

Reaction 22.83 gives an imido analogue of OsO_4. The tetrahedral shape is retained and the Os−N bond lengths of 175 pm are consistent with double bonds. Sodium amalgam reduces $Os(N^tBu)_4$ to the Os(VI) dimer $Os_2(N^tBu)_4(\mu\text{-}N^tBu)_2$ (Os−Os = 310 pm) and subsequent oxidation gives $[Os_2(N^tBu)_4(\mu\text{-}N^tBu)_2]^{2+}$ (Fig. 22.19b), a rare example of an Os(VII) complex. Trigonal planar $Os(NAr)_3$ is stabilized against dimerization if the aryl group, Ar, is very bulky, e.g. 2,6-$^i Pr_2C_6H_3$.

(22.49)

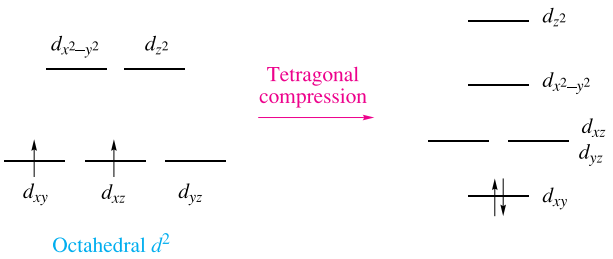
(22.50)

Complexes of M(VIII) and M(VII) are few, e.g. $[Os(N)O_3]^-$ (see above), but are well exemplified for M(VI), particularly for M = Os, with oxido, nitrido or imido ligands commonly present, e.g.



- tetrahedral: $[OsO_2(S_2O_3\text{-}S)_2]^{2-}$;
- square-based pyramidal: $[RuNBr_4]^-$, $[OsNBr_4]^-$;
- octahedral: $[OsO_2(O_2CMe)_3]^-$ (distorted, Fig. 22.19c), *trans*-$[OsO_2Cl_4]^{2-}$, *trans*-$[RuO_2Cl_4]^{2-}$, $[OsO_2Cl_2(py)_2]$ (**22.50**), *trans*-$[OsO_2(en)_2]^{2+}$.

Worked example 22.2 Osmium(VI) compounds



Rationalize why salts of *trans*-$[OsO_2(OH)_4]^{2-}$ are diamagnetic.

$[OsO_2(OH)_4]^{2-}$ contains Os(VI) and therefore has a d^2 configuration.

The structure of *trans*-$[OsO_2(OH)_4]^{2-}$ is:

An octahedral (O_h) d^2 complex would be paramagnetic, but in $[OsO_2(OH)_4]^{2-}$, the axial Os−O bonds are shorter than the equatorial Os−O bonds. The complex therefore suffers from a tetragonal distortion and, consequently, the *d* orbitals split as follows, assuming that the *z* axis is defined to lie along the O=Os=O axis:

The complex is therefore diamagnetic.

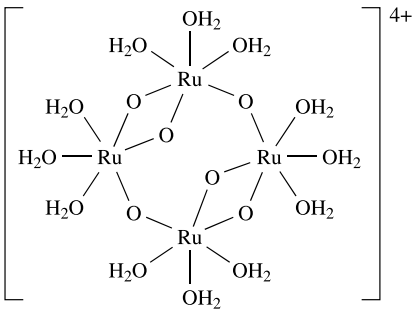
Self-study exercises

1. Rationalize why OsF_6 suffers only a *small* Jahn–Teller effect.
   [*Ans.* See 'Jahn–Teller distortions' in Section 20.3]
2. Suggest why the high oxidation state compounds of Os are dominated by those containing oxido, nitrido and fluorido ligands.
   [*Ans.* All π-donor ligands; see Section 20.4]
3. Comment on the fact that, at 300 K, μ_{eff} for OsF_6 is 1.49 μ_B.
   [*Ans.* See discussion of Kotani plots in Section 20.10]

Ruthenium(V), (IV) and osmium(V), (IV)

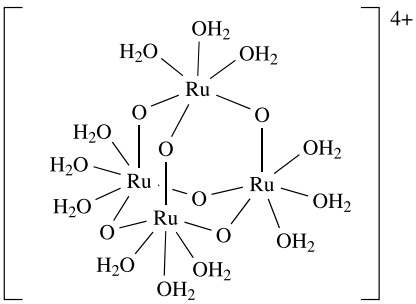
Green RuF_5 and OsF_5 (readily hydrolysed solids) are made by reactions 22.84 and 22.85 and are tetrameric like NbF_5 (**22.5**) but with non-linear bridges. Black $OsCl_5$ is the only other halide of the M(V) state and is made by reducing and chlorinating OsF_6 with BCl_3. It is dimeric, analogous to $NbCl_5$ (**22.6**).

$$2Ru + 5F_2 \xrightarrow{570K} 2RuF_5 \quad (22.84)$$



$$OsF_6 \xrightarrow{I_2,\ IF_5,\ 328\ K} OsF_5 \quad (22.85)$$

For the M(IV) state, RuF_4, OsF_4, $OsCl_4$ (two polymorphs) and $OsBr_4$ are known and are polymeric. The fluorides are made by reducing higher fluorides, and $OsCl_4$ and $OsBr_4$ by combining the elements at high temperature and, for $OsBr_4$, high pressure.

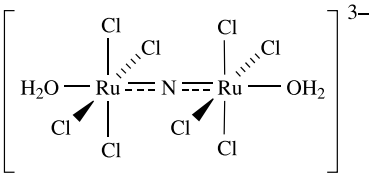


In contrast to iron, the lowest oxides formed by the heavier group 8 metals are for the M(IV) state. Both RuO_2

and OsO_2 adopt a rutile structure (Fig. 6.24); these oxides are far less important than RuO_4 and OsO_4.

The electrochemical oxidation of $[Ru(OH_2)_6]^{2+}$ in aqueous solution produces a Ru(IV) species. Its formulation as $[Ru_4O_6(OH_2)_{12}]^{4+}$ (or a protonated form depending on pH) is consistent with ^{17}O NMR spectroscopic data and, of the two proposed structures **22.51** and **22.52**, the latter is supported by EXAFS studies (see Box 25.2).

(22.51)



(22.52)

Octahedral halido complexes of Ru(V) and Os(V) are represented by $[MF_6]^-$ (M = Ru, Os) and $[OsCl_6]^-$. $K[OsF_6]$, for example, can be made by reduction of OsF_6 with KBr in anhydrous HF. The Os(V) anions [*fac*-$OsCl_3F_3]^-$, *cis*-$[OsCl_4F_2]^-$ and *trans*-$[OsCl_4F_2]^-$ are made by oxidation of the analogous Os(IV) dianions using $KBrF_4$ or BrF_3. For the +4 oxidation state, all the $[MX_6]^{2-}$ ions are known except $[RuI_6]^{2-}$. Various synthetic routes are used, e.g. $[RuCl_6]^{2-}$ can be made by heating Ru, Cl_2 and an alkali metal chloride, or by oxidizing $[RuCl_6]^{3-}$ with Cl_2. The salt $K_2[RuCl_6]$ has a magnetic moment (298 K) of 2.8 μ_B, close to μ(spin-only) for a low-spin d^4 ion but the value is temperature dependent. For $K_2[OsCl_6]$, the value of 1.5 μ_B arises from the greater spin–orbit coupling constant for the 5*d* metal ion (see Fig. 20.29 and discussion). Mixed M(IV) halido complexes are produced by halogen exchange. In reaction 22.86, the products are formed by stepwise substitution, the position of F^- entry being determined by the stronger *trans*-effect (see Section 26.3) of the chlorido ligand.

$$[OsCl_6]^{2-} \xrightarrow{BrF_3} [OsCl_5F]^{2-} + \textit{cis}\text{-}[OsCl_4F_2]^{2-} + \textit{fac}\text{-}[OsCl_3F_3]^{2-} + \textit{cis}\text{-}[OsCl_2F_4]^{2-} + [OsClF_5]^{2-} + [OsF_6]^{2-} \quad (22.86)$$

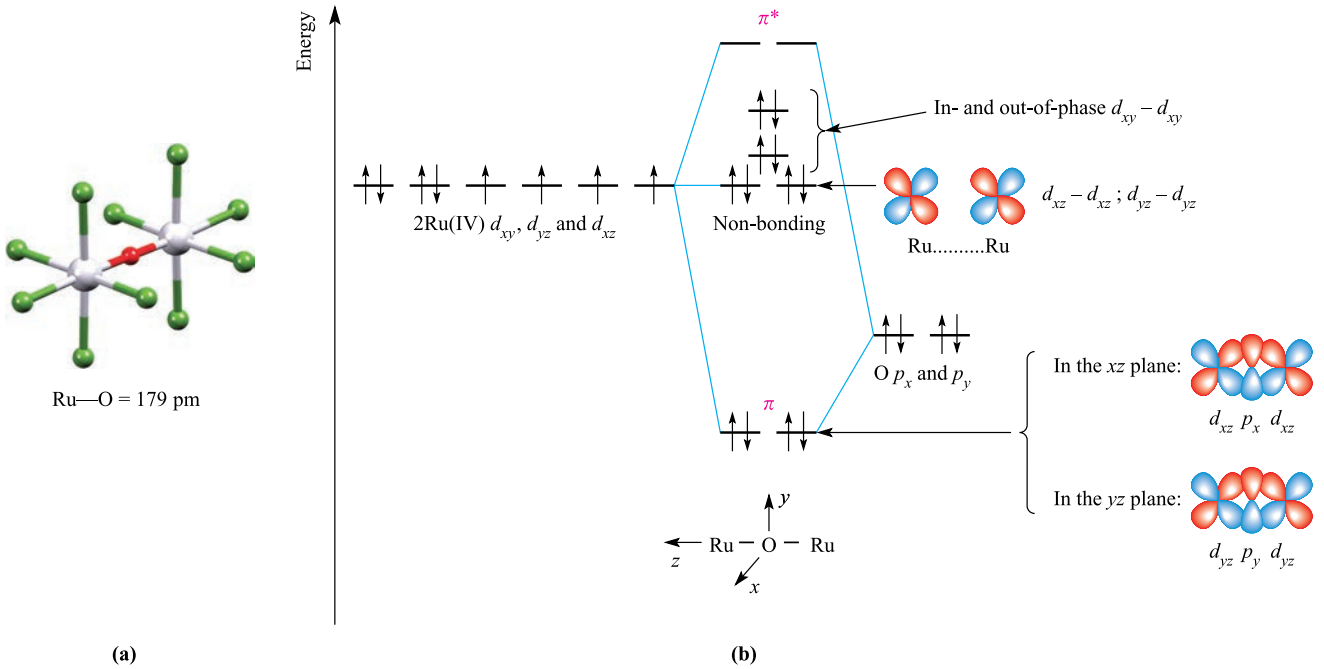
The reduction of OsO_4 by Na_2SO_3 in aqueous H_2SO_4 containing Cl^- produces $[OsCl_5(OH_2)]^-$ in addition to $[OsCl_6]^{2-}$ and $[\{Cl_3(HO)(H_2O)Os\}_2(\mu\text{-}OH)]^-$.

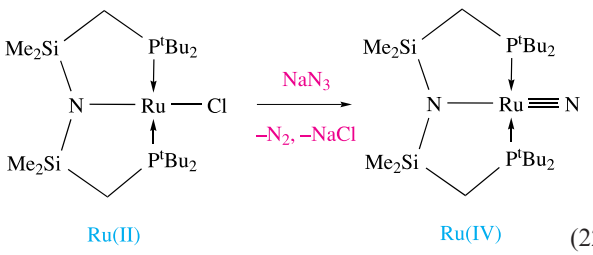
Reaction of RuO_4 in aqueous HCl in the presence of KCl gives K^+ salts of $[Ru^{IV}_2OCl_{10}]^{4-}$, $[Ru^{III}Cl_5(OH_2)]^{2-}$ and $[Ru^{III}Cl_6]^{3-}$. Each Ru(IV) centre in $[Ru_2OCl_{10}]^{4-}$ is octahedrally sited and the Ru–O–Ru bridge is linear (Fig. 22.20a). Salts of $[Ru_2OCl_{10}]^{4-}$ are diamagnetic. This is rationalized by considering the formation of two 3-centre π-interactions (Fig. 22.20b) involving the d_{xz} and d_{yz} atomic orbitals of the two low-spin Ru(IV) centres (each of configuration $d_{xy}^2 d_{xz}^1 d_{yz}^1$) and the filled p_x and p_y atomic orbitals of the O atom. In addition to the π and π^* MOs, four non-bonding MOs result from combinations of the d_{xy}, d_{xz} and d_{yz} orbitals (Fig. 22.20b). These are fully occupied in $[Ru_2OCl_{10}]^{4-}$. The same MO diagram can be used to describe the bonding in the related anions $[Os_2OCl_{10}]^{4-}$ (two d^4 metal centres), $[W_2OX_{10}]^{4-}$ (X = Cl, Br; d^2), $[Re_2OCl_{10}]^{4-}$ (d^3) and $[Ta_2OX_{10}]^{2-}$ (X = F, Cl; d^0). Changes in d^n configuration only affect the occupancy of the non-bonding MOs, leaving the metal–oxygen π-bonding MOs occupied. The diamagnetic $[Ru_2(\mu\text{-}N)Cl_8(OH_2)_2]^{3-}$ (**22.53**) is a nitrido-bridged analogue of $[Ru_2OCl_{10}]^{4-}$, and Ru–N distances of 172 pm indicate strong π-bonding; it is made by reducing $[Ru(NO)Cl_5]^{2-}$ with $SnCl_2$ in HCl.

(22.53)

While a number of dinuclear Ru(IV) complexes containing bridging nitrido ligands are known, mononuclear complexes are rare. The conversion of azide to nitride (eq. 22.87) has a high activation barrier and usually involves thermolysis or photolysis. However, $[N_3]^-$ is a useful precursor to an $[N]^{3-}$ ligand when coupled with the reducing power of Ru(II) in the absence of π-acceptor ligands and in the presence of π-donors. This is exemplified by reaction 22.88, in which the amido group acts as a π-donor.

$$[N_3]^- + 2e^- \longrightarrow N^{3-} + N_2 \quad (22.87)$$





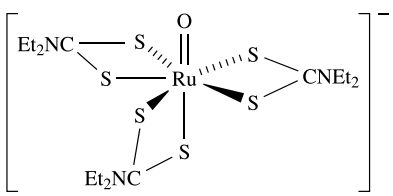


Fig. 22.20. (a) The structure of $[Ru_2(\mu\text{-}O)Cl_{10}]^{4-}$ determined by X-ray diffraction for the histaminium salt [I.A. Efimenko *et al.* (1994) *Koord. Khim.*, vol. 20, p. 294]; colour code: Ru, pale grey; Cl, green; O, red. (b) A partial MO diagram for the interaction between the d_{xy}, d_{xz} and d_{yz} atomic orbitals of the Ru(IV) centres and the p_x and p_y atomic orbitals of the O atom to give two bonding, two antibonding and four non-bonding MOs; the non-bonding MOs are derived from combinations of *d* orbitals with no oxygen contribution. Relative orbital energies are approximate, and the non-bonding MOs lie close together.

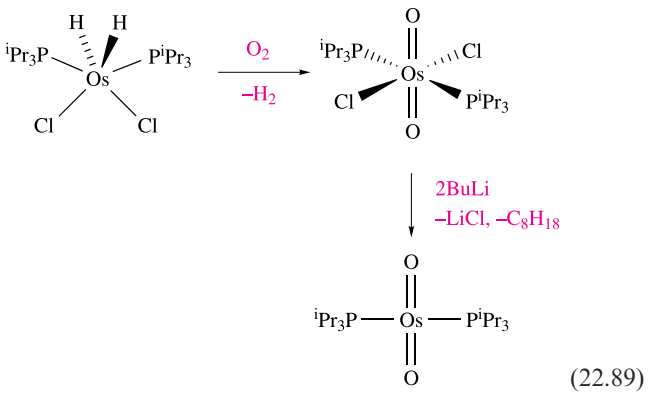

(22.88)

Although the coordination chemistry of Ru(IV) and Os(IV) is varied, halido complexes are dominant. Complexes of Os(IV) outnumber those of Ru(IV). Hexahalido complexes are common precursors (Fig. 22.21). Apart from those already described, examples with mixed ligands include octahedral *trans*-$[OsBr_4(AsPh_3)_2]$, $[OsX_4(acac)]^-$ (X = Cl, Br, I), $[OsX_4(ox)]^{2-}$ (X = Cl, Br, I), *cis*-$[OsCl_4(NCS\text{-}N)_2]^{2-}$ and *trans*-$[OsCl_4(NCS\text{-}S)_2]^{2-}$. Two complexes of special note for their stereochemistries are the pentagonal bipyramidal $[RuO(S_2CNEt_2)_3]^-$ (**22.54**) and the square planar *trans*-$[Ru(PMe_3)_2(NR)_2]$ in which R is the bulky 2,6-^{i}Pr$_2$C$_6$H$_3$.

(22.54)

Osmium(IV) complexes containing terminal Os=O units are rather rare, and it is more usual for a bridging mode to be adopted as in $[Os_2OCl_{10}]^{4-}$. One example of a mononuclear species is shown in scheme 22.89, in which the Os(IV) dioxide derivative is obtained by activation of molecular O_2 via an Os(VI) intermediate. The square planar geometry of the Os(IV) product is unusual for a d^4 configuration. The precursor in scheme 22.89 is prepared by treating $OsCl_3 \cdot xH_2O$ with P^{i}Pr$_3$, and has a distorted 6-coordinate coordination sphere.

(22.89)

Ruthenium(III) and osmium(III)

All the binary halides RuX_3 are known, but for Os, only $OsCl_3$ and OsI_3 have been established. OsF_4 is the lowest

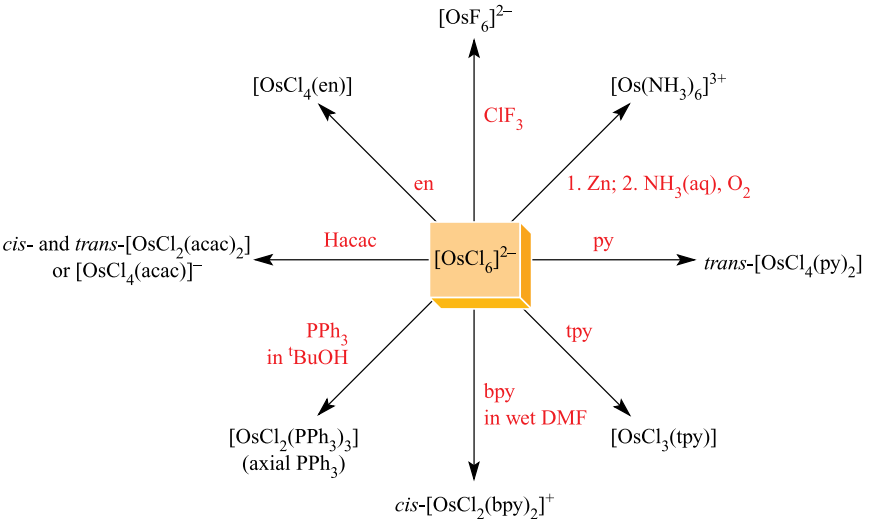

Fig. 22.21. Representative complex-forming reactions starting from $[OsCl_6]^{2-}$. Note that reduction to Os(III) occurs in three reactions, and to Os(II) in one. See Table 7.8 for ligand abbreviations; tpy = 2,2':6',2"-terpyridine.

fluoride of Os. Reduction of RuF_5 with I_2 gives RuF_3, a brown solid isostructural with FeF_3. Reactions 22.90–22.92 show preparations of $RuCl_3$, $RuBr_3$ and RuI_3. The chloride is commercially available as a hydrate of variable composition '$RuCl_3{\cdot}xH_2O$' ($x \approx 3$) and is an important starting material in Ru(III) and Ru(II) chemistry.

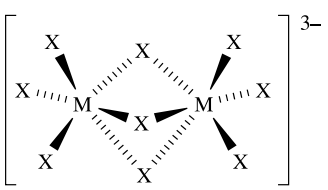
$$Ru_3(CO)_{12} \xrightarrow{Cl_2,\ 630\ K\ under\ N_2} \beta\text{-}RuCl_3 \xrightarrow{Cl_2,\ >720\ K} \alpha\text{-}RuCl_3 \qquad (22.90)$$

$$Ru \xrightarrow{Br_2,\ 720\ K,\ 20\ bar} RuBr_3 \qquad (22.91)$$

$$RuO_4 \xrightarrow{aq\ HI} RuI_3 \qquad (22.92)$$

The α-forms of $RuCl_3$ and $OsCl_3$ are isostructural with α-$TiCl_3$ (see Section 21.5), while β-$RuCl_3$ has the same structure as $CrCl_3$ (see Section 21.7). Extended structures with octahedral Ru(III) are adopted by $RuBr_3$ and RuI_3.

There are no binary oxides or oxoanions for Ru(III), Os(III) or lower oxidation states. No simple aqua ion of Os(III) has been established, but octahedral $[Ru(OH_2)_6]^{3+}$ can be obtained by aerial oxidation of $[Ru(OH_2)_6]^{2+}$ and has been isolated in the alum (see Section 13.9) $CsRu(SO_4)_2{\cdot}12H_2O$ and the salt $[Ru(OH_2)_6][4\text{-}MeC_6H_4SO_3]_3{\cdot}3H_2O$. The Ru–O bond length of 203 pm is shorter than in $[Ru(OH_2)_6]^{2+}$ (212 pm). In aqueous solution, $[Ru(OH_2)_6]^{3+}$ is acidic (compare eq. 22.93 with eq. 7.36 for Fe^{3+}) and it is less readily reduced than $[Fe(OH_2)_6]^{3+}$ (eq. 22.94).



$$[Ru(OH_2)_6]^{3+} + H_2O \rightleftharpoons [Ru(OH_2)_5(OH)]^{2+} + [H_3O]^+ \qquad pK_a \approx 2.4 \qquad (22.93)$$

$$[M(OH_2)_6]^{3+} + e^- \rightleftharpoons [M(OH_2)_6]^{2+} \qquad \begin{cases} M = Ru, & E^o = +0.25\,V \\ M = Fe, & E^o = +0.77\,V \end{cases} \qquad (22.94)$$

Substitution in Ru(III) complexes (low-spin d^5) is slow (see Chapter 26) and all members of the series $[RuCl_n(OH_2)_{6-n}]^{(n-3)-}$, including isomers, have been characterized. Aerial oxidation of $[Ru(NH_3)_6]^{2+}$ (see below) gives $[Ru(NH_3)_6]^{3+}$ (eq. 22.95).

$$[Ru(NH_3)_6]^{3+} + e^- \rightleftharpoons [Ru(NH_3)_6]^{2+} \qquad E^o = +0.10\,V \qquad (22.95)$$

Halido complexes $[MX_6]^{3-}$ are known for M = Ru, X = F, Cl, Br, I and M = Os, X = Cl, Br, I. The anions $[RuCl_5(OH_2)]^{2-}$ and $[RuCl_6]^{3-}$ are made in the same reaction as $[Ru_2OCl_{10}]^{4-}$ (see above). In aqueous solution, $[RuCl_6]^{3-}$ is rapidly aquated to $[RuCl_5(OH_2)]^{2-}$. The anion $[Ru_2Br_9]^{3-}$ can be made by treating $[RuCl_6]^{3-}$ with HBr. The ions $[Ru_2Br_9]^{3-}$, $[Ru_2Cl_9]^{3-}$ (reaction 22.96) and $[Os_2Br_9]^{3-}$ adopt structure **22.55**. The Ru–Ru distances of 273 (Cl) and 287 pm (Br) along with magnetic moments of 0.86 (Cl) and 1.18 μ_B (Br) suggest a degree of Ru–Ru bonding, a conclusion supported by theoretical studies.

M = Ru, X = Cl, Br
M = Os, X = Br

(22.55)

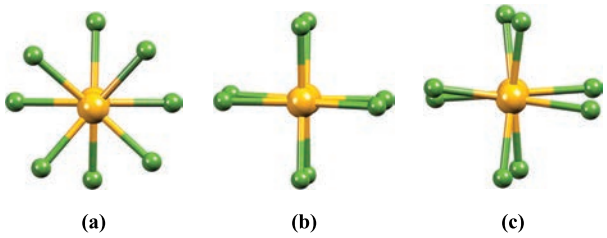


Fig. 22.22. Differences in energy between the arrangement of the chlorido ligands (staggered, eclipsed or somewhere in between) in $[Os_2Cl_8]^{2-}$ are small. The solid state structure of $[Os_2Cl_8]^{2-}$ (viewed along the Os–Os bond) in (a) the $[^nBu_4N]^+$ salt [P.A. Agaskar *et al.* (1986) *J. Am. Chem. Soc.*, vol. 108, p. 4850] ($[Os_2Cl_8]^{2-}$ is also staggered in the $[Ph_3PCH_2CH_2PPh_3]^{2+}$ salt), (b) the $[MePh_3P]^+$ salt [F.A. Cotton *et al.* (1990) *Inorg. Chem.*, vol. 29, p. 3197] and (c) the $[(Ph_3P)_2N]^+$ salt (structure determined at 83 K) [P.E. Fanwick *et al.* (1986) *Inorg. Chem.*, vol. 25, p. 4546]. In the $[(Ph_3P)_2N]^+$ salt, an eclipsed conformer is also present.

$$K_2[RuCl_5(OH_2)] \xrightarrow{520\ K} K_3[Ru_2Cl_9] \qquad (22.96)$$

$$[OsCl_6]^{2-} \xrightarrow{MeCO_2H,\ (MeCO)_2O} [Os_2(\mu\text{-}O_2CMe)_4Cl_2] \xrightarrow[X = Cl, Br, I]{HX(g),\ EtOH} [Os_2X_8]^{2-} \qquad (22.97)$$

The anions $[Os_2X_8]^{2-}$ (X = Cl, Br, I) are made in reaction sequence 22.97. In diamagnetic $[Os_2X_8]^{2-}$ and $[Os_2(\mu\text{-}O_2CMe)_4Cl_2]$, the electronic configuration of the Os_2-unit is (from Fig. 21.17) $\sigma^2\pi^4\delta^2\delta^{*2}$ corresponding to an Os≡Os triple bond. Since the δ^* MO is occupied, the influence of the δ-bond is lost and so no electronic factor restricts the orientation of the ligands (compare the eclipsed orientation of the ligands in $[Re_2Cl_8]^{2-}$ and $[Mo_2Cl_8]^{4-}$ which contain an M≡M). Crystal structures for several salts of $[Os_2Cl_8]^{2-}$ show different ligand arrangements (Fig. 22.22) and this is true also for $[Os_2Br_8]^{2-}$. For $[Os_2I_8]^{2-}$, steric factors appear to favour a staggered arrangement. Ruthenium(III) forms a number of acetate complexes. The reaction of $RuCl_3{\cdot}xH_2O$ with $MeCO_2H$ and $MeCO_2Na$ yields paramagnetic $[Ru_3(OH_2)_3(\mu\text{-}O_2CMe)_6(\mu_3\text{-}O)]^+$ (structurally analogous to the Cr(III) species in Fig. 21.15) which is reduced by PPh_3 to give the mixed-valence complex $[Ru_3(PPh_3)_3(\mu\text{-}O_2CMe)_6(\mu_3\text{-}O)]$.

Both Ru(III) and Os(III) form a range of octahedral complexes with ligands other than those already mentioned. Ru(III) complexes outnumber those of Os(III), the reverse of the situation for the M(IV) state. This reflects the relative stabilities Os(IV) > Ru(IV) but Ru(III) > Os(III). $[Os(CN)_6]^{3-}$ may be prepared by electrochemical oxidation of $[Os(CN)_6]^{4-}$, but reduction back to the Os(II) complex readily occurs. Oxidation of $[Ru(CN)_6]^{4-}$ using Ce(IV) gives $[Ru(CN)_6]^{3-}$, but isolation of its salts from aqueous solutions requires rapid precipitation. This is best achieved using $[Ph_4As]^+$ as the counter-ion. Examples of other mononuclear complexes include $[Ru(acac)_3]$, $[Ru(ox)_3]^{3-}$, $[Ru(en)_3]^{3+}$, *cis*-$[RuCl(OH_2)(en)_2]^{2+}$, *cis*-$[RuCl_2(bpy)_2]^+$, $[RuCl_4(bpy)]^-$, *trans*-$[RuCl(OH)(py)_4]^+$, *mer*-$[RuCl_3(DMSO\text{-}S)_2(DMSO\text{-}O)]$, $[Ru(NH_3)_5(py)]^{3+}$, *mer*-$[OsCl_3(py)_3]$, $[Os(acac)_3]$, $[Os(en)_3]^{3+}$, *trans*-$[OsCl_2(PMe_3)_4]^+$ and *trans*-$[OsCl_4(PEt_3)_2]^-$.

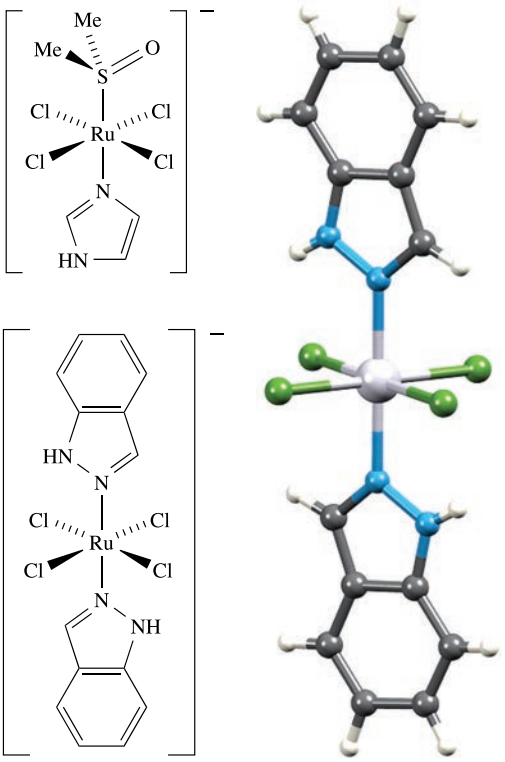

Fig. 22.23. The structures of the anions in the ruthenium(III) anti-cancer agents [HIm][*trans*-$RuCl_4$(Im)(DMSO-*S*)] and [HInd][*trans*-$RuCl_4(Ind)_2$] (Im = imidazole, Ind = indazole). The right-hand structure shows the [*trans*-$RuCl_4(Ind)_2]^-$ anion in the salt $[H(HInd)_2]$[*trans*-$RuCl_4(Ind)_2$]. [X-ray diffraction data: E. Reisner *et al.* (2004) *Inorg. Chem.*, vol. 43, p. 7083.] Colour code: Ru, pale grey; Cl, green; N, blue; C, dark grey; H, white.

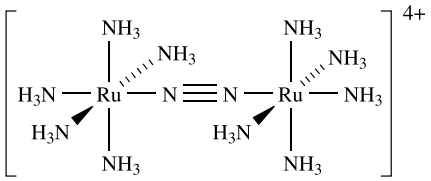
The Ru(III) compounds [HIm][*trans*-$RuCl_4$(Im)(DMSO-*S*)] and [HInd][*trans*-$RuCl_4(Ind)_2$] (Im = imidazole, Ind = indazole, Fig. 22.23) have completed phase I clinical trials as anti-cancer drugs. The former complex selectively targets metastases of solid tumours. The range of ruthenium-based compounds that exhibits anti-cancer activity includes organometallic ruthenium(II) complexes.[†]

Ruthenium(II) and osmium(II)

Binary halides of Ru(II) and Os(II) are not well characterized and there are no oxides. Heating the metal with S

[†] See: A.A. Nazarov, C.G. Hartinger and P.J. Dyson (2014) *J. Organomet. Chem.*, vol. 751, p. 251; G. Palermo *et al.* (2015) *ChemMedChem*, vol. 11, p. 1199; B.M. Blunden and M.H. Stenzel (2015) *J. Chem. Tech. Biotech.*, vol. 90, p. 1177; E. Alessio (2017) *Eur. J. Inorg. Chem.*, p. 1549.

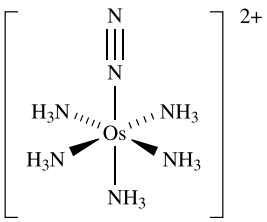
gives MS_2 (M = Ru, Os) which contain $[S_2]^{2-}$ and adopt a pyrite structure (see Fig. 21.29). Most of the chemistry of Ru(II) and Os(II) concerns complexes, all of which are diamagnetic,[†] low-spin d^6 and, with a few exceptions, are octahedral. We saw in Section 20.3 that values of Δ_{oct} (for a set of related complexes) are greater for second and third row metals than for the first member of the triad, and low-spin complexes are favoured. A vast number of Ru(II) complexes are known and we can give only a brief introduction.



The hydrido anions $[RuH_6]^{4-}$ and $[OsH_6]^{4-}$ (analogous to $[FeH_6]^{4-}$, Fig. 10.15b) are formed by heating the metal with MgH_2 or BaH_2 under a pressure of H_2. There are no simple halido complexes. H_2 or electrochemical reduction of $RuCl_3{\cdot}xH_2O$ in MeOH produces blue solutions (*ruthenium blues*) which, despite their synthetic utility for preparing Ru(II) complexes, have not been fully characterized. The blue species present have been variously formulated, but cluster anions seem likely.

Substitution reactions involving Ru(II) or Os(II) are affected by the kinetic inertness of the low-spin d^6 ion (see Section 26.2), and methods of preparation of M(II) complexes often start from higher oxidation states, e.g. $RuCl_3{\cdot}xH_2O$ or $[OsCl_6]^{2-}$. Reducing aqueous solutions of $RuCl_3{\cdot}xH_2O$ from which Cl^- has been precipitated by Ag^+ produces $[Ru(OH_2)_6]^{2+}$; there is no Os(II) analogue. In air, $[Ru(OH_2)_6]^{2+}$ readily oxidizes (eq. 22.94) but is present in Tutton salts (see Section 21.6) $M_2Ru(SO_4)_2{\cdot}6H_2O$ (M = Rb, NH_4). Its structure has been determined in the salt $[Ru(OH_2)_6][4\text{-}MeC_6H_4SO_3]_2$ (see discussion of $[Ru(OH_2)_6]^{3+}$). Under 200 bar pressure of N_2, $[Ru(OH_2)_6]^{2+}$ reacts to give $[Ru(OH_2)_5(N_2)]^{2+}$. The related $[Ru(NH_3)_5(N_2)]^{2+}$ (which can be isolated as the chloride salt and is structurally similar to **22.57**) is formed either by reaction scheme 22.98 or by N_2H_4 reduction of aqueous solutions of $RuCl_3{\cdot}xH_2O$.[‡]

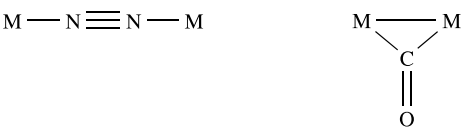
$$[Ru(NH_3)_5(OH_2)]^{3+} \xrightarrow{Zn/Hg} [Ru(NH_3)_5(OH_2)]^{2+} \xrightarrow[-H_2O]{N_2,\ 100\ bar} [Ru(NH_3)_5(N_2)]^{2+} \qquad (22.98)$$



The cation $[(H_3N)_5Ru(\mu\text{-}N_2)Ru(NH_3)_5]^{4+}$ (**22.56**) forms when $[Ru(NH_3)_5(OH_2)]^{2+}$ reacts with $[Ru(NH_3)_5(N_2)]^{2+}$, or when aqueous $[Ru(NH_3)_5Cl]^{2+}$ is reduced by Zn amalgam under N_2. Reduction of $[OsCl_6]^{2-}$ with N_2H_4 gives $[Os(NH_3)_5(N_2)]^{2+}$ (**22.57**) which can be oxidized or converted to the bis(N_2) complex (eq. 22.99); note the presence of the π-acceptor ligand to stabilize Os(II).

$$[Os(NH_3)_5(N_2)]^{2+} \begin{cases} \xrightarrow[-2H_2O]{HNO_2} cis\text{-}[Os(NH_3)_4(N_2)_2]^{2+} \\ \xrightarrow{Ce^{4+}} [Os(NH_3)_5(N_2)]^{3+} \end{cases} \qquad (22.99)$$

N–N = 112 pm Ru–N_{bridge} = 193 pm
Ru–N(NH_3) = 212–214 pm



(22.56)

N–N = 112 pm Os–N(N_2) = 184 pm
Os–N(NH_3) = 214–215 pm

(22.57)

Most dinitrogen complexes decompose when gently heated, but those of Ru, Os and Ir can be heated to 370–470 K. Although the bonding in a terminal, linear M−N≡N unit can be described in a similar manner to a terminal M−C≡O unit, the bridging modes of N_2 and CO are different as shown in **22.58**. Coordination of CO to metals is described in Section 24.2.

Typical μ-N_2 mode of bonding Typical μ-CO mode of bonding

(22.58)

The complex $[Ru(NH_3)_6]^{2+}$ (which oxidizes in air, eq. 22.95) is made by reacting $RuCl_3{\cdot}xH_2O$ with Zn dust in concentrated NH_3 solution. The analogous Os(II) complex may be formed in liquid NH_3, but is unstable. The reaction of HNO_2 with $[Ru(NH_3)_6]^{2+}$ gives the nitrosyl complex $[Ru(NH_3)_5(NO)]^{3+}$ in which the Ru−N−O angle is close to 180°. Numerous mononuclear nitrosyl complexes of ruthenium are known. In each of $[Ru(NH_3)_5(NO)]^{3+}$,

[†] The presence of 'non-innocent' ligands can lead to paramagnetic compounds. See for example: R.D. Schmidt *et al.* (2014) *Dalton Trans.*, vol. 43, p. 17729.

[‡] Much of the interest in metal complexes containing N_2 ligands arises from the potential for reduction of coordinated N_2 to NH_3. See: Y. Tanabe and Y. Nishibayashi (2013) *Coord. Chem. Rev.*, vol. 257, p. 2551; Y. Nishibayashi (2012) *Dalton Trans.*, vol. 41, p. 7447; H. Broda and F. Tuczek (2014) *Angew. Chem. Int. Ed.*, vol. 53, p. 632; N. Khoenkhoen, B. de Bruin, J.N.H. Reek and W.I. Dzik (2015) *Eur. J. Inorg. Chem.*, p. 567; R.R. Schrock (2008) *Angew. Chem. Int. Ed.*, vol. 47, p. 5512.

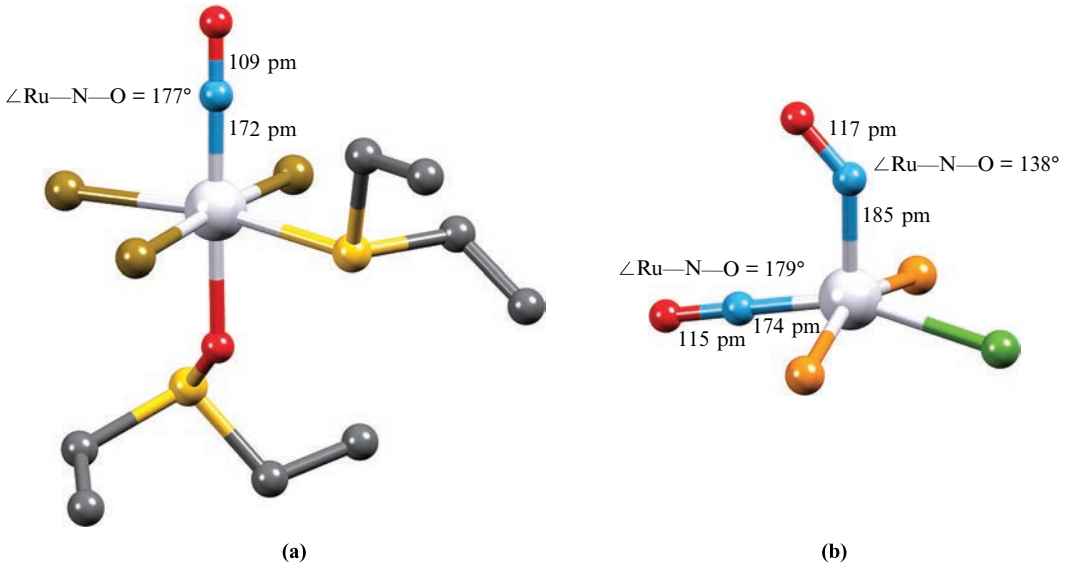


Fig. 22.24. The structures (X-ray diffraction) of (a) $[RuBr_3(Et_2S)(Et_2SO)(NO)]$ [R.K. Coll *et al.* (1987) *Inorg. Chem.*, vol. 26, p. 106] and (b) $[RuCl(NO)_2(PPh_3)_2]$ (only the P atoms of the PPh_3 groups are shown) [C.G. Pierpont *et al.* (1972) *Inorg. Chem.*, vol. 11, p. 1088]. Hydrogen atoms are omitted in (a); colour code: Ru, pale grey; Br, brown; Cl, green; O, red; N, blue; S, yellow; P, orange; C, grey.

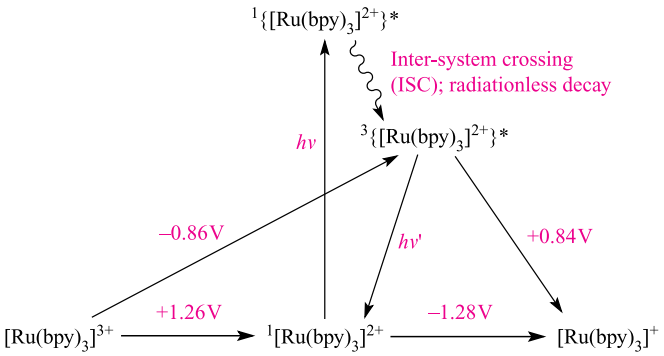
$[RuCl_5(NO)]^{2-}$, $[RuCl(bpy)_2(NO)]^{2+}$, *mer*,*trans*-$[RuCl_3(PPh_3)_2(NO)]$ and $[RuBr_3(Et_2S)(Et_2SO)(NO)]$ (Fig. 22.24a), the Ru−N−O unit is linear and an Ru(II) state is formally assigned. Without prior knowledge of structural and spectroscopic properties of nitrosyl complexes (see Section 20.4), the oxidation state of the metal centre remains ambiguous, for example in $[RuCl(NO)_2(PPh_3)_2]$ (Fig. 22.24b). Stable ruthenium nitrosyl complexes are formed during the extraction processes for the recovery of uranium and plutonium from nuclear wastes, and are difficult to remove; ^{106}Ru is a fission product from uranium and plutonium and the use of HNO_3 and TBP (see Box 7.3) in the extraction process facilitates the formation of Ru(NO)-containing complexes. While complexes containing NO ligands are well known, $[Ru(NH_3)_5(N_2O)]^{2+}$ is a rare example of an isolated complex containing an N_2O ligand.† The ligand coordinates to the Ru(II) centre through a N atom. There is significant interest in the coordination chemistry of N_2O, owing to its relevance to biological denitrification (see Box 15.9) in which the enzyme nitrous oxide reductase (the active site in which is a Cu_4 cluster unit) catalyses the final reduction step, i.e. conversion of N_2O to N_2.

The tris-chelates $[Ru(en)_3]^{2+}$, $[Ru(bpy)_3]^{2+}$ (Fig. 10.3) and $[Ru(phen)_3]^{2+}$ are made in a similar manner to $[Ru(NH_3)_6]^{2+}$. The $[Ru(bpy)_3]^{2+}$ complex is widely studied as a photosensitizer. It absorbs light at 452 nm to give an excited singlet state $^1\{[Ru(bpy)_3]^{2+}\}^*$ (Fig. 22.25), which results from transfer of an electron from the Ru(II) centre to a bpy π^*-orbital, i.e. the excited state may be considered to contain Ru(III), two bpy and one $[bpy]^-$. The singlet excited state rapidly decays to a triplet excited state,‡ the lifetime of which in aqueous solution at 298 K is 600 ns, long enough to allow redox activity to occur. The standard reduction potentials in Fig. 22.25 show that the excited $^3\{[Ru(bpy)_3]^{2+}\}^*$ state is both a better oxidant *and* reductant than the ground $[Ru(bpy)_3]^{2+}$



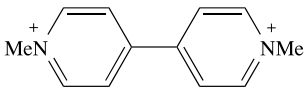


Fig. 22.25. $[Ru(bpy)_3]^{2+}$ (low-spin d^6 is a singlet state) absorbs light to give an excited state which rapidly decays to a longer-lived excited state, $^3\{[Ru(bpy)_3]^{2+}\}^*$. This state can decay by emission or can undergo electron transfer. Standard reduction potentials are given for 1-electron processes involving $[Ru(bpy)_3]^{2+}$ and $^3\{[Ru(bpy)_3]^{2+}\}^*$.

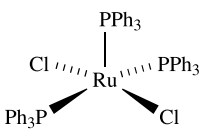
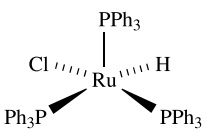
‡ For a detailed review, see: A. Juris *et al.* (1988) *Coord. Chem. Rev.*, vol. 84, p. 85 – 'Ru(II) polypyridine complexes: photophysics, photochemistry, electrochemistry and chemiluminescence'. For an introduction to photochemical principles, see: C.E. Wayne and R.P. Wayne (1996) *Photochemistry*, OUP Primer Series, Oxford.

state. In neutral solution, for example, H_2O can be oxidized or reduced by the excited complex. In practice, the system works only in the presence of a *quenching agent* such as methyl viologen (paraquat), $[MV]^{2+}$ (**22.59**) and a sacrificial donor, D, which reduces $[Ru(bpy)_3]^{3+}$ to $[Ru(bpy)_3]^{2+}$ (scheme 22.100) as described in Section 10.4.



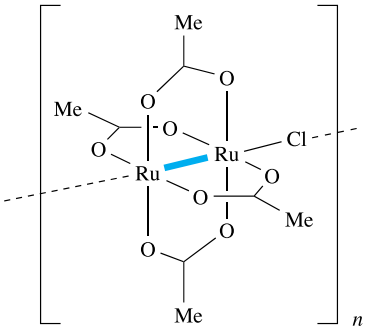
(22.59)



(22.100)

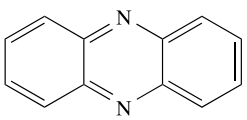
Many low oxidation state complexes of Ru and Os including those of Ru(II) and Os(II) are stabilized by PR_3 (π-acceptor) ligands. Treatment of $RuCl_3{\cdot}xH_2O$ with PPh_3 in EtOH/HCl at reflux gives *mer*-$[RuCl_3(PPh_3)_3]$ or, with excess PPh_3 in MeOH at reflux, $[RuCl_2(PPh_3)_3]$. Reaction with H_2 converts $[RuCl_2(PPh_3)_3]$ to $[HRuCl(PPh_3)_3]$ which is a hydrogenation catalyst for alk-1-enes (see Section 25.5). Both $[RuCl_2(PPh_3)_3]$ and $[HRuCl(PPh_3)_3]$ have square-based pyramidal structures (**22.60** and **22.61**).

(22.60)



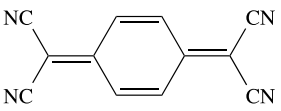
(22.61)

Mixed-valence ruthenium complexes



Equation 22.97 showed the formation of the Os(III) complex $[Os_2(\mu\text{-}O_2CMe)_4Cl_2]$. For ruthenium, the scenario is different, and in reaction 22.101, the product is an Ru(II)/Ru(III) polymer (**22.62**).

$$RuCl_3{\cdot}xH_2O \xrightarrow{MeCO_2H,\ (MeCO)_2O} [Ru_2(\mu\text{-}O_2CMe)_4Cl]_n \quad (22.101)$$

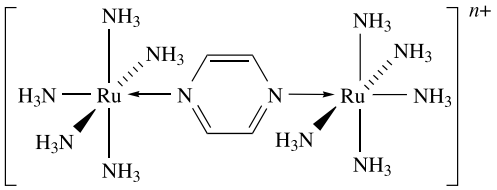


(22.62)

Complex **22.62** formally possesses a $\{Ru_2\}^{5+}$ core and from Fig. 21.17 we would predict a configuration of $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*1}$. However, the observed paramagnetism corresponding to three unpaired electrons is consistent with the π^* level lying at lower energy than the δ^*, i.e. $\sigma^2\pi^4\delta^2\pi^{*2}\delta^{*1}$. This reordering is reminiscent of the σ–π crossover amongst first row diatomics (Fig. 2.10) and illustrates the importance of utilizing *experimental facts* when constructing and interpreting qualitative MO diagrams. With three unpaired electrons, a $[Ru_2(\mu\text{-}O_2CR)_4]^+$ ion has an $S = \frac{3}{2}$ ground state and is therefore an excellent candidate as a building block for the assembly of *molecule-based magnetic materials* (see also Fig. 21.27b and associated text). Coordination polymers in which $[Ru_2(\mu\text{-}O_2CMe)_4]^+$ ions are connected by organic bridging ligands (e.g. $[N(CN)_2]^-$, $[C(CN)_3]^-$, **22.63** and **22.64**) typically show weak antiferromagnetic coupling rather than long-range ferromagnetic ordering. By using $[M(CN)_6]^{3-}$ (M = Cr, Fe), $[Ru_2(\mu\text{-}O_2CR)_4]^+$ units can be connected into 3-dimensional (for R = Me) or 2-dimensional (for R = ^{t}Bu) networks which become magnetically ordered at low temperatures.

phenazine

(22.63)



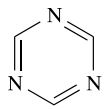
TCNQ

(22.64)

The *Creutz–Taube* cation $[(H_3N)_5Ru(\mu\text{-pz}')Ru(NH_3)_5]^{5+}$ (pz′ = pyrazine) is a member of the series of cations **22.65** (eq. 22.102). When the charge is 4+ or 6+, the complexes are Ru(II)/Ru(II) or Ru(III)/Ru(III) species respectively. For $n = 5$, a mixed-valence Ru(II)/Ru(III) species might be formulated but spectroscopic and structural data show the Ru centres are equivalent with charge delocalization across the pyrazine bridge. Such electron transfer (see Section 26.5) is not observed in all related species. For example, $[(bpy)_2ClRu(\mu\text{-pz}')RuCl(bpy)_2]^{3+}$ exhibits an intervalence charge transfer absorption in its electronic

spectrum indicating an Ru(II)/Ru(III) formulation. The complex $[(H_3N)_5Ru^{III}(\mu\text{-pz'})Ru^{II}Cl(bpy)_2]^{4+}$ is similar.

$$[Ru(NH_3)_5(OH_2)]^{2+} \xrightarrow[-2H_2O]{pz'} [(H_3N)_5Ru(\mu\text{-pz'})Ru(NH_3)_5]^{4+} \xrightarrow{Ag^+} [(H_3N)_5Ru(\mu\text{-pz'})Ru(NH_3)_5]^{5+} \xrightarrow{Ce^{4+}} [(H_3N)_5Ru(\mu\text{-pz'})Ru(NH_3)_5]^{6+} \quad (22.102)$$



$n = 4, 5, 6$

(22.65)

Self-study exercises

1. *rac-cis*-$[Ru(bpy)_2(DMSO\text{-}S)Cl]^+$ can be separated into its enantiomers by HPLC using a chiral stationary phase. (i) Draw the structure of Δ-*cis*-$[Ru(bpy)_2(DMSO\text{-}S)Cl]^+$ and suggest why it does not racemize under normal conditions. (ii) Outline the principles of HPLC. [*Ans.* See Section 4.2]
2. Triazine acts as a bridging ligand between $[Ru_2(O_2CPh)_4]$ molecules to give a 2-dimensional coordination polymer. Suggest how triazine coordinates to $[Ru_2(O_2CPh)_4]$, and predict the structure of the repeat motif that appears in one layer of the structure of the crystalline product.

triazine

[*Ans.* See S. Furukawa *et al.* (2005) *Chem. Commun.*, p. 865]

22.10 Group 9: rhodium and iridium

The metals

Rhodium and iridium are unreactive metals. They react with O_2 or the halogens only at high temperatures (see below) and neither is attacked by *aqua regia*. The metals dissolve in fused alkalis. For Rh and Ir, the range of oxidation states (Table 19.3) and the stabilities of the highest ones are less than for Ru and Os. The most important states are Rh(III) and Ir(III), i.e. d^6 which is invariably low-spin, giving diamagnetic and kinetically inert complexes (see Section 26.2).

High oxidation states of rhodium and iridium: M(VI) and M(V)

Rhodium(VI) and iridium(VI) occur only in black RhF_6 and yellow IrF_6 (see Fig. 22.17), formed by heating the metals with F_2 under pressure and quenching the volatile products. Both RhF_6 and IrF_6 are octahedral monomers. The pentafluorides are made by direct combination of the elements (eq. 22.103) or by reduction of MF_6, and are moisture-sensitive (reaction 22.104) and very reactive. They are tetramers, structurally analogous to NbF_5 (**22.5**).

$$2RhF_5 \xleftarrow{M = Rh,\ 520\ K,\ 6\ bar} 2M + 5F_2 \xrightarrow{M = Ir,\ 650\ K} 2IrF_5 \quad (22.103)$$

$$IrF_5 \xrightarrow{H_2O} IrO_2{\cdot}xH_2O + HF + O_2 \quad (22.104)$$

For M(V) and M(VI), no binary compounds with the heavier halogens and no oxides are known. Iridium(VI) fluoride is the precursor to $[Ir(CO)_6]^{3+}$, the only example to date of a tripositive, binary metal carbonyl cation. Compare reaction 22.105 (reduction of IrF_6 to $[Ir(CO)_6]^{3+}$) with reaction 22.78 (reduction of OsF_6 to $[Os(CO)_6]^{2+}$).

$$2IrF_6 + 12SbF_5 + 15CO \xrightarrow[\text{in } SbF_5]{320\ K,\ 1\ bar\ CO} 2[Ir(CO)_6][Sb_2F_{11}]_3 + 3COF_2 \quad (22.105)$$

Salts of octahedral $[MF_6]^-$ (M = Rh, Ir) can be made in HF or interhalogen solvents (reaction 22.106). On treatment with water, they liberate O_2 forming Rh(IV) and Ir(IV) compounds.

$$RhF_5 + KF \xrightarrow{HF \text{ or } IF_5} K[RhF_6] \quad (22.106)$$

A number of Ir(V) hydrido complexes are known, e.g. $[IrH_5(PMe_3)_2]$.

Rhodium(IV) and iridium(IV)

The unstable fluorides are the only established neutral halides of Rh(IV) and Ir(IV), and no halidooxidometal(IV) compounds are known. The reaction of $RhBr_3$ or $RhCl_3$ with BrF_3 yields RhF_4. IrF_4 is made by reduction of IrF_6 or IrF_5 with Ir, but above 670 K, IrF_4 disproportionates (eq. 22.107). Before 1965, reports of 'IrF_4' were erroneous and actually described IrF_5.

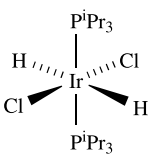
$$8IrF_5 + 2Ir \xrightarrow{670\ K} 10IrF_4 \xrightarrow{>670\ K} 5IrF_3 + 5IrF_5 \quad (22.107)$$

Iridium(IV) oxide forms when Ir is heated with O_2 and is the only well-established oxide of Ir. It is also made by controlled hydrolysis of $[IrCl_6]^{2-}$ in alkaline solution. Heating Rh and O_2 gives Rh_2O_3 (see below) unless the reaction is carried out under high pressure, in which case RhO_2 is obtained. Rutile structures (Fig. 6.24) are adopted by RhO_2 and IrO_2.

The series of paramagnetic (low-spin d^5) anions $[MX_6]^{2-}$ with M = Rh, X = F, Cl and M = Ir, X = F, Cl, Br, can be made, but the Ir(IV) species are the more stable. $[RhF_6]^{2-}$ and $[RhCl_6]^{2-}$ (eqs. 22.108 and 22.109) are hydrolysed to RhO_2 by an excess of H_2O. White alkali metal salts of $[IrF_6]^{2-}$ are made by reaction 22.110. $[IrF_6]^{2-}$ is stable in neutral or acidic solution but decomposes in alkali.

$$2KCl + RhCl_3 \xrightarrow{BrF_3} K_2[RhF_6] \qquad (22.108)$$

$$CsCl + [RhCl_6]^{3-} \xrightarrow{Cl_2,\ aqu.} Cs_2[RhCl_6] \qquad (22.109)$$



$$M[IrF_6] \xrightarrow{H_2O} M_2[IrF_6] + IrO_2 + O_2 \quad (M = Na, K, Rb, Cs) \qquad (22.110)$$

Salts of $[IrCl_6]^{2-}$ are common starting materials in Ir chemistry. Alkali metal salts are made by chlorinating a mixture of MCl and Ir. $Na_2[IrCl_6]\cdot 3H_2O$, $K_2[IrCl_6]$ and the acid $H_2[IrCl_6]\cdot xH_2O$ (*hexachloridoiridic acid*) are commercially available. The $[IrCl_6]^{2-}$ ion is quantitatively reduced (eq. 22.111) by KI or $[C_2O_4]^{2-}$ and is used as an oxidizing agent in some organic reactions. In alkaline solution, $[IrCl_6]^{2-}$ decomposes, liberating O_2, but the reaction is reversed in strongly acidic solution (see Section 8.2). In its reactions, $[IrCl_6]^{2-}$ is often reduced to Ir(III) (scheme 22.112), but reaction with Br^- yields $[IrBr_6]^{2-}$.

$$[IrCl_6]^{2-} + e^- \rightleftharpoons [IrCl_6]^{3-} \qquad E^\circ = +0.87\,V \qquad (22.111)$$

$$[IrCl_6]^{2-} \begin{cases} \xrightarrow{[CN]^-} [Ir(CN)_6]^{3-} \\ \xrightarrow{NH_3} [Ir(NH_3)_5Cl]^{2+} \xrightarrow{NH_3} [Ir(NH_3)_6]^{3+} \\ \xrightarrow{Et_2S} [IrCl_3(SEt_2)_3] \end{cases} \qquad (22.112)$$

Octahedral coordination is usual for Ir(IV). Complexes with *O*-donors are relatively few, and include $[Ir(OH)_6]^{2-}$ (the red K^+ salt is made by heating $Na_2[IrCl_6]$ with KOH), $[Ir(NO_3)_6]^{2-}$ (formed by treating $[IrBr_6]^{2-}$ with N_2O_5) and $[Ir(ox)_3]^{2-}$ (made by oxidizing $[Ir(ox)_3]^{3-}$). Complexes with group 15 donors include $[IrCl_4(phen)]$, $[IrCl_2H_2(P^iPr_3)_2]$ (**22.66**) and *trans*-$[IrBr_4(PEt_3)_2]$.

(22.66)

Rhodium(III) and iridium(III)

Binary halides MX_3 for M = Rh, Ir and X = Cl, Br and I can be made by heating mixtures of the appropriate elements. Reactions 22.113 and 22.114 show routes to MF_3. Direct reaction of M and F_2 leads to higher fluorides (e.g. eq. 22.103).

$$RhCl_3 \xrightarrow{F_2,\ 750\ K} RhF_3 \qquad (22.113)$$

$$Ir + IrF_6 \xrightarrow{750\ K} 2IrF_3 \qquad (22.114)$$

Anhydrous $RhCl_3$ and α-$IrCl_3$ adopt layer structures and are isomorphous with $AlCl_3$. Brown α-$IrCl_3$ converts to the red β-form at 870–1020 K. Water-soluble $RhCl_3\cdot 3H_2O$ (dark red) and $IrCl_3\cdot 3H_2O$ (dark green) are commercially available, being common starting materials in Rh and Ir chemistry. Figure 22.26 shows selected complex formations starting from $IrCl_3\cdot 3H_2O$. In particular, note the reaction of $IrCl_3\cdot 3H_2O$ with bpy. In the first step, *cis*-$[IrCl_2(bpy)_2]Cl$ is formed which then reacts with another equivalent of bpy to give either $[Ir(bpy)_3]Cl_3$ or $[Ir(bpy)_2(bpy\text{-}C,N)]Cl_2$. The first of these compounds contains the $[Ir(bpy)_3]^{3+}$ cation (Fig. 22.26, top right). The formation of $[Ir(bpy)_2(bpy\text{-}C,N)]^{2+}$ in the second product involves *cyclometallation* (or *orthometallation*) of a bpy ligand; deprotonation of bpy occurs in the 6-position to give an anionic ligand that coordinates to Ir(III) through one N and one C (Fig. 22.26, lower right). This leaves a non-coordinated N atom which is protonated to give the third product of the reaction, $[Ir(bpy)_2(Hbpy\text{-}C,N)]^{3+}$.

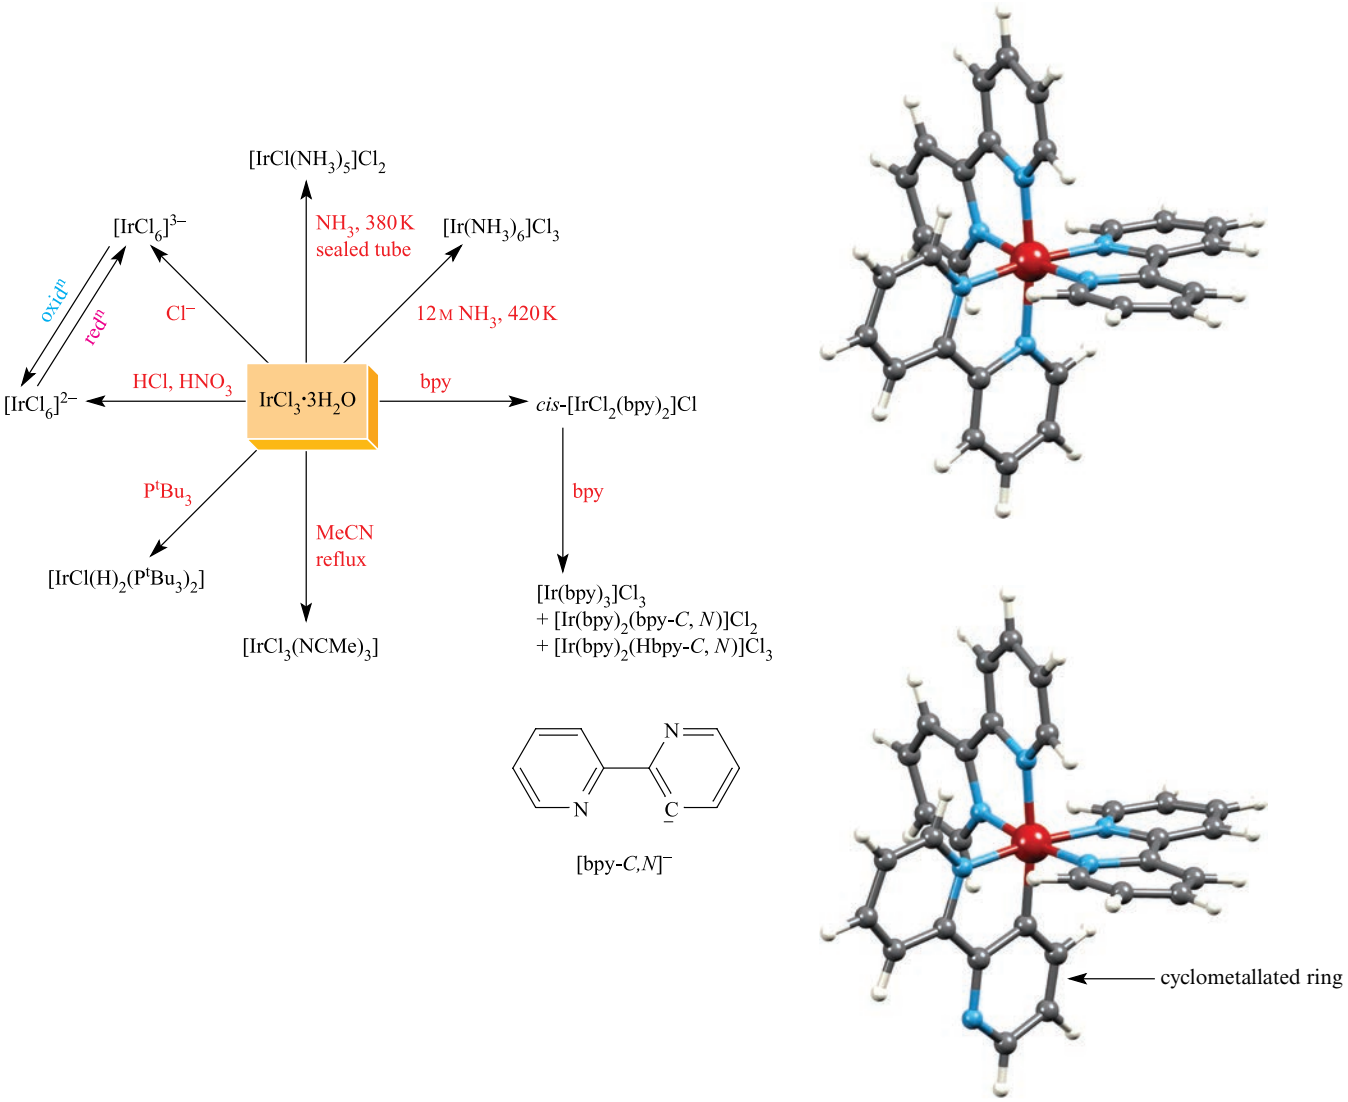
The oxide Ir_2O_3 is known only as an impure solid. Rhodium(III) oxide is well characterized, and is made by heating the elements at ordinary pressure or by thermal decomposition of $Rh(NO_3)_3$ (eq. 22.115). Several polymorphs of Rh_2O_3 are known; α-Rh_2O_3 has a corundum structure (see Section 13.7).

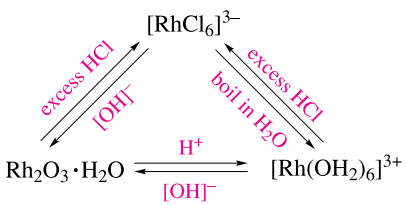
$$4Rh(NO_3)_3\cdot 6H_2O \xrightarrow{1000\ K} 2Rh_2O_3 + 24H_2O + 12NO_2 + 3O_2 \qquad (22.115)$$

In the presence of aqueous $HClO_4$, octahedral $[Rh(OH_2)_6]^{3+}$ can be formed but it hydrolyses (eq. 22.116). Crystalline $Rh(ClO_4)_3\cdot 6H_2O$ contains $[Rh(OH_2)_6]^{3+}$, i.e. it should be formulated as $[Rh(OH_2)_6][ClO_4]_3$. The $[Ir(OH_2)_6]^{3+}$ ion exists in aqueous solutions in the presence of concentrated $HClO_4$. The hexaaqua ions are present in the crystalline alums $CsM(SO_4)_2\cdot 12H_2O$ (M = Rh, Ir).

$$[Rh(OH_2)_6]^{3+} + H_2O \rightleftharpoons [Rh(OH_2)_5(OH)]^{2+} + [H_3O]^+ \quad pK_a = 3.33 \qquad (22.116)$$

When $Rh_2O_3\cdot H_2O$ is dissolved in a limited amount of aqueous HCl, $RhCl_3\cdot 3H_2O$ (better written as





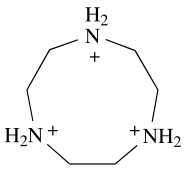


Fig. 22.26. Selected reactions of $IrCl_3{\cdot}xH_2O$. In the complexes $[Ir(bpy)_2(bpy\text{-}C,N)]^{2+}$ and $[Ir(bpy)_2(Hbpy\text{-}C,N)]^{3+}$, the ligands coordinating in a *C*,*N*-mode have undergone *cyclometallation* in which a C–H bond has been broken and a C^- coordination site formally created. The structures of the $[Ir(bpy)_3]^{3+}$ and $[Ir(bpy)_2(bpy\text{-}C,N)]^{2+}$ ions are shown on the right. Colour code: Ir, red; C, grey; N, blue; H, white.

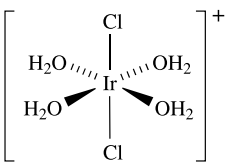
$[RhCl_3(OH_2)_3]$) forms. All members of the series $[RhCl_n(OH_2)_{6-n}]^{(3-n)+}$ ($n = 0$–6) are known and can be made in solution by reaction of $[Rh(OH_2)_6]^{3+}$ with Cl^- or by substitution starting from $[RhCl_6]^{3-}$ (see end-of-chapter problem 26.10). Interconversions involving $[Rh(OH_2)_6]^{3+}$ and $[RhCl_6]^{3-}$ are given in scheme 22.117.



(22.117)

Reduction of $[IrCl_6]^{2-}$ by SO_2 yields $[IrCl_6]^{3-}$ (Fig. 22.26) which hydrolyses in H_2O to $[IrCl_5(OH_2)]^{2-}$ (isolated as the green $[NH_4]^+$ salt), $[IrCl_4(OH_2)_2]^-$ and $[IrCl_3(OH_2)_3]$. Reaction of $[Ir(OH_2)_6]^{3+}$ with **[22.67]**Cl_3 in aqueous Cs_2SO_4 produces **[22.67]**$[IrCl_2(OH_2)_4][SO_4]_2$ containing cation **22.68** for which $pK_a(1) = 6.31$.

(22.67)

(22.68)

Routes to ammine complexes of Ir(III) are shown in Fig. 22.26. For Rh(III), it is more difficult to form $[Rh(NH_3)_6]^{3+}$ than $[Rh(NH_3)_5Cl]^{2+}$ (eq. 22.118).

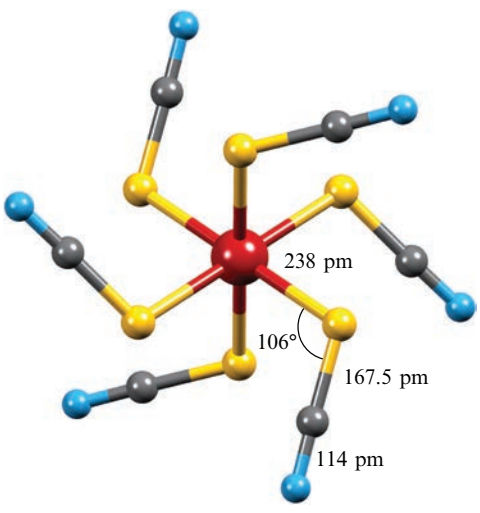
$$RhCl_3{\cdot}3H_2O \xrightarrow{\text{aq } NH_3,\ EtOH} [RhCl(NH_3)_5]Cl_2$$
$$\xrightarrow[\text{sealed tube}]{NH_3,\ 373\ K} [Rh(NH_3)_6]Cl_3 \qquad (22.118)$$

Large numbers of octahedral Rh(III) and Ir(III) complexes exist, and common precursors include $[IrCl_6]^{3-}$ (e.g. Na^+, K^+ or $[NH_4]^+$ salts), $[RhCl(NH_3)_5]Cl_2$, $[Rh(OH_2)(NH_3)_5][ClO_4]_3$ (made by treating $[RhCl(NH_3)_5]Cl_2$ with $AgClO_4$) and *trans*-$[RhCl_2(py)_4]^+$ (made from $RhCl_3{\cdot}3H_2O$ and pyridine). Schemes 22.119 and 22.120 give selected examples.

$$[IrCl_6]^{3-} \begin{cases} \xrightarrow{en,\ \Delta} [Ir(en)_3]^{3+} \\ \xrightarrow{py\ in\ EtOH} \textit{trans}\text{-}[IrCl_2(py)_4]^+ \\ \xrightarrow{ox^{2-},\ \Delta} [Ir(ox)_3]^{3-} \\ \xrightarrow{conc\ HNO_3,\ \Delta} [Ir(NO_3)_6]^{3-} \end{cases} \qquad (22.119)$$

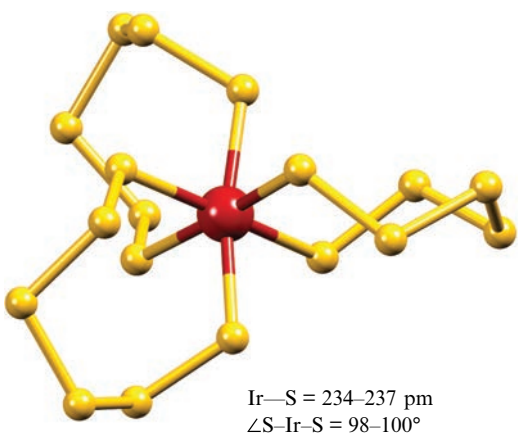
$$[RhCl_2(py)_4]^+ \begin{cases} \xrightarrow{en,\ H_2O} \textit{cis}\text{-}[RhCl(en)_2(py)]^{2+} \\ \xrightarrow{EtOH,\ \Delta} \textit{mer}\text{-}[RhCl_3(py)_3] \\ \xrightarrow{in\ CHCl_3,\ \Delta} [RhCl_3(py)_2]_n \\ \xrightarrow{NH_3} [RhCl(NH_3)_5]^{2+} \\ \xrightarrow{ox^{2-},\ \Delta} [Rh(NH_3)_4(ox)]^+ \end{cases} \qquad (22.120)$$

Rhodium(III) and iridium(III) form complexes with both hard and soft donors and examples (in addition to those above and in Fig. 22.26) include:



- *N*-donors: $[Ir(NO_2)_6]^{3-}$, *cis*-$[RhCl_2(bpy)_2]^+$, $[Rh(bpy)_2(phen)]^{3+}$, $[Rh(bpy)_3]^{3+}$, $[Rh(en)_3]^{3+}$;
- *O*-donors: $[Rh(acac)_3]$, $[Ir(acac)_3]$, $[Rh(ox)_3]^{3-}$;
- *P*-donors: *fac*- and *mer*-$[IrH_3(PPh_3)_3]$, $[RhCl_4(PPh_3)_2]^-$, $[RhCl_2(H)(PPh_3)_2]$;
- *S*-donors: $[Ir(NCS\text{-}S)_6]^{3-}$ (Fig. 22.27a), *mer*-$[IrCl_3(SEt_2)_3]$, $[Ir(S_6)_3]^{3-}$ (Fig. 22.27b).

Both metal ions form $[M(CN)_6]^{3-}$. Linkage isomerization is exhibited by $[Ir(NH_3)_5(NCS)]^{2+}$, i.e. both $[Ir(NH_3)_5(NCS\text{-}N)]^{2+}$ and $[Ir(NH_3)_5(NCS\text{-}S)]^{2+}$ can be isolated. The nitrite ligand in $[Ir(NH_3)_5(NO_2)]^{2+}$ undergoes a change from *O*- to *N*-coordination in alkaline solution.



Self-study exercises

1. $[Rh_2Cl_9]^{3-}$ and $[Rh_2Br_9]^{3-}$ possess face-sharing octahedral structures. Heating a propylene carbonate solution of the $[Bu_4N]^+$ salts of $[Rh_2Cl_9]^{3-}$ and $[Rh_2Br_9]^{3-}$ results in a mixture of $[Rh_2Cl_nBr_{9-n}]^{3-}$ ($n = 0$–9) in which all possible species are present. Suggest an experimental technique that can be used to detect these species. Assuming retention of the face-sharing octahedral structure, draw the structures of all possible isomers for $n = 5$.

2. Comment on factors that affect the trend in the values of Δ_{oct} tabulated below.

Complex	Δ_{oct} / cm^{-1}	Complex	Δ_{oct} / cm^{-1}
$[Rh(OH_2)_6]^{3+}$	25 500	$[Rh(CN)_6]^{3-}$	44 400
$[RhCl_6]^{3-}$	19 300	$[RhBr_6]^{3-}$	18 100
$[Rh(NH_3)_6]^{3+}$	32 700	$[Rh(NCS\text{-}\boldsymbol{S})_6]^{3-}$	19 600

[*Ans.* See Table 20.2 and discussion]

Rhodium(II) and iridium(II)

Mononuclear Rh(II) and Ir(II) complexes are relatively rare. The chemistry of Rh(II) is quite distinct from that of Ir(II) since dimers of type $[Rh_2(\mu\text{-}L)_4]$ (e.g. $L^- = RCO_2^-$) and $[Rh_2(\mu\text{-}L)_4L'_2]$ (where L^- is, for example, RCO_2^-, and L' is an axial ligand) are well known but Ir analogues are rare. The best-known Rh(II) dimers contain carboxylate bridges (Figs. 22.28a and 22.28b); other bridging ligands include $[RC(O)NH]^-$ and $[RC(O)S]^-$. The dimers

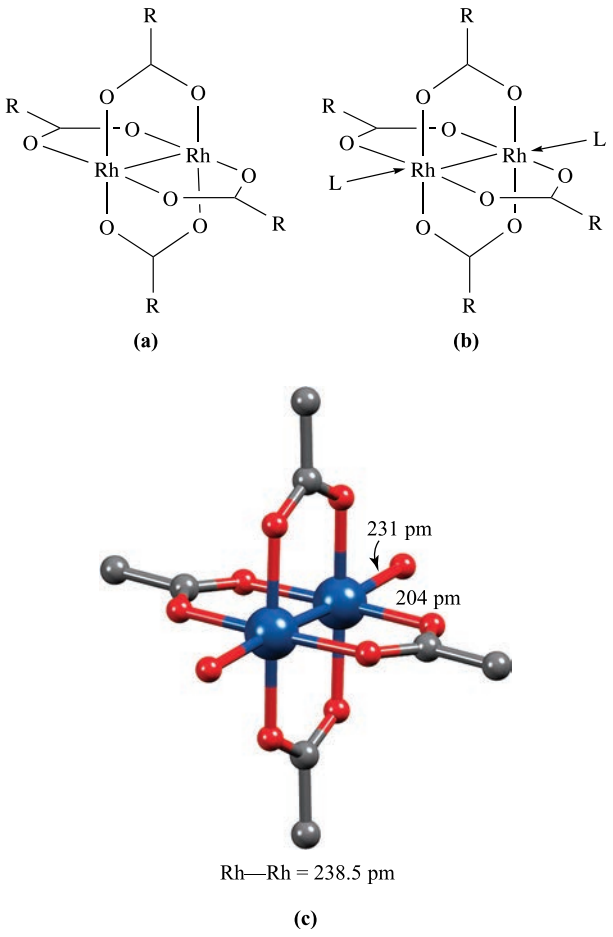

Fig. 22.28. Schematic representations of two families of Rh(II) carboxylate dimers: (a) $[Rh_2(\mu\text{-}O_2CR)_4]$ and (b) $[Rh_2(\mu\text{-}O_2CR)_4L_2]$. (c) The structure of $[Rh_2(\mu\text{-}O_2CMe)_4(OH_2)_2]$ (H atoms omitted) determined by X-ray diffraction [F.A. Cotton *et al.* (1971) *Acta Crystallogr., Sect. B*, vol. 27, p. 1664]; colour code: Rh, blue; C, grey; O, red.

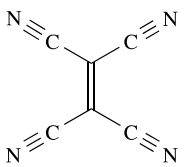
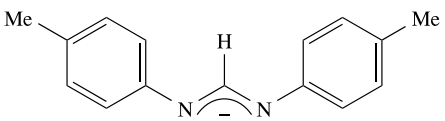


$[Rh_2(\mu\text{-}O_2CMe)_4L_2]$ (L = MeOH or H_2O) are made by reactions 22.121 and 22.122. The axial ligands can be removed by heating *in vacuo*, or replaced (e.g. reaction 22.123).

$$RhCl_3{\cdot}3H_2O \xrightarrow[MeOH\ reflux]{MeCO_2H\ /\ Na[MeCO_2]} [Rh_2(\mu\text{-}O_2CMe)_4(MeOH)_2] \quad (22.121)$$

$$[NH_4]_3[RhCl_6] \xrightarrow[EtOH,\ H_2O]{MeCO_2H} [Rh_2(\mu\text{-}O_2CMe)_4(OH_2)_2] \quad (22.122)$$

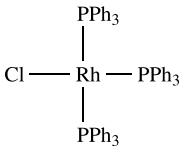


$$[Rh_2(\mu\text{-}O_2CMe)_4(OH_2)_2] \begin{cases} \xrightarrow{py} [Rh_2(\mu\text{-}O_2CMe)_4(py)_2] \\ \xrightarrow{SEt_2} [Rh_2(\mu\text{-}O_2CMe)_4(SEt_2)_2] \end{cases} \quad (22.123)$$

Figure 22.28c shows the structure of $[Rh_2(\mu\text{-}O_2CMe)_4(OH_2)_2]$, and related complexes are similar. If the axial ligand has a second donor atom appropriately oriented, polymeric chains in which L' bridges $[Rh_2(\mu\text{-}L)_4]$ units can result, e.g. when L' = phenazine (**22.63**) or **22.69**. Each dimer formally contains an $\{Rh_2\}^{4+}$ core which (from Fig. 21.17) has a $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*4}$ configuration, and a Rh—Rh *single* bond. Compare this with the multiply-bonded Mo(II), Re(III) and Os(III) dimers discussed earlier.

(22.69)

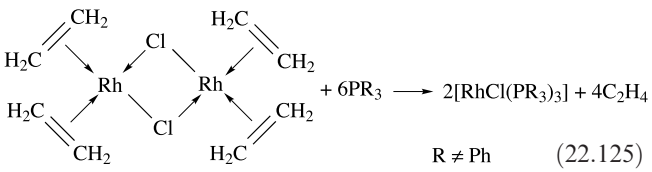
The only example of an $[Ir_2(\mu\text{-}L)_4]$ dimer containing an $\{Ir_2\}^{4+}$ core and an Ir—Ir single bond (252 pm) occurs for $L^- =$ **22.70**.



Conjugate base of *N*,*N*'-di-4-tolylformamidine

(22.70)

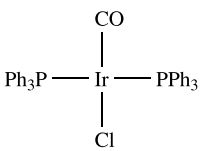
Rhodium(I) and iridium(I)



The +1 oxidation state of Rh and Ir (d^8) is stabilized by π-acceptor ligands such as phosphanes, with square planar, and to a lesser extent, trigonal bipyramidal coordination being favoured. Being low oxidation state species, it may be appropriate to consider the bonding in terms of the 18-electron rule (Section 20.4). In fact, most Rh(I) complexes are square planar, 16-electron species and

some, such as $[RhCl(PPh_3)_3]$ (*Wilkinson's catalyst*, **22.71**), have important applications in homogeneous catalysis (see Chapter 25). Preparation of $[RhCl(PPh_3)_3]$ involves reduction of Rh(III) by PPh_3 (eq. 22.124). Other $[RhCl(PR_3)_3]$ complexes are made by routes such as 22.125. Alkene complexes like that in this reaction are described in Chapter 24. Starting from $[RhCl(PPh_3)_3]$, it is possible to make a variety of square planar complexes in which phosphane ligands remain to stabilize the Rh(I) centre, e.g. scheme 22.126. Treatment of $[RhCl(PPh_3)_3]$ with $TlClO_4$ yields the perchlorate salt of the trigonal planar cation $[Rh(PPh_3)_3]^+$.

(22.71)



$$RhCl_3{\cdot}3H_2O + 6PPh_3 \xrightarrow{\text{EtOH, reflux}} [RhCl(PPh_3)_3] + \ldots \qquad (22.124)$$

$$+ 6PR_3 \longrightarrow 2[RhCl(PR_3)_3] + 4C_2H_4 \qquad R \neq Ph \qquad (22.125)$$

$$[RhCl(PPh_3)_3] \begin{cases} \xrightarrow{NaBH_4} [RhH(PPh_3)_3] \\ \xrightarrow[MeCN]{[Me_3O][BF_4]} [Rh(MeCN)(PPh_3)_3][BF_4] \\ \xrightarrow{RCO_2H} [Rh(O_2CR\text{-}O)(PPh_3)_3] \end{cases} \qquad (22.126)$$

The square planar Ir(I) complex *trans*-$[IrCl(CO)(PPh_3)_2]$ (*Vaska's compound*, **22.72**) is strictly organometallic since it contains an Ir–C bond, but it is an important precursor in Ir(I) chemistry. Both *trans*-$[IrCl(CO)(PPh_3)_2]$ and $[RhCl(PPh_3)_3]$ undergo many oxidative addition reactions (see Section 24.9) in which the M(I) centre is oxidized to M(III).

(22.72)

22.11 Group 10: palladium and platinum

The metals

At 298 K, bulk Pd and Pt are resistant to corrosion. Palladium is more reactive than Pt, and at high temperatures is attacked by O_2, F_2 and Cl_2 (eq. 22.127).

$$PdO \xleftarrow{O_2, \Delta} Pd \xrightarrow{Cl_2, \Delta} PdCl_2 \qquad (22.127)$$

Palladium dissolves in hot oxidizing acids (e.g. HNO_3), but both metals dissolve in *aqua regia* and are attacked by molten alkali metal oxides.

The dominant oxidation states are M(II) and M(IV), but the M(IV) state is more stable for Pt than Pd. Within a given oxidation state, Pd and Pt resemble each other with the exception of their behaviour towards oxidizing and reducing agents. Palladium(II) and platinum(II) form almost exclusively low-spin, square planar complexes. This contrasts with the wide range of high- and low-spin 4- and 6-coordinate nickel(II) complexes, with 4-coordinate including both square planar and tetrahedral geometries (see Section 21.11).

The highest oxidation states: M(VI) and M(V)

The M(VI) and M(V) states are confined to platinum fluorides (reactions 22.128 and 22.129, see Fig. 22.17); PtF_5 readily disproportionates to PtF_4 and PtF_6.

$$PtCl_2 \xrightarrow{F_2,\ 620\ K} PtF_5 \qquad (22.128)$$

$$Pt \xrightarrow[2.\ \text{rapid quenching}]{1.\ F_2,\ 870\ K} PtF_6 \qquad (22.129)$$

Platinum(V) fluoride is a tetramer (Fig. 22.29). PtF_6 is a red solid and has a molecular structure consisting of octahedral molecules. Neutron powder diffraction data confirm little

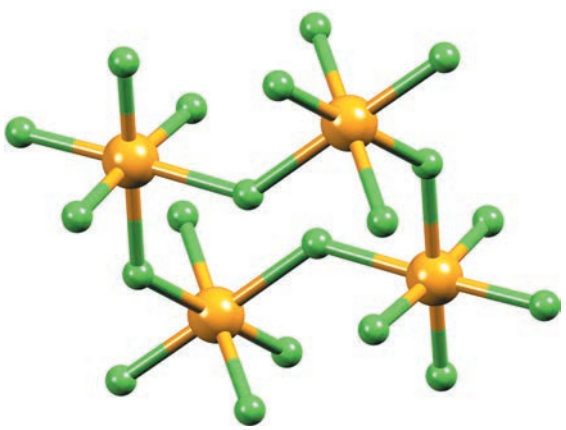


Fig. 22.29. The tetrameric structure of PtF_5 [X-ray diffraction, B.G. Müller *et al.* (1992) *Eur. J. Solid State Inorg. Chem.*, vol. 29, p. 625]. Colour code: Pt, yellow; F, green.

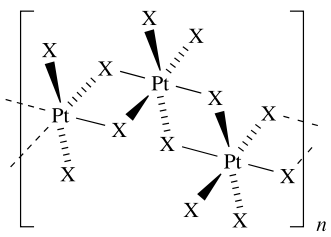
deviation from ideal O_h symmetry. The hexafluoride is a very powerful oxidizing agent (eq. 22.130, and see Section 6.17) and attacks glass. The oxidizing power of the third row *d*-block hexafluorides (for those that exist) follows the sequence $PtF_6 > IrF_6 > OsF_6 > ReF_6 > WF_6$.

$$O_2 + PtF_6 \longrightarrow [O_2]^+[PtF_6]^- \qquad (22.130)$$

In anhydrous HF, PtF_6 reacts with CO to give $[Pt^{II}(CO)_4]^{2+}[Pt^{IV}F_6]^{2-}$ (eq. 22.131), while in liquid SbF_5, reaction 22.132 occurs.

$$2PtF_6 + 7CO \xrightarrow[223\,K,\ \text{warm to } 298\,K]{1\ \text{bar CO, anhydrous HF}} [Pt(CO)_4][PtF_6] + 3COF_2 \qquad (22.131)$$



$$PtF_6 + 6CO + 4SbF_5 \xrightarrow[300\,K]{1\ \text{bar CO, liquid } SbF_5} [Pt(CO)_4][Sb_2F_{11}]_2 + 2COF_2 \qquad (22.132)$$

The fluorides PdF_5 and PdF_6 have not been confirmed,† but $[PdF_6]^-$ can be made by reaction 22.133.

$$PdF_4 + KrF_2 + O_2 \longrightarrow [O_2]^+[PdF_6]^- + Kr \qquad (22.133)$$

Palladium(IV) and platinum(IV)

The only tetrahalide of Pd(IV) is PdF_4, a diamagnetic, red solid made from the elements at 570 K. The compound 'PdF_3' (also formed from Pd and F_2) is actually $Pd^{II}[Pd^{IV}F_6]$. Both Pd centres in this solid state compound are octahedrally sited, i.e. a rare example of octahedral Pd(II). All the Pt(IV) halides are known, and $PtCl_4$ and $PtBr_4$ are formed by reactions of the halogens with Pt. Treatment of $PtCl_2$ with F_2 ($T < 475$ K) gives PtF_4 (compare reaction 22.128). In $PtCl_4$, $PtBr_4$ and PtI_4, the metal is octahedrally sited as shown in **22.73**. In PdF_4 and PtF_4, the connectivity is similar but results in a 3-dimensional structure.

X = Cl, Br, I

(22.73)

Hydrated PtO_2 is made by hydrolysing $[PtCl_6]^{2-}$ in boiling aqueous Na_2CO_3; heating converts it to black anhydrous PtO_2. Above 920 K, PtO_2 decomposes to the elements. Hydrated PtO_2 dissolves in NaOH as $Na_2[Pt(OH)_6]$ and in aqueous HCl as $H_2[PtCl_6]$ (hexachloridoplatinic acid). The latter is an important starting material in synthesis and has catalytic applications. Water hydrolyses $H_2[PtCl_6]$ to $H[PtCl_5(OH_2)]$ and $[PtCl_4(OH_2)_2]$; the reaction is reversed by adding HCl.

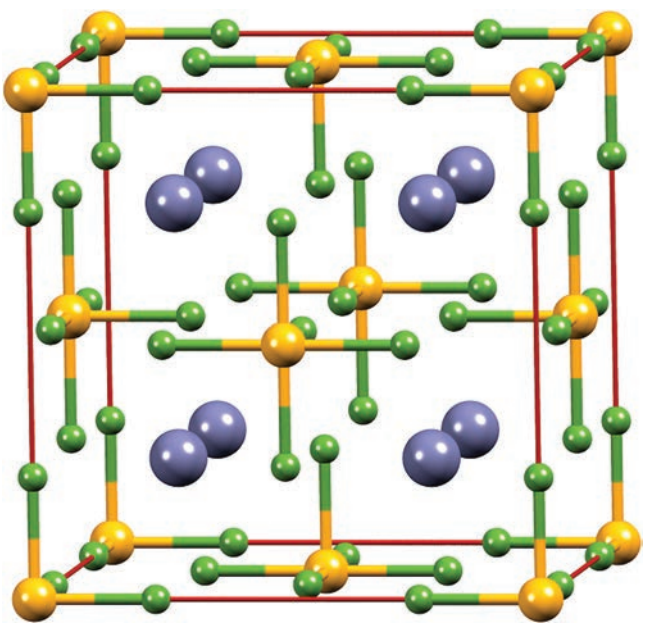
In their complexes, Pd(IV) and Pt(IV) are low-spin, octahedral and diamagnetic (d^6). The full range of halido complexes $[MX_6]^{2-}$ is known (e.g. eqs. 22.134–22.136), in contrast to PdF_4 being the only neutral Pd(IV) halide. The $[MX_6]^{2-}$ ions are stabilized by large cations.

$$M \xrightarrow{\text{aqua regia; KCl}} K_2[MCl_6] \qquad M = Pd, Pt \qquad (22.134)$$

$$K_2[PtCl_6] \xrightarrow{BrF_3} K_2[PtF_6] \qquad (22.135)$$

$$PtCl_4 \xrightarrow{HCl} H_2[PtCl_6] \begin{cases} \xrightarrow{KCl} K_2[PtCl_6] \\ \xrightarrow{KI} K_2[PtI_6] \end{cases} \qquad (22.136)$$

The greater *kinetic* inertness (see Section 26.2) of the Pt(IV) complexes is illustrated by the fact that $K_2[PdF_6]$ is decomposed in the air by moisture, but $K_2[PtF_6]$ can be crystallized from boiling water even though $[PtF_6]^{2-}$ is *thermodynamically* unstable with respect to hydrolysis. The solid state structure of $K_2[PtCl_6]$ is a structure prototype (Fig. 22.30). It can be derived from the CaF_2 structure (Fig. 6.21a) by replacing Ca^{2+} by octahedral $[PtCl_6]^{2-}$ ions, and F^- by K^+ ions. For details of $K_2[PtH_6]$, see Section 10.7.



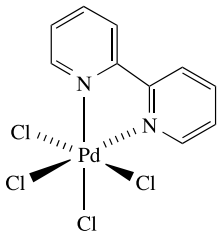


Fig. 22.30. The unit cell of $K_2[PtCl_6]$ which contains octahedral $[PtCl_6]^{2-}$ ions, each of which is shared between adjacent unit cells. Colour code: Pd, yellow; Cl, green; K, purple. The edges of the unit cell are shown in red.

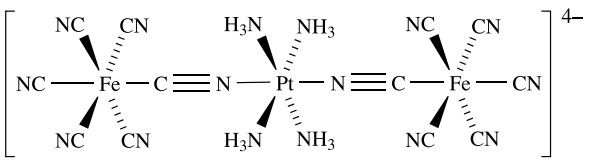
† See: A.V. Wilson *et al.* (2016) *Inorg. Chem.*, vol. 55, p. 1108 – 'A matrix isolation and computational study of molecular palladium fluorides: Does PdF_6 exist?'

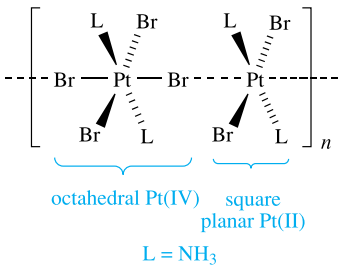
The variety of Pd(IV) complexes is far less than that of Pt(IV), and their syntheses usually involve oxidation of a related Pd(II) species, e.g. reaction 22.137. When a chelating ligand such as bpy or $Me_2PCH_2CH_2PMe_2$ is present, the complex is constrained to being *cis*, e.g. **22.74**. Palladium(IV) complexes are of limited stability.



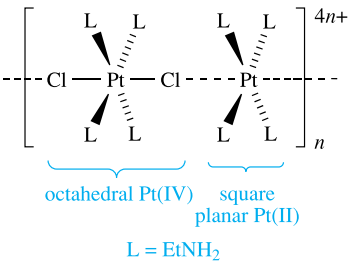
(22.74)

$$trans\text{-}[PdCl_2(NH_3)_2] + Cl_2 \longrightarrow trans\text{-}[PdCl_4(NH_3)_2] \qquad (22.137)$$

Platinum(IV) (d^6) forms a wide range of thermodynamically and kinetically inert octahedral complexes, and ammine complexes, for example, have been known since the days of Werner (see Box 21.6). In liquid NH_3 at 230 K, $[NH_4]_2[PtCl_6]$ is converted to $[Pt(NH_3)_6]Cl_4$. *Trans*-$[PtCl_2(NH_3)_4]^{2+}$ is made by oxidative addition of Cl_2 to $[Pt(NH_3)_4]^{2+}$, and, as for Pd, oxidative addition is a general strategy for Pt(II) ⟶ Pt(IV) conversions. Amine complexes include the optically active $[Pt(en)_3]^{4+}$ and *cis*-$[PtCl_2(en)_2]^{2+}$, both of which can be resolved. Although the range of ligands coordinating to Pt(IV) covers soft and hard donors (see Table 7.10), some ligands such as phosphanes tend to reduce Pt(IV) to Pt(II).



Of note is $[Pt(NH_3)_4]_2$[**22.75**]$\cdot 9H_2O$, formed when aqueous $[Pt(NH_3)_4][NO_3]_2$ reacts with $K_3[Fe(CN)_6]$. Localized Fe(II) and Pt(IV) centres in [**22.75**]$^{4-}$ have been assigned on the basis of magnetic, electrochemical and EPR spectroscopic data, and the complex exhibits an intense Fe(II) ⟶ Pt(IV) charge transfer absorption at 470 nm.

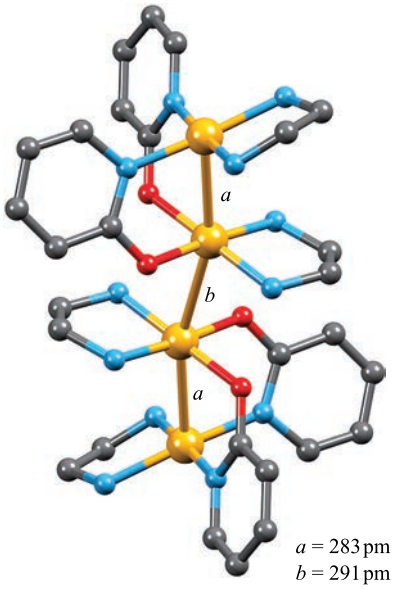


(22.75)

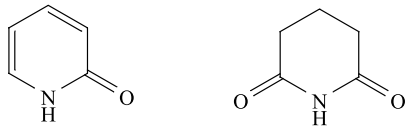
Palladium(III), platinum(III) and mixed-valence complexes

We saw above that 'PdF_3' is the mixed valence $Pd[PdF_6]$, and this cautionary note extends to some other apparently Pd(III) and Pt(III) species. Both $PtCl_3$ and $PtBr_3$ are mixed-valence compounds. The compounds of empirical formulae $Pt(NH_3)_2Br_3$ (**22.76**) and $Pt(NEtH_2)_4Cl_3\cdot H_2O$ (*Wolffram's red salt*, **22.77**) contain halide-bridged chains; extra Cl^- in the lattice of the latter balance the 4+ charge. Such mixed-valence compounds possess intense colours due to intervalence charge transfer absorptions. Partially oxidized $[Pt(CN)_4]^{2-}$ salts are described under platinum(II).

(22.76)



(22.77)



Palladium(III) and platinum(III) dimers that are structurally related to the Rh(II) dimers discussed earlier (Fig. 22.28) include $[Pd_2(\mu\text{-}SO_4\text{-}O,O')_4(OH_2)_2]^{2-}$, $[Pd_2(\mu\text{-}O_2CMe)_4(OH_2)_2]^{2+}$, $[Pt_2(\mu\text{-}HSO_4\text{-}O,O')_2(SO_4\text{-}O,O')_2]$ and $[Pt_2(SO_4\text{-}O,O')_4(OH_2)_2]$. Each formally contains a $\{Pd_2\}^{6+}$ or $\{Pt_2\}^{6+}$ core (isoelectronic with $\{Rh_2\}^{4+}$) and an M–M single bond.

The *platinum blues*[†] are mixed-valence complexes containing discrete Pt_n chains (Fig. 22.31). They are formed by hydrolysis of *cis*-$[PtCl_2(NH_3)_2]$ or *cis*-$[PtCl_2(en)]$ in aqueous $AgNO_3$ (i.e. replacing Cl^- by H_2O and precipitating AgCl) followed by treatment with *N*,*O*-donors such as pyrimidines, uracils or the compounds shown in Fig. 22.31b. Figures 22.31a and 22.31c show two examples; each formally contains a $\{Pt_4\}^{9+}$ core which can be considered as $(Pt^{III})(Pt^{II})_3$. EPR spectroscopic data show that the unpaired electron is delocalized over the Pt_4-chain. Interest in platinum blues lies in the fact that some exhibit anti-tumour activity.

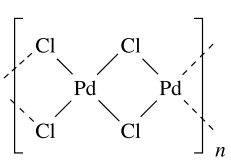
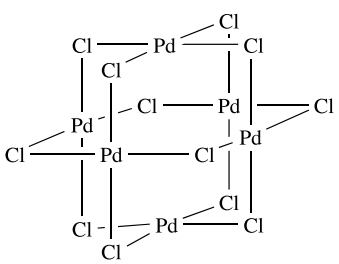
Self-study exercises



1. The anion in $K_4[Pt_4(SO_4)_5]$ can be written in the form $[Pt_4(SO_4)_4(SO_4)_{2/2}]^{4-}$. What does this notation tell you about the solid state structure of the complex?
   [*Ans.* See M. Pley *et al.* (2005) *Eur. J. Inorg. Chem.*, p. 529]

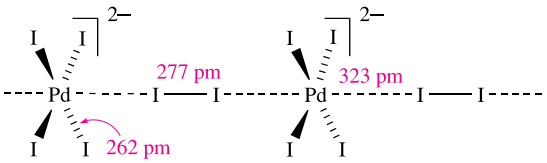
2. The structure of $PtCl_3$ consists of Pt_6Cl_{12} clusters with square planar Pt centres, and chains of edge-sharing *cis*-$[PtCl_2Cl_{4/2}]$-octahedra. (a) Explain how to interpret the formula *cis*-$[PtCl_2Cl_{4/2}]$ to give a structural diagram of part of one chain. (b) Assign oxidation states to the Pt centres in the two structural units. (c) Confirm that the overall stoichiometry is $PtCl_3$.
   [*Ans.* See H.G. von Schnering *et al.* (2004) *Z. Anorg. Allg. Chem.*, vol. 630, p. 109]



Palladium(II) and platinum(II)

In Section 20.3, we discussed the increase in crystal field splitting on descending group 10, and explained why Pd(II) and Pt(II) complexes favour a square planar arrangement of donor atoms.

All the halides of Pd(II) and Pt(II) except PtF_2 are known. Reaction of Pd and F_2 gives 'PdF_3' (see above) which is reduced to violet PdF_2 by SeF_4. Unusually for Pd(II), PdF_2 is paramagnetic ($\mu = 1.90\ \mu_B$) and each Pd(II) centre is octahedrally sited in a rutile structure (Fig. 6.24). The other dihalides are diamagnetic (low-spin d^8) and contain square planar M(II) centres in polymeric structures. Heating Pd and Cl_2 gives $PdCl_2$. The α-form is a polymer (**22.78**) and above 820 K, α-$PdCl_2$ converts to the β-form which contains hexameric units (**22.79**). Palladium(II) bromide is made from the elements, and PdI_2 by heating $PdCl_2$ with HI. Direct combination of Pt and a halogen affords $PtCl_2$, $PtBr_2$ and PtI_2. $PtCl_2$ is dimorphic like $PdCl_2$.



(22.78)

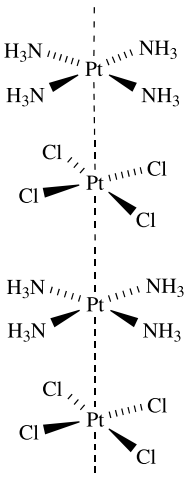
(22.79)

Black, water-insoluble PdI_2 dissolves in a solution containing CsI and I_2, and the compounds $Cs_2[PdI_4]\cdot I_2$ and $Cs_2[PdI_6]$ can be crystallized from the solution. Pressure converts $Cs_2[PdI_4]\cdot I_2$ to $Cs_2[PdI_6]$, a process that is facilitated by the presence of chains (**22.80**) in the solid state structure of $Cs_2[PdI_4]\cdot I_2$. The structure of $Cs_2[PdI_6]$ is like that of $K_2[PtCl_6]$.

(22.80)

Black PdO, formed by heating Pd and O_2, is the only well-established oxide of Pd. In contrast, PtO_2 is the only well-characterized oxide of Pt. Dissolution of PdO in perchloric acid gives $[Pd(OH_2)_4][ClO_4]_2$ containing a diamagnetic, square planar tetraaqua ion. The $[Pt(OH_2)_4]^{2+}$ ion is made in solution by treating $[PtCl_4]^{2-}$ with aqueous $AgClO_4$. Both aqua ions are considerably better oxidizing agents than aqueous Ni^{2+} (eq. 22.138), but neither $[Pd(OH_2)_4]^{2+}$ nor $[Pt(OH_2)_4]^{2+}$ is very stable. Solid $[Pt(OH_2)_4][SbF_6]_2$, containing the square planar $[Pt(OH_2)_4]^{2+}$ cation, has been isolated by dissolving $PtO\cdot H_2O$ in $[H_3O][SbF_6]$ followed by recrystallization from anhydrous HF.

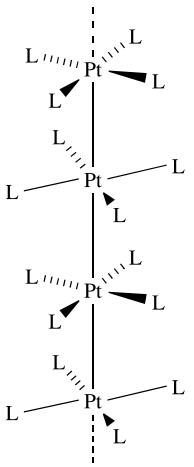
$$M^{2+} + 2e^- \rightleftharpoons M \qquad \begin{cases} M = Ni, & E^\circ = -0.25\,V \\ M = Pd, & E^\circ = +0.95\,V \\ M = Pt, & E^\circ = +1.18\,V \end{cases} \qquad (22.138)$$



Palladium(II) and platinum(II) form a wide range of square planar complexes. A tendency for Pt−Pt interactions (i.e. for the heaviest group 10 metal) is quite often observed. The mechanisms of substitution reactions in Pt(II) complexes and the *trans-effect* have been much studied (see Section 26.3). For the discussion that follows, it is important to note that mutually *trans* ligands exert an effect on one another, and this dictates the order in which ligands are displaced and, therefore, the products of substitution reactions. ***A word of caution:*** do not confuse *trans*-effect with *trans*-influence (see Box 22.7).

Important families of complexes with monodentate ligands (Fig. 22.32) include $[MX_4]^{2-}$ (e.g. X = Cl, Br, I, CN, SCN-*S*), $[MX_2L_2]$ (e.g. X = Cl, Br; L = NH_3, NR_3, RCN, py, PR_3, SR_2; or X = CN; L = PR_3) and $[ML_4]^{2+}$ (e.g. L = PR_3, NH_3, NR_3, MeCN). For $[MX_2L_2]$, *trans*- and *cis*-isomers may exist (Figs. 22.32b, c and e) and, in the absence of X-ray diffraction data, IR spectroscopy can be used to distinguish between *cis*- and *trans*-$[MX_2Y_2]$ species (Fig. 19.13). Isomers of, for example, $[PtCl_2(PR_3)_2]$ can also be distinguished using ^{31}P NMR spectroscopy (Box 19.1). Equations 22.139–22.141 show the formation of some ammine complexes, the choice of route for *cis*- and *trans*-$[PtCl_2(NH_3)_2]$ arising from the *trans*-effect (see above). Isomerization of *cis*- to *trans*-$[PtCl_2(NH_3)_2]$ occurs in solution.

$$[PtCl_6]^{2-} \xrightarrow{SO_2;\ HCl} H_2PtCl_4 \xrightarrow{\text{conc } NH_3,\ \Delta} [Pt(NH_3)_4]Cl_2 \qquad (22.139)$$



$$[PtCl_4]^{2-} + 2NH_3 \xrightarrow{\text{aq soln}} \textit{cis}\text{-}[PtCl_2(NH_3)_2] + 2Cl^- \qquad (22.140)$$

$$[Pt(NH_3)_4]^{2+} + 2HCl \xrightarrow{\text{aq soln}} \textit{trans}\text{-}[PtCl_2(NH_3)_2] + 2[NH_4]^+ \qquad (22.141)$$

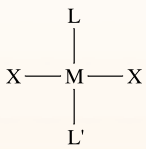
Pt–Pt = 325 pm
Torsion angle N–Pt–Pt–Cl = 28°

(22.81)

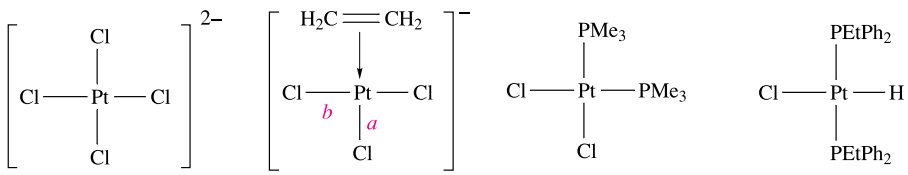
L = CN^- Pt–Pt = 288 pm
Torsion angle C–Pt–Pt–C = 45°

(22.82)

Magnus's green salt, $[Pt(NH_3)_4][PtCl_4]$ is prepared by precipitation from colourless $[Pt(NH_3)_4]Cl_2$ and pink $[PtCl_4]^{2-}$. It contains chains of alternating cations and anions (**22.81**) with significant Pt−Pt interactions, and this structural feature leads to the change in colour on going from the constituent ions to the solid salt. However, the Pt−Pt distance is not as short as in the partially oxidized $[Pt(CN)_4]^{2-}$ (see below), and $[Pt(NH_3)_4][PtCl_4]$ is, therefore, not a metallic conductor.



The cyanido complexes $[Pd(CN)_4]^{2-}$ and $[Pt(CN)_4]^{2-}$ are very stable. $K_2[Pt(CN)_4]\cdot 3H_2O$ can be isolated from the reaction of $K_2[PtCl_4]$ with KCN in aqueous solution. Aqueous solutions of $K_2[Pt(CN)_4]$ are colourless, but the hydrate forms yellow crystals. Similarly, other salts are colourless in solution but form coloured crystals. The colour change arises from stacking (non-eclipsed) of square planar anions in the solid, although the Pt····Pt separations are significantly larger (e.g. 332 pm in yellow-green



THEORY

Box 22.7 The *trans*-influence

Consider a square planar complex which contains a *trans* L–M–L' arrangement:

Ligands L and L' compete with each other for electron density because the formation of M–L and M–L' bonds uses the same metal orbitals, e.g. d_{z^2} and p_z if L and L' lie on the z axis. The existence of a *ground state trans*-influence (i.e. the influence that L has on the M–L' bond in the ground state of the complex) is established by comparing the solid state structural, and vibrational and NMR spectroscopic data for series of related complexes. Structural data are exemplified by the following series of square planar Pt(II) complexes; H^- exerts a strong *trans*-influence and as a consequence, the Pt–Cl bond in $[PtClH(PEtPh_2)_2]$ is relatively long and weak:

Pt–Cl / pm	231.6	a = 232.7 b = 230.5	237	242

IR and ^{1}H NMR spectroscopic data for a series of square planar complexes *trans*-$[PtXH(PEt_3)_2]$ are as follows:

X^-	$[CN]^-$	I^-	Br^-	Cl^-
$\bar{\nu}$(Pt–H) / cm^{-1}	2041	2156	2178	2183
δ(^{1}H for Pt–H) ppm	−7.8	−12.7	−15.6	−16.8

Values of $\bar{\nu}$(Pt–H) show that the Pt–H bond is weakest for $X^- = [CN]^-$ and the *trans*-influence of the X^- ligands follows the order $[CN]^- > I^- > Br^- > Cl^-$. The signal for the hydride in the ^{1}H NMR spectrum moves to lower frequency (higher field) with a decrease in the *trans*-influence of X^-. The *trans*-influence is not unique to square planar complexes, and may be observed wherever ligands are mutually *trans*, e.g. in octahedral species.

The *trans*-influence is *not* the same as the *trans*-effect. The *trans*-influence is a ground state phenomenon, while the *trans*-effect is a kinetic effect (see Section 26.3). The two effects are sometimes distinguished by the names *structural trans-effect* and *kinetic trans-effect*.

$Ba[Pt(CN)_4]\cdot 4H_2O$ and 309 pm in violet $Sr[Pt(CN)_4]\cdot 3H_2O$) than in Pt metal (278 pm). When $K_2[Pt(CN)_4]$ is partially oxidized with Cl_2 or Br_2, bronze complexes of formula $K_2[Pt(CN)_4]X_{0.3}\cdot 2.5H_2O$ (X = Cl, Br) are obtained. These contain isolated X^- ions and stacks of staggered $[Pt(CN)_4]^{2-}$ ions (**22.82**) with short Pt–Pt separations, and are good 1-dimensional metallic conductors. The conductivity arises from electron delocalization along the Pt_n chain, the centres no longer being localized Pt(II) after partial oxidation. Some salts do contain non-stacked $[Pt(CN)_4]^{2-}$ ions, e.g. $[PhNH_3]_2[Pt(CN)_4]$.

The paucity of complexes with *O*-donors arises because Pd(II) and Pt(II) are soft metal centres (see Table 7.10) and prefer soft donors such as *S* or *P*. Although $[Pt(OH_2)_4][SbF_6]_2$ has been structurally characterized by X-ray diffraction (see earlier in the section), the tetraaqua

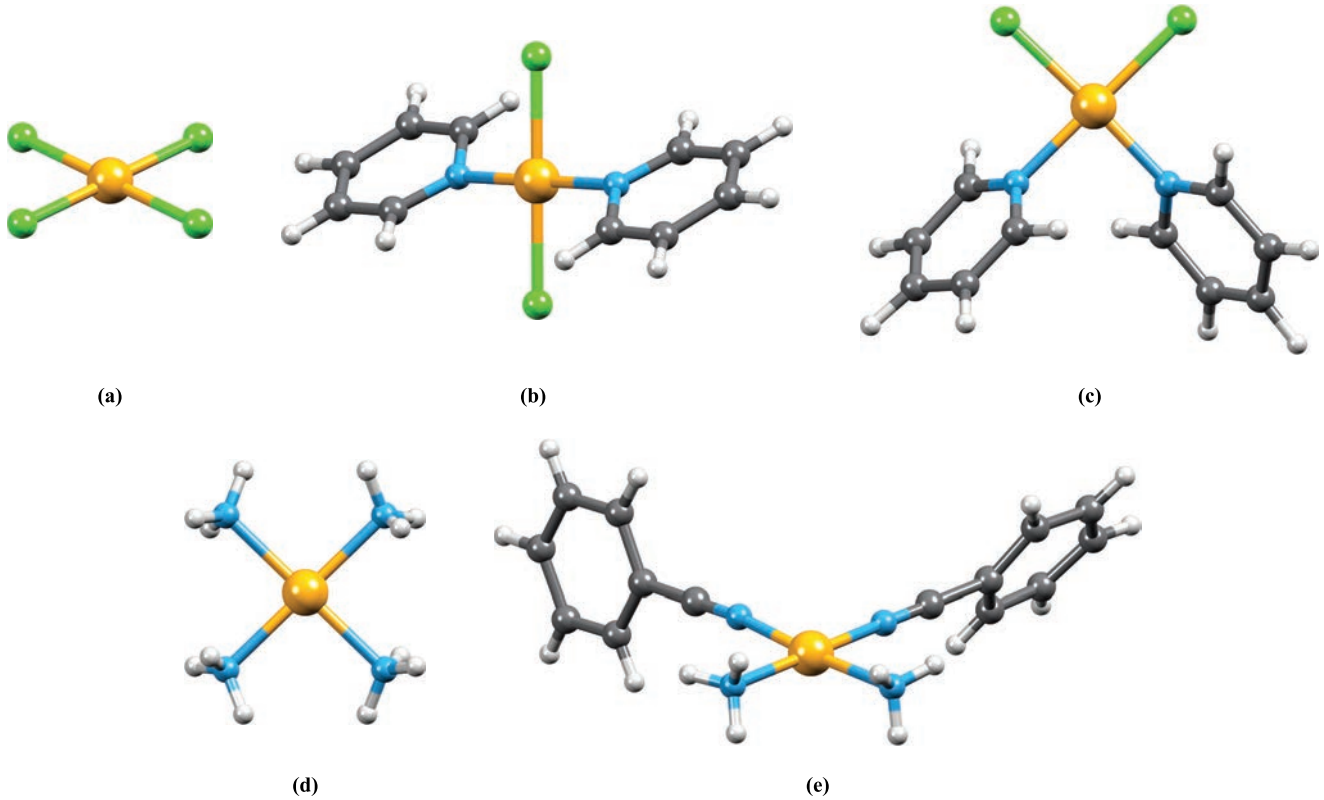

Fig. 22.32. Examples of square planar platinum(II) complexes characterized by X-ray diffraction: (a) the $[PtCl_4]^{2-}$ ion (in the 2,2'-bipyridinium salt) [A. Angeloni *et al.* (2004) *Chem. Eur. J.*, vol. 10, p. 3783], (b) *trans*-$[PtCl_2(py)_2]$, (c) *cis*-$[PtCl_2(py)_2]$ [P. Colamarino *et al.* (1975) *J. Chem. Soc., Dalton Trans.*, p. 1656], (d) the $[Pt(NH_3)_4]^{2+}$ ion (in the $[Co(ox)_2(OH_2)_2]^{2-}$ salt) [A. Zadesenets *et al.* (2011) *Polyhedron*, vol. 30, p. 1305] and (e) *cis*-$[Pt(NH_3)_2(PhCN)_2]^{2+}$ (in the perchlorate salt) [K. Uemura *et al.* (2007) *Inorg. Chim. Acta*, vol. 360, p. 2623]. Colour code: Pt, yellow; N, blue; Cl, green; C, grey; H, white.

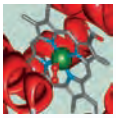
ions of Pd(II) and Pt(II) are relatively unstable. Reaction of $[PtCl_4]^{2-}$ with KOH and excess Hacac gives monomeric $[Pt(acac)_2]$. Palladium(II) and platinum(II) acetates are trimeric and tetrameric respectively. The Pd atoms in $[Pd(O_2CMe)_2]_3$ are arranged in a triangle with each Pd····Pd (non-bonded, 310–317 pm) bridged by two $[MeCO_2]^-$ ligands giving square planar coordination. In $[Pt(O_2CMe)_2]_4$, the Pt atoms form a square (Pt—Pt bond lengths = 249 pm) with two $[MeCO_2]^-$ bridging each edge. Palladium(II) acetate is an important industrial catalyst for the conversion of ethene to vinyl acetate.

Zeise's salt, $K[PtCl_3(\eta^2\text{-}C_2H_4)]$, is a well-known organometallic Pt(II) complex and is discussed in Section 24.11.

Self-study exercises



1. Explain why 4-coordinate Pt(II) complexes are usually diamagnetic.
[*Ans.* See Section 20.1 and following text]

2. Each of the mononuclear complexes **A** and **B** has the molecular formula $C_{12}H_{30}Cl_2P_2Pt$. The ^{31}P spectrum of each complex shows a singlet (δ –11.8 ppm for **A**, δ –3.1 ppm for **B**) superimposed on a doublet. For **A**, $J_{PtP} = 2400$ Hz, and for **B**, $J_{PtP} = 3640$ Hz. Suggest structures for **A** and **B**, and explain how the spectra and the different coupling constants arise. [*Ans.* See Box 19.1]

Platinum(–II)

The relativistic contraction of the 6*s* orbital (see Box 13.3) is greatest for Pt and Au. Among the properties that this influences[†] are enthalpies of electron attachment. In contrast to other *d*-block metals, Pt and Au possess *negative* values for the enthalpy of attachment of the first electron at 298 K. For reaction 22.142, $\Delta_{EA}H^\circ = -205\ kJ\ mol^{-1}$, a value comparable with that of sulfur ($\Delta_{EA}H^\circ(S, g) = -201\ kJ\ mol^{-1}$) and greater than that for oxygen ($-141\ kJ\ mol^{-1}$). Since the chalcogens readily form X^{2-} ions, it has been reasoned that Pt^{2-} may also be formed.[‡]

BIOLOGY AND MEDICINE

Box 22.8 Platinum-containing drugs for cancer treatment

Cisplatin is the square planar complex *cis*-$[PtCl_2(NH_3)_2]$ and its capacity to act as an anti-tumour drug has been known since the 1960s. It is used to treat bladder and cervical tumours, as well as testicular and ovarian cancers, but patients may suffer from side-effects of nausea and kidney damage. Carboplatin shows similar anti-tumour properties and has the advantage of producing fewer side-effects than cisplatin. The drugs operate by interacting with guanine (G) bases in strands of DNA (Fig. 10.14), with the *N*-donors of the nucleotide base coordinating to the Pt(II) centre; GG intra-strand cross-links are formed by cisplatin. Cisplatin, carboplatin and oxaliplatin are approved for medical use by the FDA (the US Food and Drug Administration). Nedaplatin, Heptaplatin and Lobaplatin have been clinically approved for use in Japan, Korea and China, respectively. Despite huge research efforts, these six Pt(II)-containing drugs are the only ones approved (as of 2017) for clinicial use. A number of other Pt(II) complexes have reached the stage of clinical trials, including a triplatinum complex which is significantly more active than cisplatin and is capable of forming interstrand cross-links involving three base pairs in DNA.

Satraplatin is one of the few Pt(IV) complexes to reach clinical trials. After entering the bloodstream, satraplatin is reduced, giving Pt(II) species as the active drug. Satraplatin (combined with prednisone, an immunosuppressant) reached Phase III clinical trials, but a file for US Food and Drug Administration (FDA) approval was rejected.

$$Pt(g) + e^- \longrightarrow Pt^-(g) \qquad (22.142)$$

The first ionization energy of Cs is the lowest of any element (see Fig. 1.16). Cs reacts with Pt sponge (a porous form of the metal with a large surface area) at 973 K followed by slow cooling to give crystals of Cs_2Pt. The red colour and transparency of the crystals provide evidence for a distinct band gap, supporting complete charge separation and the formation of Cs^+ and Pt^{2-} ions. In the solid state, each Pt^{2-} ion lies within a tricapped trigonal prismatic array of Cs^+ ions. Barium also reacts with Pt at high temperatures, and forms Ba_2Pt which is formulated as $(Ba^{2+})_2Pt^{2-}{\cdot}2e^-$. The free electrons in this system result in metallic behaviour.

22.12 Group 11: silver and gold

The metals

Silver and gold are generally inert, and are not attacked by O_2 or non-oxidizing acids. Silver dissolves in HNO_3 and liberates H_2 from concentrated HI owing to the formation of stable iodido complexes. Where sulfide (e.g. as H_2S) is present, Ag tarnishes as a surface coating of Ag_2S forms. Gold dissolves in concentrated HCl in the presence of oxidizing agents due to the formation of chlorido complexes (eq. 22.143).

$$[AuCl_4]^- + 3e^- \rightleftharpoons Au + 4Cl^- \qquad E^o_{[Cl^-]=1} = +1.00\,V \qquad (22.143)$$

Both metals react with halogens (see below), and gold dissolves in liquid BrF_3, forming $[BrF_2]^+[AuF_4]^-$. The dissolution of Ag and Au in cyanide solutions in the presence of air is used in their extraction from crude ores (eq. 22.4).

Stable oxidation states for the group 11 metals differ: in contrast to the importance of Cu(II) and Cu(I), silver has only one stable oxidation state, Ag(I), and for gold, Au(III) and Au(I) are dominant, with Au(III) being the more stable. Relativistic effects (see Box 13.3) are considered to be important in stabilizing Au(III). As we have already noted, discussing oxidation states of the heavy *d*-block metals in terms of independently obtained physicochemical data is usually impossible owing to the absence of *IE* values and the scarcity of simple ionic compounds or aqua ions. Data are more plentiful for Ag than for many of the heavier metals, and some comparisons with Cu are possible. Although the enthalpy of atomization of Ag < Cu (Table 22.3), the greater ionic radius for the silver ion along with relevant ionization energies (Table 22.3) make Ag more noble than Cu (eqs. 22.144–22.146). Gold is more noble still (eq. 22.147).

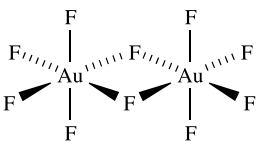
$$Ag^+ + e^- \rightleftharpoons Ag \qquad E^o = +0.80\,V \qquad (22.144)$$

$$Cu^+ + e^- \rightleftharpoons Cu \qquad E^o = +0.52\,V \qquad (22.145)$$

Table 22.3 Selected physical data for Cu and Ag.

Quantity	Cu	Ag
IE_1 / kJ mol^{-1}	745.5	731.0
IE_2 / kJ mol^{-1}	1958	2073
IE_3 / kJ mol^{-1}	3555	3361
$\Delta_a H^o$(298 K) / kJ mol^{-1}	338	285

$$Cu^{2+} + e^- \rightleftharpoons Cu^+ \qquad E^o = +0.34\,V \qquad (22.146)$$



$$Au^+ + e^- \rightleftharpoons Au \qquad E^o = +1.69\,V \qquad (22.147)$$

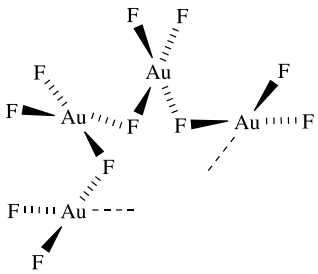
Gold(V) and silver(V)

Gold(V) is found only in AuF_5 and $[AuF_6]^-$ (eqs. 22.148 and 22.149). AuF_5 is highly reactive and possesses dimeric structure **22.83** in the solid state.

$$Au + O_2 + 3F_2 \xrightarrow{670\,K} [O_2]^+[AuF_6]^- \xrightarrow{430\,K} AuF_5 + O_2 + \tfrac{1}{2}F_2 \qquad (22.148)$$

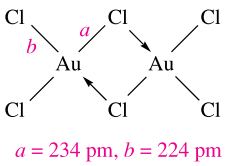
$$2Au + 7KrF_2 \xrightarrow[-5\,Kr]{293\,K} 2[KrF]^+[AuF_6]^- \xrightarrow{335\,K} 2AuF_5 + 2Kr + 2F_2 \qquad (22.149)$$

(22.83)



It has been reported that AuF_5 reacts with atomic F to produce AuF_7. However, the results of DFT calculations (see Section 4.13) show that elimination of F_2 from AuF_7 is a highly exothermic reaction with a low activation energy. Hence, the report of AuF_7 is probably in error (see Fig. 22.17).[†]

Gold(III) and silver(III)



For gold, AuF_3, $AuCl_3$ and $AuBr_3$ are known, but AgF_3 is the only high oxidation state halide of silver. It is made in anhydrous HF by treating $K[AgF_4]$ with BF_3, $K[AgF_4]$ being prepared from fluorination of a KCl and AgCl mixture. Red AgF_3 is diamagnetic (d^8) and isostructural

[†] See: S. Riedel and M. Kaupp (2006) *Inorg. Chem.*, vol. 45, p. 1228 – 'Has AuF_7 been made?'

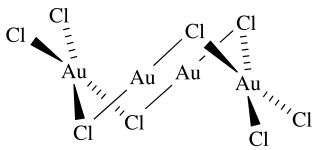
with AuF_3. AuF_3 is made from Au with F_2 (1300 K, 15 bar) or by reaction 22.150. It is a polymer consisting of helical chains. Part of one chain is shown in **22.84**. Each Au(III) centre is in a square planar environment (Au–F = 191–203 pm), with additional weak Au---F interactions (269 pm) between chains. Diamagnetic $K[AuF_4]$ contains square planar anions.

(22.84)

(22.85)

$$Au \xrightarrow{BrF_3} [BrF_2][AuF_4] \xrightarrow{330\ K} AuF_3 \qquad (22.150)$$

Red $AuCl_3$ and brown $AuBr_3$ (made by direct combination of the elements) are diamagnetic, planar dimers (**22.85**). In hydrochloric acid, $AuCl_3$ forms $[AuCl_4]^-$. This reacts with Br^- to give $[AuBr_4]^-$, but with I^- to yield AuI and I_2. The acid $HAuCl_4{\cdot}xH_2O$ (tetrachloridoauric acid), its bromido analogue, $K[AuCl_4]$ and $AuCl_3$ are commercially available and are valuable starting materials in Au(III) and Au(I) chemistry.



The hydrated oxide $Au_2O_3{\cdot}H_2O$ is precipitated by alkali from solutions of $Na[AuCl_4]$, and reacts with an excess of $[OH]^-$ to give $[Au(OH)_4]^-$. $Au_2O_3{\cdot}H_2O$ is the only established oxide of gold. For Ag, the thermodynamic stability of the oxides is lowest for Ag(III): Ag_2O_3 is thermodynamically unstable with respect to decomposition to Ag_2O and O_2. The oxide, AgO, is the mixed oxidation state $Ag^{III}Ag^{I}O_2$ (see later).[†]

Limited numbers of Ag(III) complexes are known. Examples are paramagnetic CsK_2AgF_6 and diamagnetic $K[AgF_4]$. Numerous gold(III) complexes have been made, and square planar coordination (d^8 metal centre) predominates. The anions $[AuX_4]^-$ (X = F, Cl, Br, see above) can be made by oxidation of Au metal (e.g. eq. 22.143). The unstable $[AuI_4]^-$ is made by treating $[AuCl_4]^-$ with anhydrous, liquid HI. Other simple complexes include $[Au(CN)_4]^-$ (from $[AuCl_4]^-$ with $[CN]^-$), $[Au(NCS\text{-}S)_4]^-$, $[Au(N_3)_4]^-$ and $[Au(NO_3\text{-}O)_4]^-$ (eq. 22.151). Complexes of type R_3PAuCl_3 can be made by oxidative addition of Cl_2 to Ph_3PAuCl.

[†]For a thermodynamic treatment, see: D. Tudela (2008) *J. Chem. Educ.*, vol. 85, p. 863.

$$Au \xrightarrow{N_2O_5} [NO_2][Au(NO_3)_4] \xrightarrow{KNO_3} K[Au(NO_3)_4] \qquad (22.151)$$

Most compounds which may appear to contain gold(II) are mixed-valence compounds, e.g. '$AuCl_2$' is actually the tetramer $(Au^I)_2(Au^{III})_2Cl_8$ (**22.86**), and $CsAuCl_3$ is $Cs_2[AuCl_2][AuCl_4]$. Both compounds contain square planar Au(III) and linear Au(I), and their dark colours arise from charge transfer between Au(I) and Au(III).

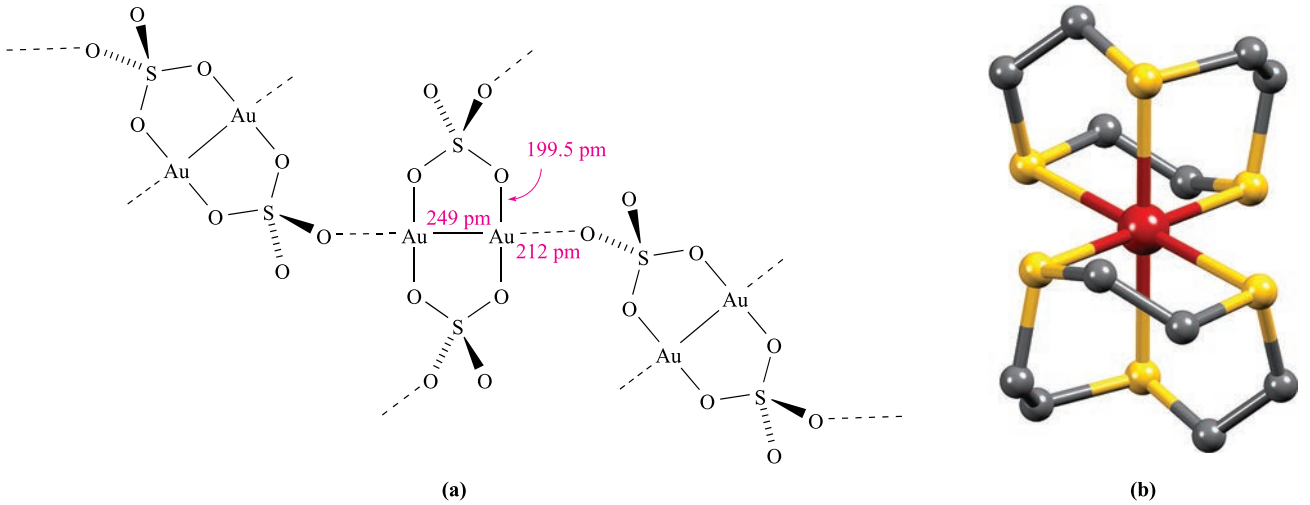
(22.86)

Gold(II) and silver(II)

True gold(II) compounds are rare (see above) and are represented by $[AuXe_4]^{2+}$ (eq. 18.26), and *trans*- and *cis*-$[AuXe_2]^{2+}$ (structure **18.22**). In anhydrous HF/SbF_5, AuF_3 is reduced or partially reduced to give $Au_3F_8{\cdot}2SbF_5$, $Au_3F_7{\cdot}3SbF_5$ or $[Au(HF)_2][SbF_6]_2{\cdot}2HF$ depending on reaction conditions. For many years, $AuSO_4$ was formulated as the mixed-valence compound $Au^IAu^{III}(SO_4)_2$, but in 2001, a crystal structure determination confirmed it to be an Au(II) compound containing an $[Au_2]^{4+}$ unit (Fig. 22.33a). This dinuclear core is present in a range of complexes that formally contain Au(II). However, Fig. 22.33b shows a rare example of a *mononuclear* Au(II) complex; in the solid state, a Jahn–Teller distortion is observed as expected for a d^9 electronic configuration ($Au{-}S_{axial} = 284$ pm, $Au{-}S_{equatorial} = 246$ pm).

Silver(II) is stabilized in the compounds $Ag^{II}M^{IV}F_6$ (M = Pt, Pd, Ti, Rh, Sn, Pb) in which each Ag(II) and M(IV) centre is surrounded by six octahedrally arranged F atoms. Brown AgF_2 is obtained by reacting F_2 and Ag at 520 K, but is instantly decomposed by H_2O. AgF_2 is paramagnetic (Ag^{2+}, d^9) but the magnetic moment of 1.07 μ_B reflects antiferromagnetic coupling. In solid AgF_2, the environments of Ag^{2+} centres are Jahn–Teller distorted (elongated) octahedral, $Ag{-}F = 207$ and 259 pm. The $[AgF]^+$ ion has been characterized in $[AgF]^+[AsF_6]^-$ which, in anhydrous HF, undergoes partial disproportionation to give $[AgF]^+_2[AgF_4]^-[AsF_6]^-$ (eq. 22.152). Crystalline $[AgF]_2[AgF_4][AsF_6]$ consists of polymeric $[AgF]_n^{n+}$ chains with linear Ag(II), square planar $[Ag^{III}F_4]^-$ ions and octahedral $[AsF_6]^-$ ions.

$$4[AgF][AsF_6] \xrightarrow[HF]{anhydrous} Ag[AsF_6] + [AgF]_2[AgF_4][AsF_6] + 2AsF_5 \qquad (22.152)$$



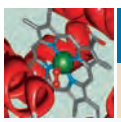


Fig. 22.33. (a) Schematic representation of part of one chain in the solid state structure of $AuSO_4$, which contains $[Au_2]^{4+}$ units; the $[SO_4]^{2-}$ act as both bridging and monodentate ligands. (b) The structure (X-ray diffraction) of $[AuL_2]^{2+}$ (L = 1,4,7-trithiacyclononane, see Fig. 22.34) determined for the $[BF_4]^-$ salt [A.J. Blake *et al*. (1990) *Angew. Chem. Int. Ed.*, vol. 29, p. 197]; H atoms are omitted; colour code: Au, red; S, yellow; C, grey.

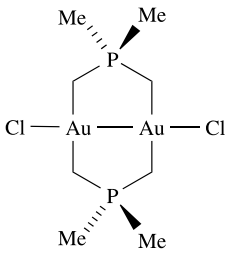
BIOLOGY AND MEDICINE

Box 22.9 Bactericidal effects of silver sols

Solutions of silver sols (i.e. colloidal dispersions of Ag in aqueous solution) have some application as bactericidal agents. The active agent is Ag^+, with the metabolism of bacteria being disrupted by its presence. A silver sol exhibits a large metal surface area, and oxidation by atmospheric O_2 occurs to some extent to give Ag_2O. While this is only sparingly soluble in water, the concentration of Ag^+ in solution is sufficient to provide the necessary bactericidal effects. For example, Johnson & Johnson market the dressing 'Actisorb Silver' which consists of activated carbon impregnated with metallic silver, manufactured as a carbonized fabric enclosed in nylon fibres. The photograph shows a coloured scanning electron micrograph (SEM) of an 'Actisorb Silver' wound dressing. The charcoal and silver can be seen as the black layer while the nylon fibres appear in white. The dressing is designed not only to kill bacteria, but also to absorb toxins and to minimize the smell of the wound. Such dressings are used on infected wounds (e.g. fungal lesions and leg ulcers). Over-exposure to Ag, however, results in argyria: this is a darkening of the skin, caused by absorption of metallic Ag, which cannot be medically reversed.

An SEM image of a silver-impregnated 'Actisorb Silver' wound dressing.



The black solid of composition AgO which is precipitated when $AgNO_3$ is warmed with persulfate solution is diamagnetic and contains Ag(I) (with two O nearest neighbours) and Ag(III) (4-coordinate). However, when AgO dissolves in aqueous $HClO_4$, the paramagnetic $[Ag(OH_2)_4]^{2+}$ ion is formed. This ion (eq. 22.153), AgO and Ag(II) complexes are very powerful oxidizing agents, e.g. AgO converts Mn(II) to $[MnO_4]^-$ in acidic solution.

$$Ag^{2+} + e^- \rightleftharpoons Ag^+ \qquad E^o = +1.98\,V \qquad (22.153)$$

Silver(II) complexes can be precipitated from aqueous solution of Ag(I) salts by using a very strong oxidizing agent in the presence of an appropriate ligand. They are paramagnetic and usually square planar. Examples include $[Ag(py)_4]^{2+}$, $[Ag(bpy)_2]^{2+}$ and $[Ag(bpy)(NO_3\text{-}O)_2]$.

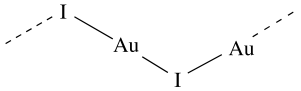
Self-study exercises

1. The compound $AgRhF_6$ is prepared from $RhCl_3$, Ag_2O (2:1 ratio) and F_2 at 770 K for 15 days. For Ag, Rh and F, what oxidation state changes occur in this reaction?
2. Justify why the following compound is classed as containing Au(II).

3. The reaction of Au(CO)Cl with $AuCl_3$ gives a diamagnetic product formulated as '$AuCl_2$'. Comment on these results.
[*Ans*. See: D.B. Dell'Amico *et al*. (1977) *J. Chem. Soc., Chem. Commun*., p. 31]

Gold(I) and silver(I)

Many Ag(I) salts are familiar laboratory reagents. They are nearly always anhydrous and (except for AgF, $AgNO_3$ and $AgClO_4$) are usually sparingly soluble in water. Topics already covered are:



- solubilities of Ag(I) halides (Section 7.9);
- common-ion effect, exemplified with AgCl (Section 7.10);
- half-cells involving Ag(I) halides (Section 8.3);
- Frenkel defects illustrated by the structure of AgBr (Section 6.18).

Yellow AgF can be made from the elements or by dissolving AgO in HF. It adopts an NaCl structure (Fig. 6.18) as do AgCl and AgBr. Precipitation reactions 22.154 are used to prepare AgCl (white), AgBr (pale yellow) and AgI (yellow); for K_{sp} values, see Table 7.5.

$$AgNO_3(aq) + X^-(aq) \longrightarrow AgX(s) + [NO_3]^-(aq) \quad (X = Cl, Br, I) \qquad (22.154)$$

Silver(I) iodide is polymorphic. The stable form at 298 K and 1 bar pressure, γ-AgI, has a zinc blende structure (Fig. 6.21). At high pressures, this converts to δ-AgI with an NaCl structure, the Ag−I distance increasing from 281 to 304 pm. Between 409 and 419 K, the β-form exists with a wurtzite structure (Fig. 6.23). Above 419 K, α-AgI becomes a fast ion electrical conductor (see Section 28.2), the conductivity at the transition temperature increasing by a factor of ≈4000. In this form, the I^- ions occupy positions in a CsCl structure (Fig. 6.19) but the much smaller Ag^+ ions move freely between sites of 2-, 3- or 4-coordination among the easily deformed I^- ions. The high-temperature form of Ag_2HgI_4 shows similar behaviour.

Although gold(I) fluoride has not been isolated, it has been prepared by laser ablation of Au metal in the presence of SF_6. From its microwave spectrum, an equilibrium Au−F bond length of 192 pm has been determined from rotational constants. Yellow AuCl, AuBr and AuI can be made by reactions 22.155 and 22.156. Overheating AuCl and AuBr results in decomposition to the elements. Crystalline AuCl, AuBr and AuI possess zigzag chain structures (**22.87**). The halides disproportionate when treated with H_2O. Disproportionation of Au(I) (eq. 22.157) does not parallel that of Cu(I) to Cu and Cu(II).

Au–I = 262 pm; ∠Au-I-Au = 72°

(22.87)

$$AuX_3 \xrightarrow{\Delta} AuX + X_2 \quad (X = Cl, Br) \qquad (22.155)$$

$$2Au + I_2 \xrightarrow{\Delta} 2AuI \qquad (22.156)$$

$$3Au^+ \longrightarrow Au^{3+} + 2Au \qquad (22.157)$$

Silver(I) oxide is precipitated by adding alkali to solutions of Ag(I) salts. It is a brown solid which decomposes above 423 K. Aqueous suspensions of Ag_2O are alkaline and absorb atmospheric CO_2. In alkalis, Ag_2O dissolves, forming $[Ag(OH)_2]^-$. No gold(I) oxide has been confirmed.

In complexes of gold(I), linear coordination is usual, although Au····Au interactions in the solid state are a common feature (Fig. 22.34a). Trigonal planar and tetrahedral complexes are also found. For Ag(I), linear and tetrahedral complexes are common, but the metal ion can tolerate a range of environments and coordination numbers from 2 to 6 (the latter is rare) are well established. Both Ag(I) and Au(I) favour soft donor atoms, and there are many complexes with M−P and M−S bonds, including some thiolate complexes with intriguing structures (Fig. 16.13d and Fig. 22.34b).

Dissolving Ag_2O in aqueous NH_3 gives the linear $[Ag(NH_3)_2]^+$, but in liquid NH_3 tetrahedral $[Ag(NH_3)_4]^+$ forms. Trigonal planar $[Ag(NH_3)_3]^+$ can be isolated as the nitrate. Equation 22.4 showed the formation of $[M(CN)_2]^-$ (M = Ag, Au) during metal extraction. The cyanido

Fig. 22.34. Yau *et al.* (1995) *J. Chem. Soc., Dalton Trans.*, p. 2575], (b) the trimer $[Ag_3L_3]^{3+}$ where L is the sulfur-containing macrocycle 1,4,7-trithiacyclononane shown in the inset [H.-J. Kuppers *et al.* (1987) *Angew. Chem. Int. Ed.*, vol. 26, p. 575], (c) the planar $[Au_2(CS_3)_2]^{2-}$ (from the $[(Ph_3P)_2N]^+$ salt) [J. Vicente *et al.* (1995) *J. Chem. Soc., Chem. Commun.*, p. 745] and (d) $[Au_2(TeS_3)_2]^{2-}$ (from the $[Me_4N]^+$ salt) [D.-Y. Chung *et al.* (1995) *Inorg. Chem.*, vol. 34, p. 4292]. Hydrogen atoms are omitted for clarity; colour code: Au, red; Ag, dark blue; S, yellow; N, light blue; Te, brown; C, grey.

complexes are also made by dissolving MCN in aqueous KCN. Both AgCN and AuCN are linear polymers (**22.88**). Their solid state structures suffer from disorder problems, but total neutron diffraction† has been used to give the accurate structural data shown in diagram **22.88**. The fact that the Au−C/N distance is smaller than the Ag−C/N bond length is attributed to relativistic effects. The same phenomenon is observed in the discrete, linear $[Au(CN)_2]^-$ and $[Ag(CN)_2]^-$ ions.

(22.88)

† See: S.J. Hibble, A.C. Hannon and S.M. Cheyne (2003) *Inorg. Chem.*, vol. 42, p. 4724; S.J. Hibble, S.M. Cheyne, A.C. Hannon and S.G. Eversfield (2002) *Inorg. Chem.*, vol. 41, p. 1042.

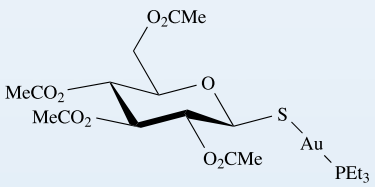
In contrast to the bridging mode of $[CN]^-$ in $[Ag(CN)_2]^-$, the complex $[Ag(CN)(NH_3)]$ crystallizes with discrete linear molecules. At room temperature, $[Ag(CN)(NH_3)]$ rapidly loses NH_3, decomposing to AgCN.

Dissolution of AgX in aqueous halide solutions produces $[AgX_2]^-$ and $[AgX_3]^{2-}$. In aqueous solutions, the ions $[AuX_2]^-$ (X = Cl, Br, I) are unstable with respect to disproportionation but can be stabilized by adding excess X^- (eq. 22.158).

$$3[AuX_2]^- \rightleftharpoons [AuX_4]^- + 2Au + 2X^- \qquad (22.158)$$

Routes to Au(I) complexes often involve reduction of Au(III) as illustrated by the formation of R_3PAuCl and R_2SAuCl species (eqs. 22.159 and 22.160).

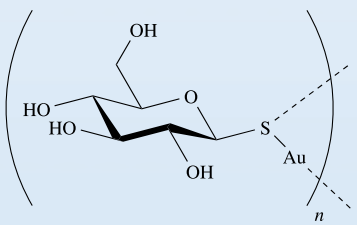
$$[AuCl_4]^- + 2R_3P \longrightarrow [R_3PAuCl] + R_3PCl_2 + Cl^- \qquad (22.159)$$



Box 22.10 Gold complexes in medicine

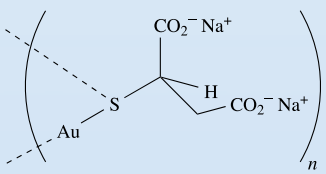
Gold(I) complexes containing thiolate, $[RS]^-$, ligands are used as *disease-modifying antirheumatic drugs* in the treatment of rheumatoid arthritis. Crucial to their application is the lability of the ligands: gold(I)-containing drugs are *prodrugs*, i.e. they are not themselves pharmacologically active, but instead undergo ligand exchange to produce an active drug *in vivo*. The mode of action is not fully determined, but it is proposed that the soft *S*-donors of cysteine residues in proteins displace soft *S*-donor ligands in the prodrug. This can be represented by the equilibrium:

$$RSAuL + RS'H \rightleftharpoons R'SAuL + RSH$$



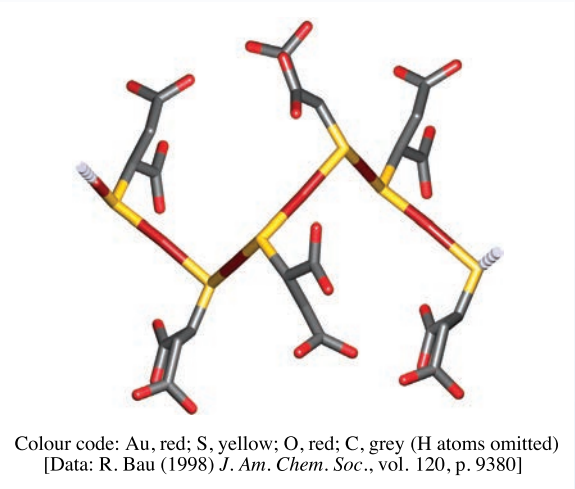
However, a structural (X-ray diffraction) study of the interaction of Et_3PAuCl with the enzyme cyclophilin reveals that a histidine residue (see Table 29.2) displaces Cl^-. Unexpectedly, the gold(I) unit is bound by a histidine *N*-donor in preference to the available cysteine *S*-donors.

Three important rheumatoid arthritic drugs are Auranofin, Myochrysine and Solganol. Auranofin is orally administered, and has been approved by the US Food and Drug Administration (FDA) since 1976. It is lipophilic and is readily absorbed by the body from the intestine after ingestion. Auranofin is typically used to treat adult patients who show no response to non-steroidal anti-inflammatory drugs (NSAIDs).



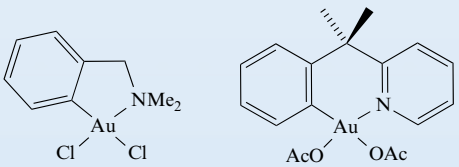
Auranofin

Whereas Auranofin is monomeric, the gold(I) rheumatoid arthritic prodrugs Solganol and Myochrysine are polymeric (see end-of-chapter problem 22.33) and are administered by injection to both adults and children. The polymeric structure of Myochrysine is shown opposite.



Solganol

Myochrysine



The polymeric structure of Myochrysine:

Colour code: Au, red; S, yellow; O, red; C, grey (H atoms omitted)
[Data: R. Bau (1998) *J. Am. Chem. Soc.*, vol. 120, p. 9380]

Thioneins are small protein molecules in which about one-third of the amino acids are cysteine residues. Nature has evolved thioneins to transport and remove toxic metal ions such as Hg(II) and Cd(II), but, like the latter, Au(I) is soft and readily interacts with thioneins. As a result, thioneins are implicated in cell resistance to gold(I) drugs.

The use of Au(I) complexes to control rheumatoid arthritis is well established, but more recently, it has been recognized that some Au(III) complexes have the potential to function as anti-cancer drugs. There are electronic and structural parallels between Au(III) and Pt(II): both are d^8 metal ions with a preference for square planar coordination. Building upon the medicinal successes of cisplatin, carboplatin and oxaliplatin (see Box 22.8), development of Au(III)-containing anti-cancer agents is now an active area of research. Most of these complexes contain chelating cyclometallated ligands, ligands with *N*-donors or dithiocarbamates. Cyclo-metallated Au(III) complexes have the advantage of being stable with respect to reduction to Au(I) by glutathione or ascorbic acid present in cells. Examples of cyclometallated Au(III) complexes include the following:

$$[AuCl_4]^- + 2R_2S + H_2O \longrightarrow [R_2SAuCl] + R_2SO + 2H^+ + 3Cl^- \qquad (22.160)$$

Molecules of R_3PAuCl and R_2SAuCl (for which many examples with different R groups are known) contain linear Au(I), but aggregation in the solid state by virtue of Au····Au interactions (similar to those in Fig. 22.34a) is often observed. Other than the expectation of a linear Au(I) environment, structures may be hard to predict. For example in $[Au_2(CS_3)_2]^{2-}$ (made from $[Au(SH)_2]^-$ and CS_2), there is a short Au–Au contact, but in $[Au_2(TeS_3)_2]^{2-}$ (made from AuCN and $[TeS_3]^{2-}$), the Au(I) centres are out of bonding range (Figs. 22.34c, d).

Gold(−I) and silver(−I)

Relativistic effects (see Box 13.3) have a profound influence on the ability of gold to exist in the −1 oxidation state.[†] The enthalpy of attachment of the first electron to Au (eq. 22.161) is –223 kJ mol^{-1}, a value that lies between those for iodine (–295 kJ mol^{-1}) and sulfur (–201 kJ mol^{-1}).

$$Au(g) + e^- \longrightarrow Au(g) \qquad (22.161)$$

The choice of metal for the reduction of Au to Au^- is Cs, the latter having the lowest first ionization energy of any element. Caesium also reduces Pt (see the end of Section 22.11). Caesium auride, CsAu, can be formed from the elements at 490 K. It adopts a CsCl structure (see Fig. 6.19) and is a semiconductor with a band gap of 2.6 eV. Golden-brown CsAu dissolves in liquid NH_3 to give yellow solutions from which a blue ammoniate $CsAu{\cdot}NH_3$ can be crystallized. The Cs^+ ion in CsAu can be exchanged for $[Me_4N]^+$ using an ion-exchange resin. Crystalline $[Me_4N]^+Au^-$ is isostructural with $[Me_4N]^+Br^-$.

Although the argentide anion, Ag^-, has not yet been isolated in a crystalline compound, spectroscopic and electrochemical data have provided evidence for its formation in liquid NH_3.

22.13 Group 12: cadmium and mercury

The metals

Cadmium is chemically very like Zn, and any differences are attributable to the larger sizes of the Cd atom and Cd^{2+} ion versus Zn. Among the group 12 metals, Hg is distinct. It bears some resemblance to Cd, but in many respects is very like Au and Tl. It has been suggested that the relative inertness of Hg towards oxidation is a manifestation of the thermodynamic 6*s* inert pair effect (see Box 13.4).

Cadmium is a reactive metal and dissolves in non-oxidizing and oxidizing acids, but unlike Zn, it does not dissolve in aqueous alkali. In moist air, Cd slowly oxidizes, and when heated in air, it forms CdO. When heated, Cd reacts with the halogens and sulfur.

Mercury is less reactive than Zn and Cd. It is attacked by oxidizing (but not non-oxidizing) acids, with products dependent on conditions, e.g. with dilute HNO_3, Hg forms $Hg_2(NO_3)_2$ (containing $[Hg_2]^{2+}$, see below) but with concentrated HNO_3, the product is $Hg(NO_3)_2$. Reaction of the metal with hot concentrated H_2SO_4 gives $HgSO_4$ and SO_2. Mercury reacts with the halogens (eqs. 22.162 and 22.163). It combines with O_2 at 570 K to give HgO, but at higher temperatures HgO decomposes back to the elements, and, if sulfur is present, HgS is produced rather than the oxide.

$$Hg + X_2 \xrightarrow{\Delta} HgX_2 \qquad (X = F, Cl, Br) \qquad (22.162)$$

$$3Hg + 2I_2 \xrightarrow{\Delta} HgI_2 + Hg_2I_2 \qquad (22.163)$$

Mercury dissolves many metals to give *amalgams* (see Box 22.2). In the Na–Hg system, for example, Na_3Hg_2, NaHg and $NaHg_2$ have been characterized. Solid Na_3Hg_2 contains square $[Hg_4]^{6-}$ units (Hg–Hg = 298 pm), the structure and stability of which have been rationalized in terms of aromatic character.

For cadmium, the +2 oxidation state is of most importance, but compounds of Hg(I) and Hg(II) are both well known. Mercury is unique among the group 12 metals in forming a stable $[M_2]^{2+}$ ion. There is evidence for $[Zn_2]^{2+}$ and $[Cd_2]^{2+}$ in metal–metal halide melts, and $Cd_2[AlCl_4]$ has been isolated from a molten mixture of Cd, $CdCl_2$ and $AlCl_3$. However, it is not possible to obtain $[Zn_2]^{2+}$ and $[Cd_2]^{2+}$ in aqueous solution. Species which formally contain Zn_2^{2+} cores are known (see 'Zinc(I)' in Section 21.13). Force constants (60, 110 and 250 N m^{-1} for M = Zn, Cd and Hg calculated from Raman spectra of $[M_2]^{2+}$) show that the bond in $[Hg_2]^{2+}$ is stronger than those in $[Zn_2]^{2+}$ and $[Cd_2]^{2+}$. However, given that Hg has the lowest value of Δ_aH^o of all the *d*-block metals (Table 6.2), the stability of $[Hg_2]^{2+}$ (**22.89**) is difficult to rationalize. Other polycations of mercury are known; $[Hg_3]^{2+}$ (**22.90**) is formed as the $[AlCl_4]^-$ salt in molten Hg, $HgCl_2$ and $AlCl_3$, and $[Hg_4]^{2+}$ (**22.91**) is produced as the $[AsF_6]^-$ salt from reaction of Hg with AsF_5 in liquid SO_2.

$$\left[\,Hg\text{—}Hg\,\right]^{2+} \qquad \left[\,Hg\text{—}Hg\text{—}Hg\,\right]^{2+}$$

[†] For relevant discussions of relativistic effects, see footnote references on p. 858.

Table 22.4 Selected physical data for the group 12 metals.

Quantity	Zn	Cd	Hg
IE_1 / kJ mol^{-1}	906.4	867.8	1007
IE_2 / kJ mol^{-1}	1733	1631	1810
$\Delta_a H^o$(298 K) / kJ mol^{-1}	130	112	61
E^o (M^{2+}/M) / V	−0.76	−0.40	+0.85
r_{ion} for M^{2+} / pm†	74	95	101

† For Hg, the value is based on the structure of HgF_2, one of the few mercury compounds with a typical ionic lattice.

(22.91)

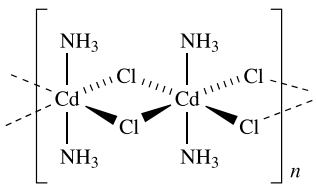
Ionization energies decrease from Zn to Cd but increase from Cd to Hg (Table 22.4). Whatever the origin of the high ionization energies for Hg, it is clear that they far outweigh the small change in $\Delta_a H^o$ and make Hg a noble metal. The reduction potentials in Table 22.4 reveal the relative electropositivities of the group 12 metals.

Since much of the chemistries of Cd and Hg are distinct, we deal with the two metals separately. In making this decision, we are effectively saying that the consequences of the lanthanoid contraction are of minor significance for the heavier metals of the last group of the *d*-block.

Cadmium(II)

All four Cd(II) halides are known. The action of HF on $CdCO_3$ gives CdF_2, and of gaseous HCl on Cd (720 K) yields $CdCl_2$. $CdBr_2$ and CdI_2 are formed by direct combination of the elements. White CdF_2 adopts a CaF_2 structure (Fig. 6.21), while $CdCl_2$ (white), $CdBr_2$ (pale yellow) and CdI_2 (white) have layer structures (see Section 6.11). The fluoride is sparingly soluble in water, while the other halides are readily soluble, giving solutions containing aquated Cd^{2+} and a range of halido complexes, e.g. CdI_2 dissolves to give an equilibrium mixture of $[Cd(OH_2)_6]^{2+}$, $[Cd(OH_2)_5I]^+$, $[CdI_3]^-$ and $[CdI_4]^{2-}$, while 0.5 M aqueous $CdBr_2$ contains $[Cd(OH_2)_6]^{2+}$, $[Cd(OH_2)_5Br]^+$, $[Cd(OH_2)_5Br_2]$, $[CdBr_3]^-$ and $[CdBr_4]^{2-}$. In contrast to Zn^{2+}, the stability of halido complexes of Cd^{2+} increases from F^- to I^-, i.e. Cd^{2+} is a softer metal centre than Zn^{2+} (Table 7.10).

Cadmium(II) oxide (formed by heating Cd in O_2, and varying in colour from green to black) adopts an NaCl structure. It is insoluble in H_2O and alkalis, but dissolves in acids, i.e. CdO is more basic than ZnO. Addition of dilute alkali to aqueous solutions of Cd^{2+} precipitates white $Cd(OH)_2$, and this dissolves only in *concentrated* alkali to give $[Cd(OH)_4]^{2-}$ (contrast $[Zn(OH)_4]^{2-}$, **21.77**). Equation 22.5 showed the role of $Cd(OH)_2$ in NiCd cells. Yellow CdS (the stable α-form has a wurtzite structure, Fig. 6.23) is commercially important as a pigment and phosphor. CdSe and CdTe are semiconductors (see Section 22.2).



In aqueous solutions, $[Cd(OH_2)_6]^{2+}$ is present and is weakly acidic (eq. 22.164); in concentrated solutions, aquated $[Cd_2(OH)]^{3+}$ is present.

$$[Cd(OH_2)_6]^{2+} + H_2O \rightleftharpoons [Cd(OH_2)_5(OH)]^+ + H^+ \qquad pK_a \approx 9 \qquad (22.164)$$

In aqueous NH_3, tetrahedral $[Cd(NH_3)_4]^{2+}$ is present, but at high concentrations, $[Cd(NH_3)_6]^{2+}$ forms. The lack of LFSE for Cd^{2+} (d^{10}) means that a range of coordination geometries is observed. Coordination numbers of 4, 5 and 6 are most common, but higher coordination numbers can be forced upon the metal centre by using macrocyclic ligands. Examples of complexes include:

- tetrahedral: $[CdCl_4]^{2-}$, $[Cd(NH_3)_4]^{2+}$, $[Cd(en)_2]^{2+}$;
- trigonal bipyramidal: $[CdCl_5]^{3-}$;
- octahedral: $[Cd(DMSO\text{-}O)_6]^{2+}$, $[Cd(en)_3]^{2+}$, $[Cd(acac)_3]^-$, $[CdCl_6]^{4-}$;
- hexagonal bipyramidal: $[CdBr_2$(18-crown-6] (see Section 11.8).

As we have seen previously, formulae can be deceptive in terms of structure, e.g. $[Cd(NH_3)_2Cl_2]$ is polymeric with octahedral Cd^{2+} and bridging chlorido ligands (**22.92**).

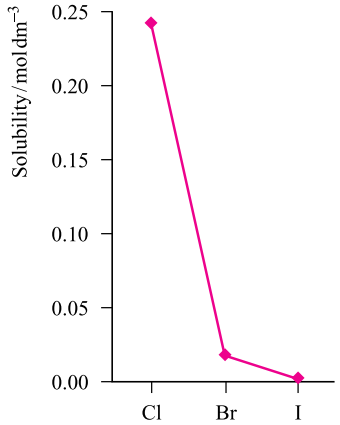
(22.92)

Mercury(II)

All four Hg(II) halides can be prepared from the elements. A fluorite structure (Fig. 6.21) is adopted by HgF_2 (Hg−F = 225 pm). It is completely hydrolysed by H_2O (eq. 22.165).

$$HgF_2 + H_2O \longrightarrow HgO + 2HF \qquad (22.165)$$

The chloride and bromide are volatile solids, soluble in H_2O (in which they are un-ionized), EtOH and Et_2O. The solids contain HgX_2 units packed to give distorted octahedral Hg(II) centres (two long Hg−X contacts to adjacent molecules). Below 400 K, HgI_2 is red with a layer structure, and above 400 K is yellow with HgI_2 molecules assembled into a lattice with distorted octahedral metal centres. The vapours contain linear HgX_2 molecules with bond distances of 225, 244 and 261 pm for X = Cl, Br and I respectively.



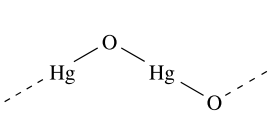


Fig. 22.35. The trend in solubilities of Hg(II) halides in water; HgF_2 decomposes.

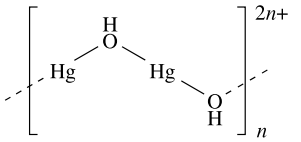
Figure 22.35 shows the trend in solubilities of the halides; for HgI_2, $K_{sp} = 2.82 \times 10^{-29}$.

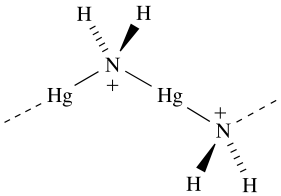


Mercury(II) oxide exists in both a yellow form (formed by heating Hg in O_2 or by thermal decomposition of $Hg(NO_3)_2$) and a red form (prepared by precipitation from alkaline solutions of Hg^{2+}). Both have infinite chain structures (**22.93**) with linear Hg(II). The thermal decomposition of HgO (eq. 22.166) led to the discovery of O_2 by Priestley in 1774.

$$2HgO \xrightarrow{>670\,K} 2Hg + O_2 \qquad (22.166)$$

Although the oxide dissolves in acids, it is only weakly basic. In aqueous solution, Hg(II) salts that are ionized (e.g. $Hg(NO_3)_2$ and $HgSO_4$) are hydrolysed to a considerable extent and many basic salts are formed, e.g. $HgO{\cdot}HgCl_2$ and $[O(HgCl)_3]Cl$ (a substituted oxonium salt). Solid $Hg(OH)_2$ is unknown. However, $[Hg(OH)][NO_3]{\cdot}H_2O$ (hydrated 'basic mercury(II) nitrate') can be isolated. In the solid state, this contains zigzag chains (**22.94**) to which H_2O molecules are loosely connected.

(22.93)

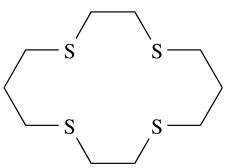


(22.94)

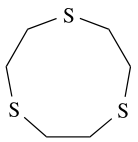
In its complexes, Hg(II) (d^{10}) exhibits coordination numbers of 2 to 6. Like Cd^{2+}, Hg^{2+} is a soft metal centre (see Table 7.9 and discussion) and coordination to *S*-donors is especially favoured. Complex chlorides, bromides and iodides are formed in aqueous solution, and the tetrahedral $[HgI_4]^{2-}$ is particularly stable. A solution of $K_2[HgI_4]$ (*Nessler's reagent*) gives a characteristic brown compound, $[Hg_2N]^+I^-$, on treatment with NH_3 and may be used in determination of NH_3. In solid $[Hg_2N]I$, the $[Hg_2N]^+$ cations assemble into an infinite network related to that of β-cristobalite (Fig. 6.22c) and containing linear Hg(II). Reaction 22.167 shows the formation of its hydroxide.

$$2HgO + NH_3 \xrightarrow{aq} Hg_2N(OH) + H_2O \qquad (22.167)$$

The salt $[Hg(NH_3)_2]Cl_2$ (eq. 22.168) contains linear $[Hg(NH_3)_2]^{2+}$ ions and dissolves in aqueous NH_3 to give $[Hg(NH_2)]Cl$ which contains polymeric chains (**22.95**).



$$HgCl_2 + 2NH_3(g) \longrightarrow [Hg(NH_3)_2]Cl_2 \qquad (22.168)$$



(22.95)

Examples of Hg(II) complexes illustrating different coordination environments (see Table 7.8 for ligand abbreviations) include:

- linear: $[Hg(NH_3)_2]^{2+}$, $[Hg(CN)_2]$, $[Hg(py)_2]^{2+}$, $[Hg(SEt)_2]$, $[Hg(SePh)_2]$ (Fig. 22.36a);
- trigonal planar: $[HgI_3]^-$ (Fig. 22.36b);
- tetrahedral: $[Hg(py)_2Br_2]$ (Fig. 22.36c), $[Hg(en)_2]^{2+}$, $[Hg(NCS\text{-}S)_4]^{2-}$, $[HgI_4]^{2-}$, $[Hg(S_4\text{-}S,S')_2]^{2-}$, $[Hg(Se_4\text{-}Se,Se')_2]^{2-}$, $[Hg(phen)_2]^{2+}$;
- trigonal bipyramidal: $[HgCl_2(tpy)]$, $[HgCl_2(dien)]$, $[HgCl_5]^{3-}$ (Fig. 22.36d);
- square-based pyramidal: $[Hg(OH_2)L]^{2+}$ (L = **22.96**);
- octahedral: $[Hg(en)_3]^{2+}$, *fac*-$[HgL_2]^{2+}$ (L = **22.97**) (Fig. 22.36e);
- square antiprism: $[Hg(NO_2\text{-}O,O')_4]^{2-}$.

(22.96)

(22.97)

Mercury(I)

The chemistry of Hg(I) is that of the $[Hg_2]^{2+}$ unit which contains an Hg–Hg single bond (**22.89**). The general method of preparation of Hg(I) compounds is by the action of Hg metal on Hg(II) compounds, e.g. reaction 22.169 in which Hg_2Cl_2 (*calomel*) is freed from $HgCl_2$ by washing with hot water. The *standard calomel electrode* (see Box 8.3) is a reference electrode (eq. 22.170) consisting of a Pt wire dipping into

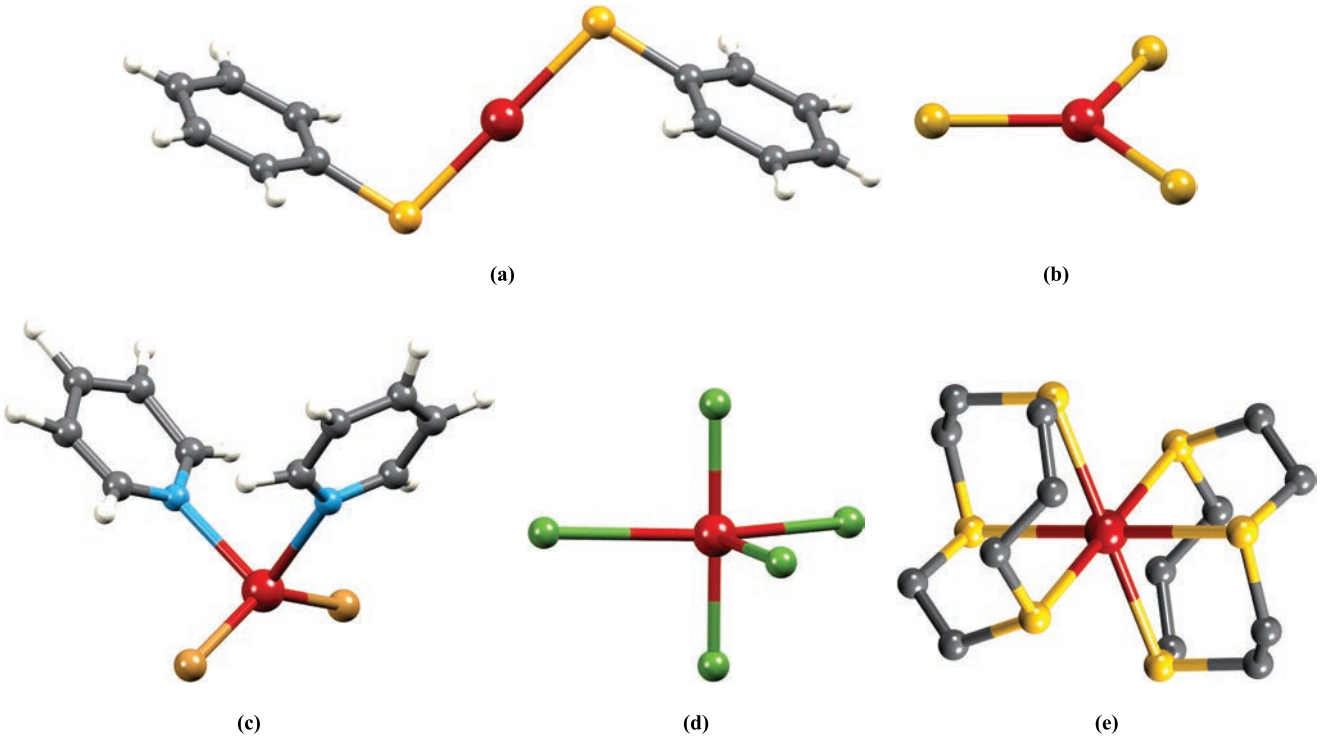


Fig. 22.36. Crystallographically determined structures of mercury(II) compounds showing linear, trigonal planar, tetrahedral, trigonal bipyramidal and octahedral coordination. (a) $[Hg(SePh)_2]$ [T.J. Emge *et al.* (2010) *Inorg. Chem.*, vol. 49, p. 7304]. (b) The $[HgI_3]^-$ ion in $[^nBu_4N][HgI_3]$ [P.L. Goggin *et al.* (1982) *J. Chem. Soc., Dalton Trans.*, p. 875]. (c) $[Hg(py)_2Br_2]$ [A.J. Canty *et al.* (1982) *J. Chem. Soc., Dalton Trans.*, p. 15]. (d) The $[HgCl_5]^{3-}$ ion in $[H_3NCH_2CH_2NH_2CH_2CH_2NH_3]_2[HgCl_5]Cl_3$ [L.P. Battaglia *et al.* (1986) *J. Chem. Soc., Dalton Trans.*, p. 2529]; the equatorial Hg−Cl bonds are significantly longer (303 pm) than the axial bonds (238 pm). (e) The *fac*-$[HgL_2]^{2+}$ ion (L = **22.97**) in $[HgL_2][PF_6]_2$ with H atoms omitted [M.L. Helm *et al.* (2003) *J. Chem. Cryst.*, vol. 33, p. 625]. Colour code: Hg, red; Se, yellow; Cl, green; I, bronze; Br, brown; N, blue; C, grey; H, white.

Hg in contact with Hg_2Cl_2 and immersed in 1 M KCl solution. This electrode is more convenient to use than the standard hydrogen electrode which requires a source of purified gas.

$$HgCl_2 + Hg \xrightarrow{\Delta} Hg_2Cl_2 \qquad (22.169)$$

$$Hg_2Cl_2 + 2e^- \rightleftharpoons 2Hg + 2Cl^- \qquad E^\circ = +0.268\,V \text{ (in 1 M aq KCl)} \qquad (22.170)$$

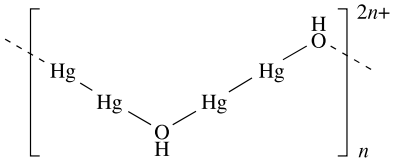
Potential diagrams for Hg are shown in scheme 22.171, and the data in acidic solution illustrate that the disproportionation of Hg(I) (eq. 22.172) has a small and positive ΔG° value at 298 K.

$$\begin{array}{ccccc} Hg^{2+} & \xrightarrow{+0.91} & [Hg_2]^{2+} & \xrightarrow{+0.77} & Hg \quad pH = 0 \\ & & \underset{+0.84}{\longrightarrow} & & \uparrow \\ HgO & \xrightarrow{+0.10} & Hg & & pH = 14 \end{array} \qquad (22.171)$$

$$[Hg_2]^{2+} \rightleftharpoons Hg^{2+} + Hg \quad K = 4.3 \times 10^{-3}\,(298\,K) \qquad (22.172)$$

Reagents that form insoluble Hg(II) salts or stable Hg(II) complexes upset equilibrium 22.172 and decompose Hg(I) salts, e.g. addition of $[OH]^-$, S^{2-} or $[CN]^-$ results in formation of Hg and HgO, HgS or $[Hg(CN)_4]^{2-}$. The Hg(I) compounds Hg_2O, Hg_2S and $Hg_2(CN)_2$ are not known. Mercury(II) forms more stable complexes than the larger $[Hg_2]^{2+}$ and relatively few Hg(I) compounds are known. The most important are the halides (**22.98**).† Whereas Hg_2F_2 decomposes to Hg, HgO and HF on contact with water, the later halides are sparingly soluble.

X—Hg—Hg—X



X	Hg–Hg / pm
F	251
Cl	252
Br	258
I	269

(22.98)

† Theoretical data cast doubt on the reliability of the Hg−Hg bond lengths for X = Br and I; see: M.S. Liao and W.H.E. Schwarz (1997) *J. Alloy. Compd.*, vol. 246, p. 124.

Basic mercury(I) has been stabilized in the salt $[Hg_2(OH)][BF_4]$, made by reaction 22.173. In the solid state, zigzag chains (**22.99**) are connected together through weak Hg---O interactions to form layers, with $[BF_4]^-$ ions occupying the spaces between adjacent layers.

$$HgO + Hg + HBF_4 \xrightarrow{H_2O} [Hg_2(OH)][BF_4] \qquad (22.173)$$

Hg–Hg = 250 pm

(22.99)

Other Hg(I) salts include $Hg_2(NO_3)_2$, Hg_2SO_4 and $Hg_2(ClO_4)_2$. The nitrate is commercially available as the dihydrate, the solid state structure of which contains $[(H_2O)HgHg(OH_2)]^{2+}$ cations. Scheme 22.174 summarizes some reactions of hydrated $Hg_2(NO_3)_2$.

$$Hg_2(NO_3)_2 \begin{cases} \xrightarrow{KSCN} Hg_2(SCN)_2 \xrightarrow{\text{decomp.}} Hg(SCN)_2 + Hg \\ \xrightarrow{NaN_3} Hg_2(N_3)_2 \text{ (explosive)} \\ \xrightarrow{H_2SO_4} Hg_2SO_4 \end{cases} \qquad (22.174)$$

Crystalline, anhydrous $Hg_2(NO_3)_2$ can be prepared by drying $Hg_2(NO_3)_2 \cdot 2H_2O$ over concentrated H_2SO_4.

PROBLEMS

22.1 (a) Write out the first row *d*-block metals in sequence and then complete each triad of metals. (b) Between which two metals is the series of lanthanoid metals?

22.2 Briefly discuss trends in (a) metallic radii and (b) values of $\Delta_a H^\circ(298\,K)$ for the *d*-block metals.

22.3 (a) Estimate the value of $\Delta_f H^\circ(WCl_2)$ assuming it to be an ionic compound. Comment on any assumptions made. [Data needed in addition to those in Tables 21.1, 22.1 and the Appendices: $\Delta_f H^\circ(CrCl_2) = -397\,kJ\,mol^{-1}$.] (b) What does your answer to (a) tell you about the likelihood of WCl_2 being ionic?

22.4 Comment on the following observations:
(a) The density of HfO_2 ($9.68\,g\,cm^{-3}$) is much greater than that of ZrO_2 ($5.73\,g\,cm^{-3}$).
(b) NbF_4 is paramagnetic but $NbCl_4$ and $NbBr_4$ are essentially diamagnetic.

22.5 Suggest products in the following reactions: (a) CsBr heated with $NbBr_5$ at 383 K; (b) KF and TaF_5 melted together; (c) NbF_5 with bpy at 298 K. (d) Comment on the structures of the group 5 metal halides in the starting materials and give possible structures for the products.

22.6 TaS_2 crystallizes with a layer structure related to that of CdI_2, whereas FeS_2 adopts a distorted NaCl structure. Why would you not expect TaS_2 and FeS_2 to crystallize with similar structure types?

22.7 Comment on the observation that $K_3[Cr_2Cl_9]$ is strongly paramagnetic but $K_3[W_2Cl_9]$ is diamagnetic.

22.8 (a) Interpret the formula $[Mo_6Cl_8]Cl_2Cl_{4/2}$ in structural terms, and show that the formula is consistent with the stoichiometry $MoCl_2$. (b) Show that the $[W_6Br_8]^{4+}$ cluster can be considered to contain W–W single bonds.

22.9 Give a short account of Tc(V) and Re(V) oxido species.

22.10 Briefly summarize similarities and differences between Mn and Tc chemistries.

22.11 Draw the structure of $[Re_2Cl_8]^{2-}$. Discuss the metal–metal bonding in the anion and its consequences on ligand orientation.

22.12 Suggest reasons for the variation in Re–Re bond lengths in the following species: $ReCl_4$ (273 pm), Re_3Cl_9 (249 pm), $[Re_2Cl_8]^{2-}$ (224 pm), $[Re_2Cl_9]^-$ (270 pm) and $[Re_2Cl_4(\mu\text{-}Ph_2PCH_2CH_2PPh_2)_2]$ (224 pm).

22.13 When $K_2[OsCl_4]$ is heated with NH_3 under pressure, compound **A** of composition $Os_2Cl_5H_{24}N_9$ is isolated. Treatment of a solution of **A** with HI precipitates a compound in which three of the five chlorines have been replaced by iodine. Treating 1 mmol of **A** with KOH releases 9 mmol NH_3. Compound **A** is diamagnetic and none of the stronger absorption bands in the IR spectrum is Raman active. Suggest a structure for **A** and account for the diamagnetism.

22.14 Give an account of the halides of Ru and Os.

22.15 (a) Give an account of the methods of synthesis of Rh(IV) and Ir(IV) halides and halido anions. (b) Reaction of $[IrCl_6]^{2-}$ with PPh_3 and $Na[BH_4]$ in EtOH gives $[IrH_3(PPh_3)_3]$. Give the structures of the isomers of this complex and suggest how you would distinguish between them using NMR spectroscopy.

22.16 $[Ir(CN)_6]^{3-}$ has a regular octahedral structure. For $K_3[Ir(CN)_6]$, the wavenumbers corresponding to the C≡N stretching modes are 2167 (A_{1g}), 2143 (E_g) and 2130 (T_{1u}) cm^{-1}. (a) To which point group does $[Ir(CN)_6]^{3-}$ belong? (b) What would you observe in the IR spectrum of $K_3[Ir(CN)_6]$ in the region between 2200 and 2000 cm^{-1}?

22.17 When $RhBr_3$ in the presence of $MePh_2As$ is treated with H_3PO_2, a monomeric compound **X** is formed. **X** contains 2 Br and 3 $MePh_2As$ per Rh, and is a non-electrolyte. Its IR spectrum has a band at $2073\,cm^{-1}$, and the corresponding band if the complex is made using D_3PO_2 in a deuterated solvent is $1483\,cm^{-1}$. Spectrophotometric titration of **X** with Br_2 shows that one molecule of **X** reacts with one molecule of Br_2; treating the product with excess mineral acid regenerates $RhBr_3$. What can you conclude about the products?

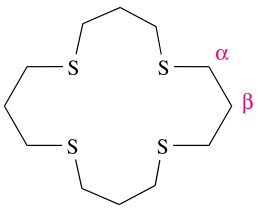
22.18 (a) Compare the structures of β-$PdCl_2$ and $[Nb_6Cl_{12}]^{2+}$. (b) Discuss, with examples, the existence (or not) of Pt(III) species. (c) Discuss the variation in stereochemistries of Ni(II), Pd(II) and Pt(II) complexes.

22.19 (a) Describe the methods by which *cis*- and *trans*-$[PtCl_2(NH_3)_2]$ can be distinguished from each other and from $[Pt(NH_3)_4][PtCl_4]$. (b) Another possible isomer would be $[(H_3N)_2Pt(\mu\text{-}Cl)_2Pt(NH_3)_2]Cl_2$. What diagnostic data would enable you to rule out its formation?

22.20 Suggest products in the reactions of $K_2[PtCl_4]$ with (a) excess KI; (b) aqueous NH_3; (c) phen; (d) tpy;

(e) excess KCN. What are the expected structures of these products?

22.21 Complexes of the type $[PtCl_2(R_2P(CH_2)_nPR_2)]$ may be monomeric or dimeric. Suggest factors that might influence this preference and suggest structures for the complexes.



22.22 Comment on each of the following observations:
(a) Unlike $[Pt(NH_3)_4][PtCl_4]$, $[Pt(EtNH_2)_4][PtCl_4]$ has an electronic absorption spectrum that is the sum of those of the constituent ions.
(b) AgI is readily soluble in saturated aqueous $AgNO_3$, but AgCl is not.
(c) When $Hg(ClO_4)_2$ is shaken with liquid Hg, the ratio [Hg(I)]/[Hg(II)] in the resulting solution is independent of the value of [Hg(II)].

22.23 Discuss the variation in stable oxidation states for the group 11 metals, using examples of metal halides, oxides and complexes to illustrate your answer.

22.24 'The group 12 metals differ significantly from the *d*-block metals in groups 4–11'. Discuss this statement.

22.25 The ligand shown at the end of the problem, 16-S-4, forms the complex $[Hg(16\text{-S-}4)]^{2+}$. The solution ^{1}H NMR spectrum of $[Hg(16\text{-S-}4)][ClO_4]_2$ consists of two signals at δ 3.40 and 2.46 ppm with relative integrals of 2:1. From the spectrum, the following coupling constants can be measured: $J_{^1H^1H}$ = 6.0 Hz, $J_{^1H(\alpha)^{199}Hg}$ = 93.6 Hz. [Data: ^{199}Hg: $I = \frac{1}{2}$, 16.6%]

(a) Explain why complex formation between Hg(II) and *S*-donor ligands is particularly favoured.
(b) What coordination number do you expect for the Hg(II) centre in $[Hg(16\text{-S-}4)]^{2+}$? On what basis have you made your choice?
(c) Sketch the ^{1}H NMR spectrum of $[Hg(16\text{-S-}4)][ClO_4]_2$.

22.26 Studies of the heavier *d*-block metals are often used to introduce students to (a) metal–metal bonding, (b) high coordination numbers, (c) metal halido clusters and (d) polyoxometallates. Write an account of each topic, and include examples that illustrate why the first row metals are not generally as relevant as their heavier congeners for discussing these topics.

OVERVIEW PROBLEMS

22.27 (a) The reaction of $ReCl_4$ and PCl_5 at 570 K under vacuum gives $[PCl_4]_2[Re_2Cl_{10}]$. However, when $ReCl_5$ reacts with an excess of PCl_5 at 520 K, the products are $[PCl_4]_3[ReCl_6]_2$ and Cl_2. Comment on the nature of $[PCl_4]_3[ReCl_6]_2$ and write equations for both reactions, paying attention to the oxidation states of P and Re.
(b) The ^{19}F NMR spectrum of $[Me_4N][fac\text{-}OsO_3F_3]$ exhibits one signal with satellites (J = 32 Hz). What is the origin of the satellite peaks? Sketch the spectrum and indicate clearly the nature of the coupling pattern. Show where J is measured.

22.28 (a) 'The salt $[NH_4]_3[ZrF_7]$ contains discrete ions with 7-coordinate Zr(IV). On the other hand, in a compound formulated as $[NH_4]_3[HfF_7]$, Hf(IV) is octahedral'. Comment on this statement and suggest possible structures for $[ZrF_7]^{3-}$.
(b) ^{93}Nb NMR spectroscopy has provided evidence for halide exchange when $NbCl_5$ and $NbBr_5$ are dissolved in MeCN. What would be the basis for such evidence?

22.29 (a) Figure 22.37 shows eight corner-sharing ReO_6 octahedra in the solid state structure of ReO_3. From this, derive a diagram to show the unit cell of ReO_3. Explain the relationship between your diagram and that in Fig. 21.5, and confirm the stoichiometry of the oxide from the unit cell diagram.

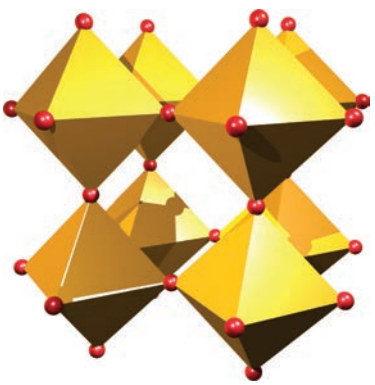


Fig. 22.37 Figure for problem 22.29a.

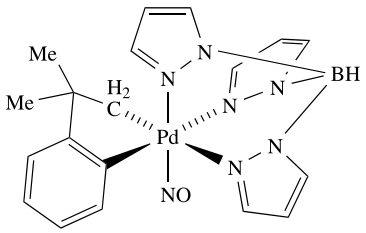


(b) A qualitative test for $[PO_4]^{3-}$ is to add an excess of an acidified aqueous solution of ammonium molybdate to an aqueous solution of the phosphate. A yellow precipitate forms. Suggest a possible identity for the precipitate and write an equation for its formation.

22.30 (a) Rationalize why each of the following is diamagnetic: $[Os(CN)_6]^{4-}$, $[PtCl_4]^{2-}$, OsO_4 and *trans*-$[OsO_2F_4]^{2-}$.

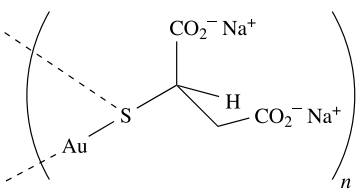
(b) Solution ^{77}Se and ^{13}C NMR spectra for the octahedral anions in the compounds $[Bu_4N]_3[Rh(SeCN)_6]$ and $[Bu_4N]_3$[*trans*-$Rh(CN)_2(SeCN)_4$] are tabulated below. Assign the spectra and explain the origin of the observed coupling patterns. [Additional data: see Table 4.3]

Anion	δ ^{77}Se ppm	δ ^{13}C ppm
$[Rh(SeCN)_6]^{3-}$	−32.7 (doublet, $J = 44$ Hz)	111.2 (singlet)
[*trans*-$Rh(CN)_2(SeCN)_4]^{3-}$	−110.7 (doublet, $J = 36$ Hz)	111.4 (singlet) 136.3 (doublet, $J = 36$ Hz)

22.31 (a) The complex shown below is the first example of a Pd(IV) complex containing a nitrosyl ligand (see also structure **20.9** for another view of the tridentate ligand). On the basis of the assignment of an oxidation state of +4 for Pd, what formal charge does the nitrosyl ligand carry? In view of your answer, comment on the fact that structural and spectroscopic data for the complex include the following parameters: —Pd–N–O = 118°, N–O = 115 pm, $\bar{\nu}$(NO) = 1650 cm^{-1} (a strong absorption).

(b) The reaction of equimolar equivalents of $[Bu_4N]_2[C_2O_4]$ with [*cis*-$Mo_2(\mu\text{-}L)_2(MeCN)_4][BF_4]_2$ where L^- is a formamidine ligand closely related to **22.70** leads to a neutral compound **A** which is a so-called 'molecular square'. Bearing in mind the structure of $[C_2O_4]^{2-}$, suggest a structure for **A**. This compound might also be considered as a [4 + 4] assembly. What experimental techniques would be useful in distinguishing compound **A** from a possible [3 + 3] product?

INORGANIC CHEMISTRY MATTERS



22.32 Comment on the following statements in terms of the properties of the elements mentioned.

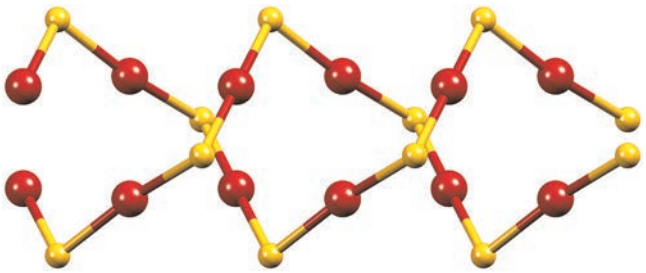
(a) For many decades, tungsten was used to make filaments in incandescent light bulbs. Tungsten is used in preference to copper even though the electrical resistivity of tungsten is greater than that of copper.

(b) Incandescent light bulbs are filled with a gas such as Ar or Xe.

(c) A halogen lamp contains a tungsten filament in a quartz bulb filled with halogen gas. The halogen is Br_2 or I_2, but not F_2 or Cl_2. The lifetime of the filament is prolonged with respect to that in an incandescent bulb.

22.33 Myochrysine contains the thiomalate ligand and is an anti-arthritic drug and has a polymeric structure in the solid state:

The backbone of the polymer is a helical chain of alternating Au and S atoms, and pairs of chains form double helices (Fig. 22.38). (a) Is the double



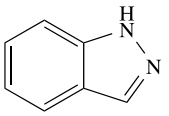


Fig. 22.38. Part of one double helix defined by the gold and sulfur atoms in the solid state structure of Myochrysine. [Data: R. Bau (1998) *J. Am. Chem. Soc.*, vol. 120, p. 9380.]

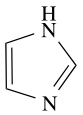
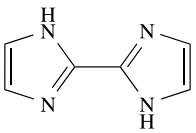


helix in Fig. 22.38 chiral? Rationalize your answer. (b) Why is the thiolate ligand chiral? (c) Starting with a racemic mixture of (*R*)- and (*S*)-thiomalate, two structurally distinct double helices are observed in the unit cell of Myochrysine. Explain why this is. (d) The shortest Au ··· Au contacts between the two chains in the double helix in Fig. 22.38 are 323 pm. Comment on the importance of such interactions in Au(I) chemistry. (e) Myochrysine is a prodrug. Explain what this means, and outline a possible means for uptake of Au(I) by the body.

22.34 (a) What is the fundamental difference between electrochromic, thermochromic and photochromic materials? (b) WO_3 is widely used in electrochromic materials. Explain why WO_3 is suited to this application. Give a brief description of how an electrochromic window based on WO_3 works. (c) Both WO_3- and IrO_2-based electrochromic glasses switch between colourless and dark blue. How do the ways in which the colour changes occur differ in the two glasses?



22.35 Two complexes that have entered clinical trials as anti-cancer drugs are [HIm][$RuCl_4$(im)(DMSO)] and [HInd][$RuCl_4(Ind)_2$]. In the search for related active complexes, [$RuCl_2(DMSO)_2$(Biim)] and [$RuCl_3$(DMSO)(Biim)] have been tested; the latter is more cytotoxic against selected human cancer cell lines than the former.

indazole (Ind)

imidazole (Im)

2,2'-biimidazole (Biim)

(a) What is the oxidation state of the ruthenium in each of the four complexes? (b) Suggest how each of the ligands Im, Ind and Biim coordinates to ruthenium. (c) Draw the structures of possible isomers of each complex.

Try also end-of-chapter problem 20.42: ruthenium(II) photosensitizers.

23 Organometallic compounds of *s*- and *p*-block elements

23.1 Introduction

This chapter provides an introduction to the large area of the organometallic chemistry of *s*- and *p*-block elements.

An ***organometallic*** compound contains one or more metal–carbon bonds.

Compounds containing M−C bonds where M is an *s*-block element are readily classified as being organometallic. However, when we come to the *p*-block, the trend from metallic to non-metallic character means that a discussion of strictly *organometallic* compounds would ignore compounds of the semi-metals and synthetically important organoboron compounds. For the purposes of this chapter, we have broadened the definition of an organometallic compound to include species with B−C, Si−C, Ge−C, As−C, Sb−C, Se−C or Te−C bonds. Compounds containing Xe–C bonds are covered in Chapter 18. Also relevant to this chapter is the earlier discussion of fullerenes (see Section 14.4). Quite often compounds containing, for example, Li−N or Si−N bonds are included in discussions of organometallics, but we have chosen to incorporate these in Chapters 11–15. We do not detail applications of main group organometallic compounds in organic synthesis. Abbreviations for the organic substituents mentioned in this chapter are defined in Appendix 2.

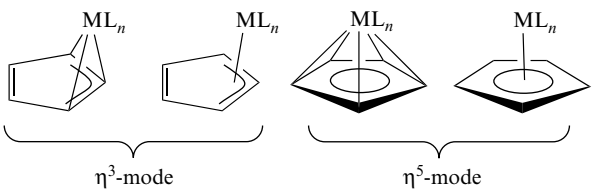
In organometallic compounds, ligands that bond to metal atoms in different ways are often encountered. These modes of coordination are distinguished by use of a prefix (η or κ) as detailed in Box 23.1.

23.2 Group 1: alkali metal organometallics

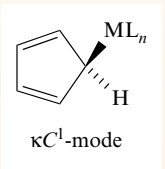
Organic compounds such as terminal alkynes (RC≡CH) which contain relatively acidic hydrogen atoms form salts with the alkali metals, e.g. reactions 23.1, 23.2 and 14.34.

$$2EtC{\equiv}CH + 2Na \longrightarrow 2Na^+[EtC{\equiv}C]^- + H_2 \qquad (23.1)$$

$$MeC{\equiv}CH + K[NH_2] \longrightarrow K^+[MeC{\equiv}C]^- + NH_3 \qquad (23.2)$$

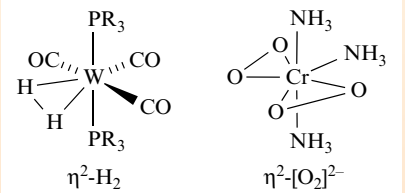


Similarly, in reaction 23.3, the acidic CH_2 group in cyclopentadiene can be deprotonated to prepare the cyclopentadienyl ligand which is synthetically important in organometallic chemistry (see also Chapter 24). Na[Cp] can also be made by direct reaction of Na with C_5H_6. Na[Cp] is pyrophoric in air, but its air-sensitivity can be lessened by complexing the Na^+ ion with 1,2-dimethoxyethane (dme). In the solid state, [Na(dme)][Cp] is polymeric (Fig. 23.1).

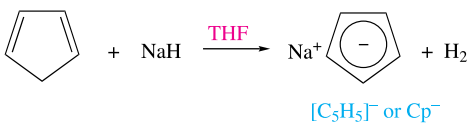


THEORY

Box 23.1 η-Nomenclature for ligands



In organometallic compounds in particular, use is made of the prefix η to give information about the mode of coordination of a ligand. The IUPAC recommends that this prefix is used only if the coordinating atoms of the ligand are directly bonded to one another. The prefix η (eta) describes the number of atoms which directly bond to the metal centre; this is the *hapticity* of the ligand. Consider the cyclopentadienyl ligand, $[C_5H_5]^-$ or Cp^-, which is versatile in its modes of bonding. The diagrams below show the η^3-mode (three adjacent C atoms bond to the metal M) and the η^5-mode (all five C atoms bond to the metal M) of the Cp^- ligand. Note the different ways in which you can represent each mode:



If the organic ligand bonds to the metal through only one atom, the κ nomenclature (see p. 242) should be used. Thus for a Cp^- ligand bonded to a metal centre through one C atom:

The η-terminology is also used for ligands such as dihydrogen and peroxido:

(23.3)

A ***pyrophoric*** material is one that burns spontaneously when exposed to air.

Colourless alkyl derivatives of Na and K may be obtained by *transmetallation* reactions starting from mercury dialkyls (eq. 23.4).

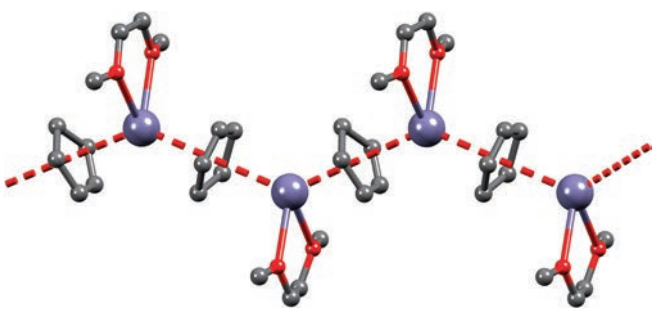


Fig. 23.1 Part of a chain that makes up the polymeric structure of [Na(dme)][Cp] (dme = 1,2-dimethoxyethane); the zigzag chain is emphasized by the hashed, red line. The structure was determined by X-ray diffraction [M.L. Coles *et al.* (2002) *J. Chem. Soc., Dalton Trans.*, p. 896]. Hydrogen atoms have been omitted for clarity; colour code: Na, purple; O, red; C, grey.

$$HgMe_2 + 2Na \longrightarrow 2NaMe + Hg \qquad (23.4)$$

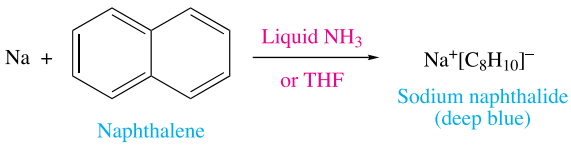
Organolithium compounds are of particular importance among the group 1 organometallics. They may be synthesized by treating an organic halide, RX, with Li (eq. 23.5) or by metallation reactions (eq. 23.6) using *n*-butyllithium which is commercially available as solutions in hydrocarbon (e.g. hexane) solvents.

$$^{n}BuCl + 2Li \xrightarrow{\text{hydrocarbon solvent}} {}^{n}BuLi + LiCl \qquad (23.5)$$

$$^{n}BuLi + C_6H_6 \longrightarrow {}^{n}BuH + C_6H_5Li \qquad (23.6)$$

Solvent choices for reactions involving organometallics of the alkali metals are critical. For example, ^{n}BuLi is decomposed by Et_2O to give ^{n}BuH, C_2H_4 and LiOEt. Organolithium, -sodium or -potassium reagents are considerably more reactive in solution in the presence of certain diamines (e.g. $Me_2NCH_2CH_2NMe_2$), and we return to this point later.

Alkali metal organometallics are extremely reactive and must be handled in air- and moisture-free environments; NaMe, for example, burns explosively in air.[†]



Lithium alkyls and aryls are more stable thermally than the corresponding compounds of the heavier group 1

[†] A useful source of reference is: D.F. Shriver and M.A. Drezdon (1986) *The Manipulation of Air-sensitive Compounds*, 2nd edn., Wiley, New York.

metals (though they ignite spontaneously in air) and mostly differ from them in being soluble in hydrocarbons and other non-polar organic solvents and in being liquids or solids of low melting points. Sodium and potassium alkyls are insoluble in most organic solvents and, when stable enough with respect to thermal decomposition, have fairly high melting points. In the corresponding benzyl and triphenylmethyl compounds, $Na^+[PhCH_2]^-$ and $Na^+[Ph_3C]^-$ (eq. 23.7), the negative charge in the organic anions can be delocalized over the aromatic systems, thus enhancing stability. The salts are red in colour.

$$NaH + Ph_3CH \longrightarrow Na^+[Ph_3C]^- + H_2 \qquad (23.7)$$

Sodium and potassium also form intensely coloured salts with many aromatic compounds (e.g. reaction 23.8). In reactions such as this, the oxidation of the alkali metal involves the transfer of one electron to the aromatic system producing a paramagnetic *radical anion*.

(23.8)

A ***radical anion*** is an anion that possesses an unpaired electron.

Lithium alkyls are polymeric both in solution and in the solid state. Table 23.1 illustrates the extent to which MeLi, ^{n}BuLi and ^{t}BuLi aggregate in solution. In an $(RLi)_4$ tetramer, the Li atoms form a tetrahedral unit, while in an $(RLi)_6$ hexamer, the Li atoms define an octahedron. Figures 23.2a and 23.2b show the structure of $(MeLi)_4$; the average Li–Li bond length is 261 pm compared with 267 pm in Li_2 (see Table 2.1). The bonding in lithium alkyls is the subject

Table 23.1 Degree of aggregation of selected lithium alkyls at room temperature (unless otherwise stated).

Compound	Solvent	Species present
MeLi	Hydrocarbons	$(MeLi)_6$
MeLi	Ethers	$(MeLi)_4$
^{n}BuLi	Hydrocarbons	$(^n BuLi)_6$
^{n}BuLi	Ethers	$(^n BuLi)_4$
^{n}BuLi	THF at low temperature	$(^n BuLi)_4 \rightleftharpoons 2(^n BuLi)_2$
^{t}BuLi	Hydrocarbons	$(^t BuLi)_4$
^{t}BuLi	Et_2O	Mainly solvated $(^t BuLi)_2$
^{t}BuLi	THF	Mainly solvated ^{t}BuLi

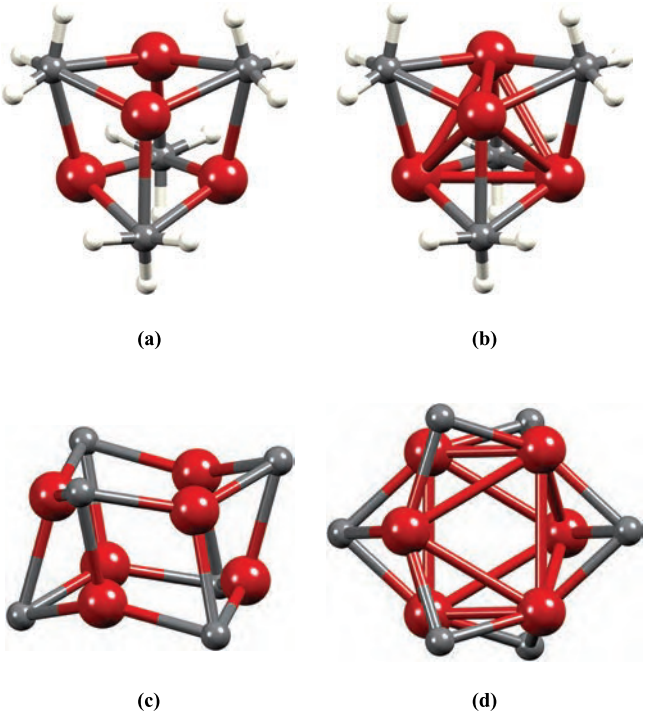


Fig. 23.2 (a) The structure of $(MeLi)_4$ (X-ray diffraction) for the perdeuterated compound [E. Weiss *et al.* (1990) *Chem. Ber.*, vol. 123, p. 79]; the Li atoms define a tetrahedral array while the Li_4C_4-unit forms a distorted cube. For clarity, the Li–Li interactions are not shown in (a) but diagram (b) shows these additional interactions. (c) The Li_6C_6-core of $(LiC_6H_{11})_6$ (X-ray diffraction) [R. Zerger *et al.* (1974) *J. Am. Chem. Soc.*, vol. 96, p. 6048]; the Li_6C_6-core can be considered as a distorted hexagonal prism with Li and C atoms at alternate corners. (d) An alternative view of the structure of the Li_6C_6-core of $(LiC_6H_{11})_6$ which also shows the Li–Li interactions (these were omitted from (c) for clarity); the Li atoms define an octahedral array. Colour code: Li, red; C, grey; H, white.

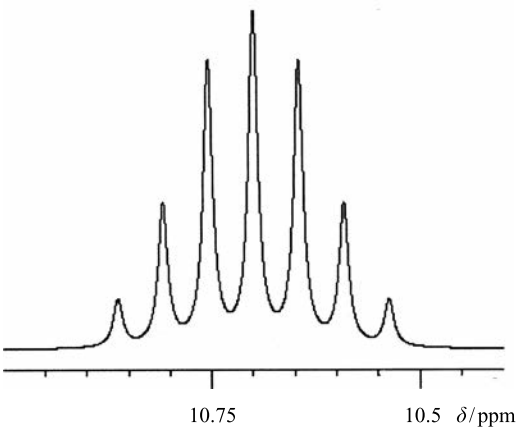
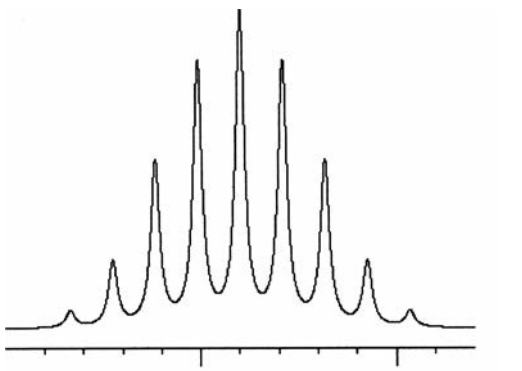


of end-of-chapter problem 23.2. Figures 23.2c and d show the structure of the Li_6C_6-core of $(LiC_6H_{11})_6$ (C_6H_{11} = *cyclohexyl*); six Li–Li bond distances lie in the range 295–298 pm, while the other six are significantly shorter (238–241 pm). The presence of such aggregates in solution can be determined by using multinuclear NMR spectroscopy. Lithium possesses two spin-active isotopes (see Section 4.8 and Table 11.1) and the solution structures of lithium alkyls can be studied using ^{6}Li, ^{7}Li and ^{13}C NMR spectroscopies as worked example 23.1 illustrates. The alkyls of Na, K, Rb and Cs crystallize with extended structures (e.g. KMe adopts the NiAs structure, Fig. 15.12) or are amorphous solids.

Worked example 23.1 NMR spectroscopy of $(^t BuLi)_4$



The structure of $(^t BuLi)_4$ is similar to that of $(MeLi)_4$ shown in Fig. 23.2a, but with each H atom replaced by a methyl group. The 75 MHz ^{13}C NMR spectrum of a

sample of $(^{t}BuLi)_4$, prepared from ^{6}Li metal, consists of two signals, one for the methyl carbons and one for the quaternary carbon atoms. The signal for the quaternary carbons is shown below: (a) at 185 K and (b) at 299 K. Explain how these signals arise.

[Data: for ^{6}Li, $I = 1$.]

(a)

(b)

First, note that the lithium present in the sample is ^{6}Li, and this is spin-active ($I = 1$). The multiplet nature of the signals arises from ^{13}C–^{6}Li spin–spin coupling.

Multiplicity of signal (number of lines) $= 2nI + 1$

Consider Fig. 23.2a with each H atom replaced by an Me group to give $(^{t}BuLi)_4$. The quaternary C atoms are those bonded to the Li centres, and, *in the static structure*, each ^{13}C nucleus can couple with *three* adjacent and equivalent ^{6}Li nuclei.

Multiplicity of signal $= (2 \times 3 \times 1) + 1 = 7$

This corresponds to the seven lines (a septet) observed in figure (a) for the low-temperature spectrum. Note that the pattern is *non-binomial*. At 299 K, a nonet is observed (non-binomial).

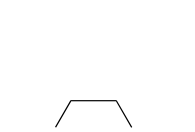
Multiplicity of signal $= (2 \times n \times 1) + 1 = 9$

$n = 4$

This means that the molecule is fluxional, and each quaternary ^{13}C nucleus 'sees' four equivalent ^{6}Li nuclei on the NMR spectroscopic timescale. We can conclude that at 185 K, the molecule possesses a static structure but as the temperature is raised to 299 K, sufficient energy becomes available to allow a fluxional process to occur which exchanges the ^{t}Bu groups.

For a full discussion, see: R.D. Thomas *et al.* (1986) *Organometallics*, vol. 5, p. 1851.

[For details of NMR spectroscopy: see Section 4.8. Case study 4 in this section is concerned with a non-binomial multiplet.]



Self-study exercises

1. From the data above, what would you expect to see in the ^{13}C NMR spectrum at 340 K?

   [*Ans.* Non-binomial nonet]

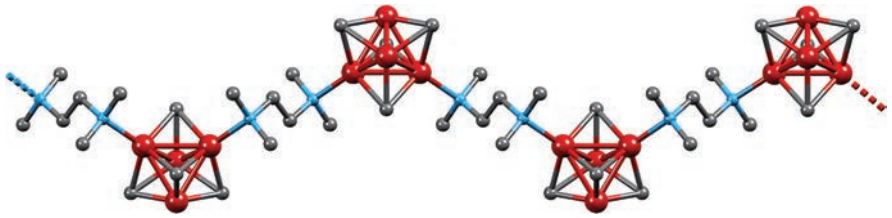
2. The ^{13}C NMR spectrum of $(^{t}BuLi)_4$ at 185 K is called the 'limiting low-temperature spectrum'. Explain what this means.

Amorphous alkali metal alkyls such as $^{n}BuNa$ are typically insoluble in common solvents, but are solubilized by the chelating ligand TMEDA (**23.1**).[†] Addition of this ligand may break down the aggregates of lithium alkyls to give lower nuclearity complexes, e.g. $[^{n}BuLi{\cdot}TMEDA]_2$, **23.2**. However, detailed studies have revealed that this system is far from simple, and under different conditions, it is possible to isolate crystals of either $[^{n}BuLi{\cdot}TMEDA]_2$ or $[(^{n}BuLi)_4{\cdot}TMEDA]_\infty$ (Fig. 23.3). In the case of $(MeLi)_4$, the addition of TMEDA does not lead to cluster breakdown, and an X-ray diffraction study of $(MeLi)_4{\cdot}2TMEDA$ confirms the presence of tetramers and amine molecules in the solid state.

(23.1)

(23.2)

[†] The abbreviation TMEDA comes from the non-IUPAC name *N*,*N*,*N*',*N*'-tetramethylethylenediamine.



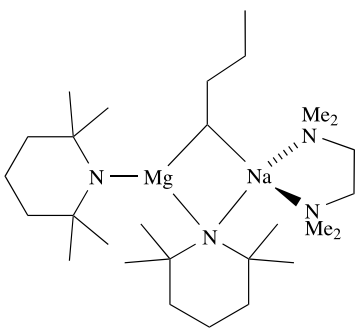


Fig. 23.3 Part of one polymeric chain of $[(^{n}BuLi)_4 \cdot TMEDA]_\infty$ found in the solid state; the structure was determined by X-ray diffraction. Only the first carbon atom of each ^{n}Bu chain is shown, and all H atoms are omitted for clarity. TMEDA molecules link $(^{n}BuLi)_4$ units together through the formation of Li–N bonds [N.D.R. Barnett *et al.* (1993) *J. Am. Chem. Soc.*, vol. 115, p. 1573]. Colour code: Li, red; C, grey; N, blue.

Solutions of TMEDA-complexed organoalkali metal reagents provide convenient homogeneous systems for metallations. For example, the metallation of benzene (reaction 23.6) proceeds more efficiently if $^{n}BuLi \cdot TMEDA$ is used in place of $^{n}BuLi$. Alkylbenzenes are metallated by $^{n}BuLi \cdot TMEDA$ at the alkyl group in preference to a ring position. Thus the reaction between $C_6H_5CH_3$ and $^{n}BuLi \cdot TMEDA$ in hexane (303 K, 2 hours) gives $C_6H_5CH_2Li$ as the regioselective (92%) product. Metallation at the *ortho*- and *meta*-ring sites occurs under these conditions to an extent of only 2 and 6%, respectively. It is possible, however, to reverse the regioselectivity[†] in favour of the *meta*-position by using the heterometallic reagent **23.3** which is prepared from $^{n}BuNa$, $^{n}Bu_2Mg$, 2,2,3,3-tetramethylpiperidine and TMEDA.

(23.3)

A ***regioselective*** reaction is one that could proceed in more than one way but is observed to proceed only, or predominantly, in one way.

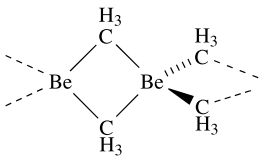
Organolithium compounds (in particular MeLi and $^{n}BuLi$) are of great importance as synthetic reagents. Among the many uses of organolithium alkyls and aryls are the conversions of boron trihalides to organoboron compounds (eq. 23.9) and similar reactions with other *p*-block halides (e.g. $SnCl_4$).

[†] For details of this unexpected observation, see: P.C. Andrikopoulis *et al.* (2005) *Angew. Chem. Int. Ed.*, vol. 44, p. 3459.

$$3\,^{n}BuLi + BCl_3 \longrightarrow {}^{n}Bu_3B + 3LiCl \qquad (23.9)$$

Lithium alkyls are important catalysts in the synthetic rubber industry for the stereospecific polymerization of alkenes.

23.3 Group 2 organometallics



Beryllium

Beryllium alkyls and aryls are best made by reaction types 23.10 and 23.11 respectively. They are hydrolysed by water and they inflame in air.

$$HgMe_2 + Be \xrightarrow{383\,K} Me_2Be + Hg \qquad (23.10)$$

$$2PhLi + BeCl_2 \xrightarrow{Et_2O} Ph_2Be + 2LiCl \qquad (23.11)$$

In the vapour phase, Me_2Be is monomeric, with a linear C–Be–C unit (Be–C = 170 pm). The bonding was described in Section 5.2. The solid state structure is polymeric (**23.4**), and resembles that of $BeCl_2$ (Fig. 12.4b). However, whereas the bonding in $BeCl_2$ can be described in terms of a localized bonding scheme (Fig. 12.4c), there are insufficient valence electrons available in $(Me_2Be)_n$ for an analogous bonding picture. Instead, 3c-2e bonds are invoked as described for BeH_2 (see Fig. 10.16 and associated text). Higher alkyls are progressively polymerized to a lesser extent, and the *tert*-butyl derivative is monomeric under all conditions.

(23.4)

$$2Na[Cp] + BeCl_2 \longrightarrow Cp_2Be + 2NaCl \qquad (23.12)$$

Reaction 23.12 leads to the formation of Cp_2Be, and in the solid state, the structure (Fig. 23.4a) is in accord with the description $(\kappa C^1\text{-Cp})(\eta^5\text{-Cp})Be$. Electron diffraction and spectroscopic studies of Cp_2Be in the gas phase have

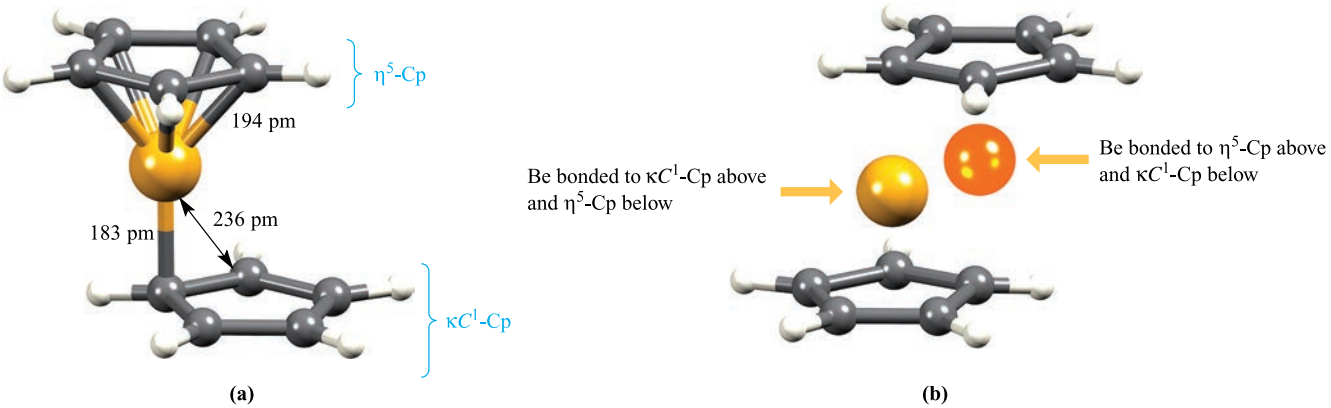


Fig. 23.4 (a) The solid state structure of Cp_2Be determined by X-ray diffraction at 128 K [K.W. Nugent *et al.* (1984) *Aust. J. Chem.*, vol. 37, p. 1601]. (b) The same structure showing the two equivalent sites over which the Be atom is disordered; only one site is occupied at any one time. Colour code: Be, yellow, orange; C, grey; H, white.

provided conflicting views of the structure, but current data indicate that it resembles that found in the solid state rather than the $(\eta^5\text{-Cp})_2Be$ originally proposed. Furthermore, the solid state structure is not as simple as Fig. 23.4a shows. The Be atom is *disordered* (see Box 15.5) over two equivalent sites shown in Fig. 23.4b. Variable temperature NMR spectroscopic studies show that Cp_2Be is fluxional both in the solid state and in solution. In the solid state, an activation energy of 36.9 kJ mol^{-1} has been experimentally determined for the 'molecular inversion' in which the two Cp rings effectively exchange between κC^1 and η^5-coordination modes. In solution, each of the ^1H and ^{13}C NMR spectra shows only one signal even as low as 138 K, indicating that a fluxional process makes all the proton and all the carbon environments equivalent. The compound $(C_5HMe_4)_2Be$ can be prepared at room temperature from $BeCl_2$ and $K[C_5HMe_4]$. In the solid state at 113 K, it is structurally similar to Cp_2Be although, in $(C_5HMe_4)_2Be$, the Be atom is not disordered. Solution ^1H NMR spectroscopic data for $(C_5HMe_4)_2Be$ are consistent with the molecule being fluxional down to 183 K. The fully methylated derivative $(C_5Me_5)_2Be$ is made by reaction 23.13. In contrast to Cp_2Be and $(C_5HMe_4)_2Be$, $(C_5Me_5)_2Be$ possesses a *sandwich* structure in which the two C_5-rings are coparallel and staggered (Fig. 23.5), i.e. the compound is formulated as $(\eta^5\text{-}C_5Me_5)_2Be$.

$$2K[C_5Me_5] + BeCl_2 \xrightarrow[388\,K]{Et_2O/\text{toluene}} (C_5Me_5)_2Be + 2KCl \qquad (23.13)$$

In a ***sandwich complex***, the metal centre lies between two π-bonded hydrocarbon (or derivative) ligands. Complexes of the type $(\eta^5\text{-Cp})_2M$ are called **metallocenes**.

We consider bonding schemes for complexes containing Cp^- ligands in Box 23.2.

Self-study exercise

Give a bonding description for the interaction between a metal atom and an κC^1-Cp ring, e.g. in a general complex $L_nMH(\kappa C^1\text{-Cp})$. Is the M–C interaction localized or delocalized?

Magnesium

Alkyl and aryl magnesium halides (Grignard reagents, represented by the formula RMgX) are extremely well known on account of their uses in synthetic organic chemistry. The general preparation of a Grignard reagent

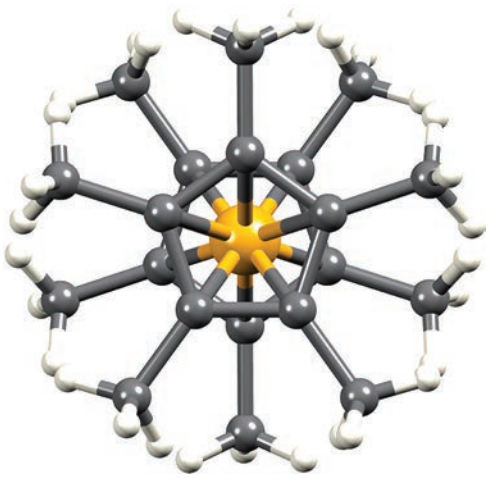

Fig. 23.5 The solid state structure (X-ray diffraction at 113 K) of $(\eta^5\text{-}C_5Me_5)_2Be$ [M. del Mar Conejo *et al.* (2000) *Angew. Chem. Int. Ed.*, vol. 39, p. 1949]. The two C_5-rings are in a staggered conformation. Colour code: Be, yellow; C, grey; H, white.

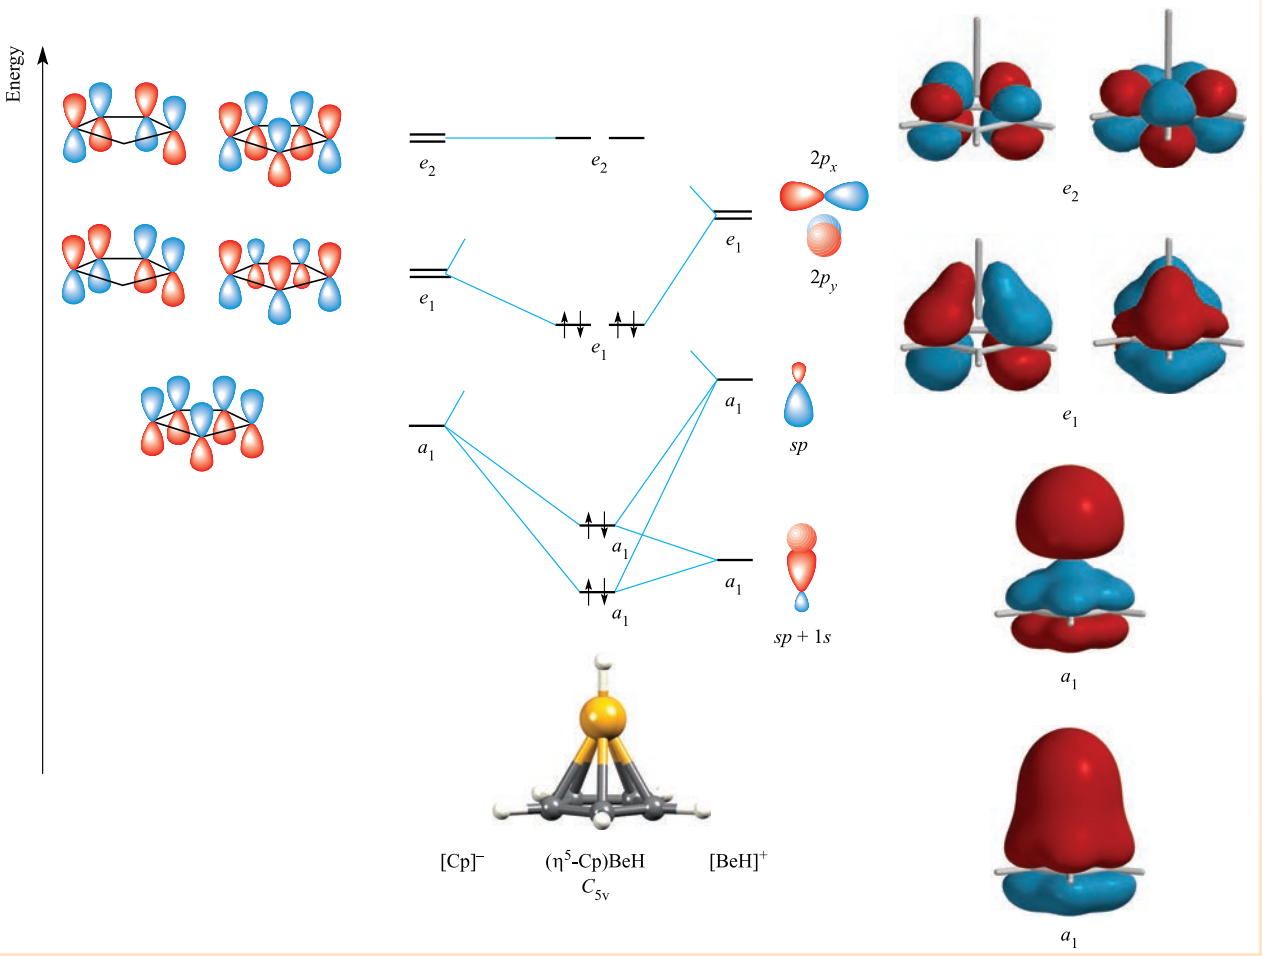
THEORY



Box 23.2 Bonding in cyclopentadienyl complexes: η^5-mode

If all five C atoms of the cyclopentadienyl ring interact with the metal atom, the bonding is most readily described in terms of an MO scheme. Once the σ-bonding framework of the $[Cp]^-$ ligand has been formed, there is one $2p_z$ atomic orbital per C atom remaining, and five combinations are possible. The MO diagram below shows the formation of (η^5-Cp)BeH (C_{5v}), a model compound that allows us to see how the $[\eta^5\text{-Cp}]^-$ ligand interacts with an *s*- or *p*-block metal fragment. For the formation of the $[BeH]^+$ fragment, we can use an *sp* hybridization scheme. One *sp* hybrid points at the H atom and the other points at the Cp ring. Using the methods from Chapter 5, the orbitals of the $[BeH]^+$ unit are classified as having a_1 or e_1 symmetry within the C_{5v} point group. To work out the π-orbitals of the $[Cp]^-$ ligand, we first determine how many C $2p_z$ orbitals are unchanged by each symmetry operation in the C_{5v} point group (Appendix 3). The resultant row of characters is:

E	$2C_5$	$2C_5^2$	$5\sigma_v$
5	0	0	1

This row can be obtained by adding the rows of characters for the A_1, E_1 and E_2 representations in the C_{5v} character table. Thus, the five π-orbitals of $[Cp]^-$ possess a_1, e_1 and e_2 symmetries. By applying the methods described in Chapter 5, the wavefunctions for these orbitals can be determined. The orbitals are shown schematically on the left-hand side of the diagram. The MO diagram is constructed by matching the symmetries of the fragment orbitals. Mixing can occur between the two a_1 orbitals of the $[BeH]^+$ fragment. Four bonding MOs (a_1 and e_1) result. The e_2 $[Cp]^-$ orbitals are non-bonding with respect to Cp–BeH interactions. (Antibonding MOs have been omitted from the diagram.) Eight electrons are available to occupy the a_1 and e_1 MOs. Representations of the a_1, e_1 and e_2 MOs are shown at the right-hand side of the figure: the e_1 set possesses Be–C bonding character, while both a_1 MOs have Be–C and Be–H bonding character.

Bonding in cyclopentadienyl complexes of *d*-block metals (see Chapter 24) can be described in a similar manner but must allow for the participation of metal *d*-orbitals.

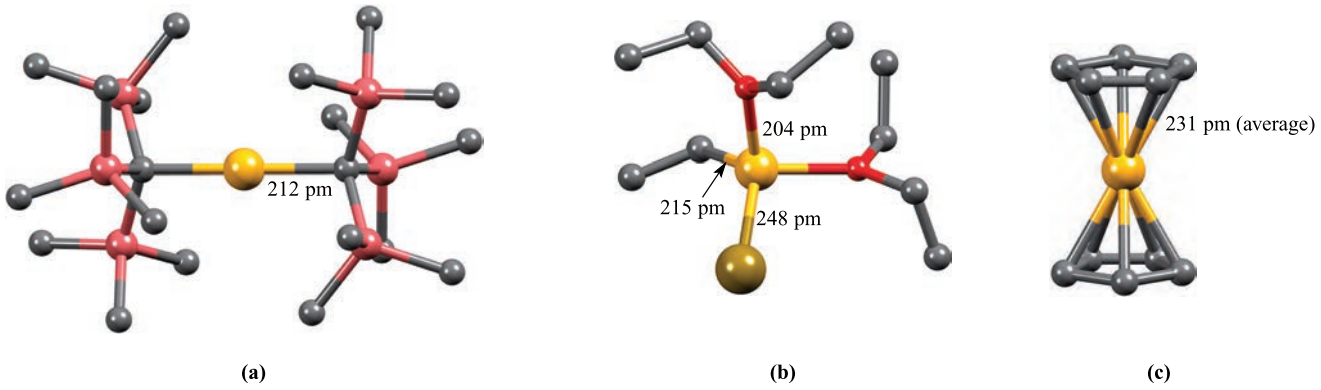


Fig. 23.6 The solid state structures, determined by X-ray diffraction, of (a) $Mg\{C(SiMe_3)_3\}_2$ [S.S. Al-Juaid *et al.* (1994) *J. Organomet. Chem.*, vol. 480, p. 199], (b) $EtMgBr{\cdot}2Et_2O$ [L.J. Guggenberger *et al.* (1968) *J. Am. Chem. Soc.*, vol. 90, p. 5375] and (c) Cp_2Mg in which each ring is in an η^5-mode and the two rings are mutually staggered [W. Bunder *et al.* (1975) *J. Organomet. Chem.*, vol. 92, p. 1]. Hydrogen atoms have been omitted for clarity; colour code: Mg, yellow; C, grey; Si, pink; Br, brown; O, red.

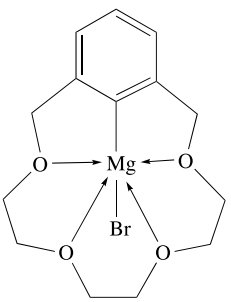
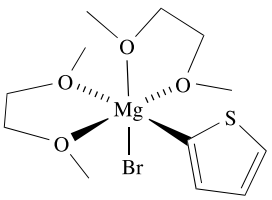
(eq. 23.14) requires initial activation of the metal, e.g. by addition of I_2.



$$Mg + RX \xrightarrow{Et_2O} RMgX \qquad (23.14)$$

Transmetallation of a suitable organomercury compound is a useful means of preparing pure Grignard reagents (eq. 23.15), and transmetallation 23.16 can be used to synthesize compounds of type R_2Mg.



$$Mg + RHgBr \longrightarrow Hg + RMgBr \qquad (23.15)$$

$$Mg + R_2Hg \longrightarrow Hg + R_2Mg \qquad (23.16)$$

Although eqs. 23.14–23.16 show the magnesium organometallics as simple species, this is an oversimplification. Two-coordination at Mg in R_2Mg is only observed in the solid state when the R groups are especially bulky, e.g. $Mg\{C(SiMe_3)_3\}_2$ (Fig. 23.6a). Grignard reagents are generally solvated, and crystal structure data show that the Mg centre is typically tetrahedrally sited, e.g. in $EtMgBr{\cdot}2Et_2O$ (Fig. 23.6b) and $PhMgBr{\cdot}2Et_2O$. A few examples of 5- and 6-coordination have been observed, e.g. in **23.5** where the macrocyclic ligand imposes the higher coordination number on the metal centre. The preference for an octahedral structure can be controlled by careful choice of the organic substituent, e.g. complex **23.6**. The introduction of two or more bidentate ligands into the octahedral coordination sphere leads to the possibility of *stereoisomerism*, e.g. **23.6** is chiral (see Sections 3.8 and 19.8). Enantiomerically pure Grignard reagents have potential for use in stereoselective organic synthesis. Solutions of Grignard reagents may contain several species, e.g. RMgX, R_2Mg, MgX_2, $RMg(\mu\text{-}X)_2MgR$, which are further complicated by solvation. The positions of equilibria between these species are markedly dependent on concentration, temperature and solvent. Strongly donating solvents favour monomeric species in which they coordinate to the metal centre.

(23.5)

(23.6)

In contrast to its beryllium analogue, Cp_2Mg has the structure shown in Fig. 23.6c, i.e. two η^5-cyclopentadienyl ligands, and is structurally similar to ferrocene (see Section 24.14). The reaction between Mg and C_5H_6 yields Cp_2Mg, which is decomposed by water; the compound is therefore often inferred to be ionic and, indeed, significant ionic character is suggested by the long Mg–C bonds in the solid state and also by IR and Raman spectroscopic data.

Calcium, strontium and barium

The heavier group 2 metals are highly electropositive, and metal–ligand bonding is generally considered to be predominantly ionic. Nonetheless, this remains a topic for debate and theoretical investigation. While Cp_2Be and Cp_2Mg are monomeric and are soluble in hydrocarbon solvents, Cp_2Ca, Cp_2Sr and Cp_2Ba are polymeric and are insoluble in ethers and hydrocarbons. Increasing the steric

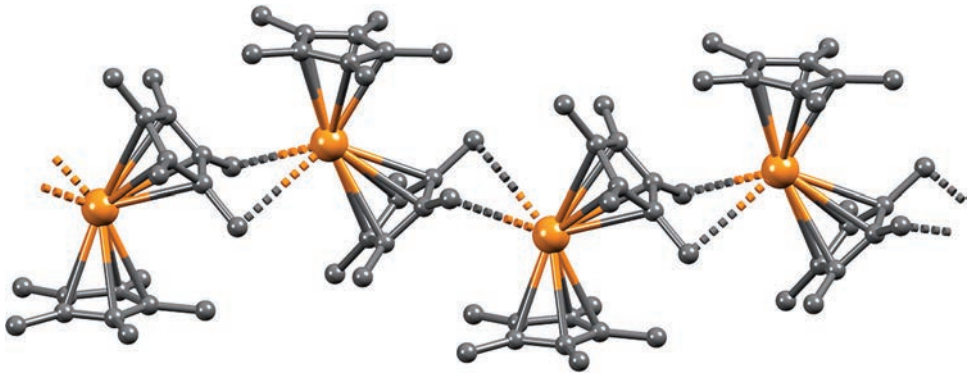


Fig. 23.7 Part of a chain in the polymeric structure (X-ray diffraction 118 K) of $(\eta^5\text{-}C_5Me_5)_2Ba$ illustrating the bent metallocene units [R.A. Williams *et al.* (1988) *J. Chem. Soc., Chem Commun.*, p. 1045]. Hydrogen atoms have been omitted; colour code: Ba, orange; C, grey.

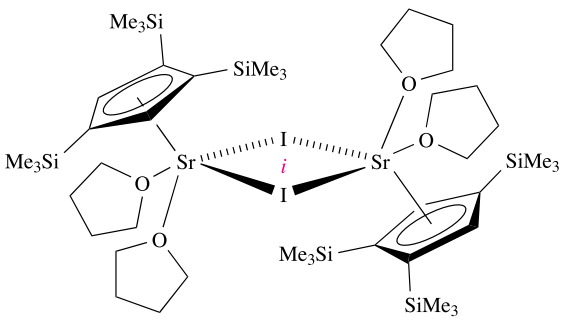
demands of the substituents on the C_5-rings leads to structural changes in the solid state and to changes in solution properties, e.g. $(C_5Me_5)_2Ba$ is polymeric, $\{1,2,4\text{-}(SiMe_3)_3C_5H_2\}_2Ba$ is dimeric and $(^iPr_5C_5)_2Ba$ is monomeric. Oligomeric metallocene derivatives of Ca^{2+}, Sr^{2+} and Ba^{2+} typically exhibit bent $C_5{-}M{-}C_5$ units (Fig. 23.7 and see the end of Section 23.5), but in $(^iPr_5C_5)_2Ba$, the C_5-rings are coparallel. The $^iPr_5C_5$-rings are very bulky, and sandwich the Ba^{2+} ion protectively, making $(^iPr_5C_5)_2Ba$ air-stable. The 1990s saw significant development of the organometallic chemistry of the heavier group 2 metals, with one driving force being the search for precursors for use in chemical vapour deposition (see Chapter 28). Some representative synthetic methodologies are given in eqs. 23.17–23.20, where M = Ca, Sr or Ba.[†]

$$Na[C_5R_5] + MI_2 \xrightarrow[\text{(e.g. THF, } Et_2O)]{\text{ether}} NaI + (C_5R_5)MI(\text{ether})_x \qquad (23.17)$$

$$2C_5R_5H + M\{N(SiMe_3)_2\}_2 \xrightarrow{\text{toluene}} (C_5R_5)_2M + 2NH(SiMe_3)_2 \qquad (23.18)$$

$$3K[C_5R_5] + M(O_2SC_6H_4\text{-}4\text{-}Me)_2 \xrightarrow{\text{THF}} K[(C_5R_5)_3M](THF)_3 + 2K[O_2SC_6H_4\text{-}4\text{-}Me] \qquad (23.19)$$

$$(C_5R_5)CaN(SiMe_3)_2(THF) + HC{\equiv}CR' \xrightarrow{\text{toluene}} (C_5R_5)(THF)Ca(\mu\text{-}C{\equiv}CR')_2Ca(THF)(C_5R_5) \qquad (23.20)$$



[†]For greater detail, see: T.P. Hanusa (2000) *Coord. Chem. Rev.*, vol. 210, p. 329; W.D. Buchanan, D.G. Allis and K. Ruhlandt-Senge (2010) *Chem. Commun.*, vol. 46, p. 4449.

Worked example 23.2 Cyclopentadienyl complexes of Ca^{2+}, Sr^{2+} and Ba^{2+}

In the solid state, $(\eta^5\text{-}1,2,4\text{-}(SiMe_3)_3C_5H_2)SrI(THF)_2$ exists as dimers, each with an inversion centre. Suggest how the dimeric structure is supported and draw a diagram to show the structure of the dimer.

The iodide ligands have the potential to bridge between two Sr centres.

When drawing the structure, ensure that the two halves of the dimer are related by an inversion centre, *i* (see Section 3.2):

Self-study exercises

1. '$(\eta^5\text{-}C_5{}^iPr_4H)CaI$' can be stabilized in the presence of THF as a THF complex. However, removal of coordinated THF by heating results in the reaction:

   $2(\eta^5\text{-}C_5{}^iPr_4H)CaI \longrightarrow (\eta^5\text{-}C_5{}^iPr_4H)_2Ca + CaI_2$

   Comment on these observations.

2. The reaction of BaI_2 with $K[1,2,4\text{-}(SiMe_3)_3C_5H_2]$ yields a compound **A** and an ionic salt. The solution ^1H NMR spectrum of **A** shows singlets at δ 6.69 (2H),

0.28 (18H) and 0.21 (9H) ppm. Suggest an identity for **A** and assign the ^{1}H NMR spectrum.

[Exercises 1 and 2: For more information and answers, see: M.J. Harvey *et al.* (2000) *Organometallics*, vol. 19, p. 1556.]

3. The reaction of dibenzylbarium with two equivalents of $(C_5R_5)H$ (R = 4-^{n}BuC_6H_4) leads to a centrosymmetric metallocene, **B**. The second product is toluene. Identify **B** and explain how the toluene arises. How are the two C_5R_5-units arranged with respect to one another in **B**, and is the metallocene 'linear' or 'bent'? Give an explanation for your answers.
[*Ans.* See: L. Orzechowski *et al.* (2008) *Dalton Trans.*, p. 4742]

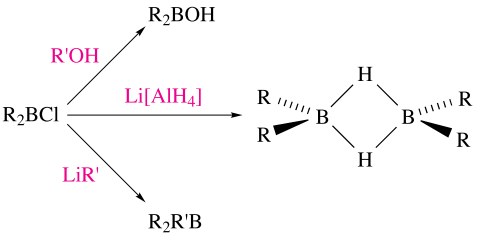
23.4 Group 13

Boron

The following aspects of organoboron compounds have already been discussed:

- reactions of alkenes with B_2H_6 to give R_3B compounds (see Fig. 13.8);
- the preparation of $B_4{}^tBu_4$ (eq. 13.42);
- organoboranes which contain B–N bonds (Section 13.8).

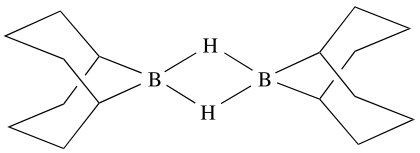
Organoboranes of type R_3B can be prepared by reaction 23.21, or by the hydroboration reaction mentioned above.



$$Et_2O{\cdot}BF_3 + 3RMgX \longrightarrow R_3B + 3MgXF + Et_2O \qquad (R = \text{alkyl or aryl}) \qquad (23.21)$$

Trialkylboranes are monomeric and inert towards water, but are pyrophoric. Triaryl compounds are less reactive. Both sets of compounds contain planar 3-coordinate B and act as Lewis acids towards amines and carbanions (see also Sections 13.5 and 13.6). Reaction 23.22 shows an important example: sodium tetraphenylborate is water-soluble but salts of larger monopositive cations (e.g. K^+) are insoluble. This makes $Na[BPh_4]$ useful in the precipitation of large metal ions.

$$BPh_3 + NaPh \longrightarrow Na[BPh_4] \qquad (23.22)$$



Compounds of the types R_2BCl and $RBCl_2$ can be prepared by transmetallation reactions (e.g. eq. 23.23) and are synthetically useful (e.g. reactions 13.67 and 23.24).

$$\begin{array}{c} BCl_3 + Ph_4Sn \\ \swarrow \qquad \searrow \\ PhBCl_2 + Ph_3SnCl \qquad Ph_2BCl + Ph_2SnCl_2 \end{array} \qquad (23.23)$$

(23.24)

The bonding in $R_2B(\mu\text{-}H)_2BR_2$ can be described in a similar manner to that in B_2H_6 (see Section 5.8). An important member of this family is **23.7**, commonly known as 9-BBN,[†] which is used for the regioselective reduction of ketones, aldehydes, alkynes and nitriles.

(23.7)

By using bulky organic substituents (e.g. mesityl = 2,4,6-$Me_3C_6H_2$), it is possible to stabilize compounds of type $R_2B{-}BR_2$. These should be contrasted with $X_2B{-}BX_2$ where X = halogen or NR_2 in which there is X ⟶ B π-overlap (see Sections 13.6 and 13.8). Two-electron reduction of $R_2B{-}BR_2$ gives $[R_2B{=}BR_2]^{2-}$, an isoelectronic analogue of an alkene. The planar B_2C_4 framework has been confirmed by X-ray diffraction for $Li_2[B_2(2,4,6\text{-}Me_3C_6H_2)_3Ph]$, although there is significant interaction between the B=B unit and two Li^+ centres. The shortening of the B–B bond on going from $B_2(2,4,6\text{-}Me_3C_6H_2)_3Ph$ (171 pm) to $[B_2(2,4,6\text{-}Me_3C_6H_2)_3Ph]^{2-}$ (163 pm) is less than might be expected and this observation is attributed to the large Coulombic repulsion between the two B^- centres.[‡]

Aluminium

Aluminium alkyls can be prepared by the transmetallation reaction 23.25, or from Grignard reagents (eq. 23.26). On an industrial scale, the direct reaction of Al with a terminal alkene and H_2 (eq. 23.27) is employed.

$$2Al + 3R_2Hg \longrightarrow 2R_3Al + 3Hg \qquad (23.25)$$

$$AlCl_3 + 3RMgCl \longrightarrow R_3Al + 3MgCl_2 \qquad (23.26)$$

$$Al + \tfrac{3}{2}H_2 + 3R_2C{=}CH_2 \longrightarrow (R_2CHCH_2)_3Al \qquad (23.27)$$

Reactions between Al and alkyl halides yield alkyl aluminium halides (eq. 23.28). Note that **23.8** is in equilibrium with $[R_2Al(\mu\text{-}X)_2AlR_2]$ and $[RXAl(\mu\text{-}X)_2AlRX]$ via a redistribution reaction, but **23.8** predominates in the mixture.

[†] The systematic name for 9-BBN is 9-borabicyclo[3.3.1]nonane.

[‡] For insight into B–B multiple bonding, see: H. Braunschweig and R.D. Dewhurst (2014) *Organometallics*, vol. 33, p. 6271 – 'Boron–boron multiple bonding: From charged to neutral and back again'.

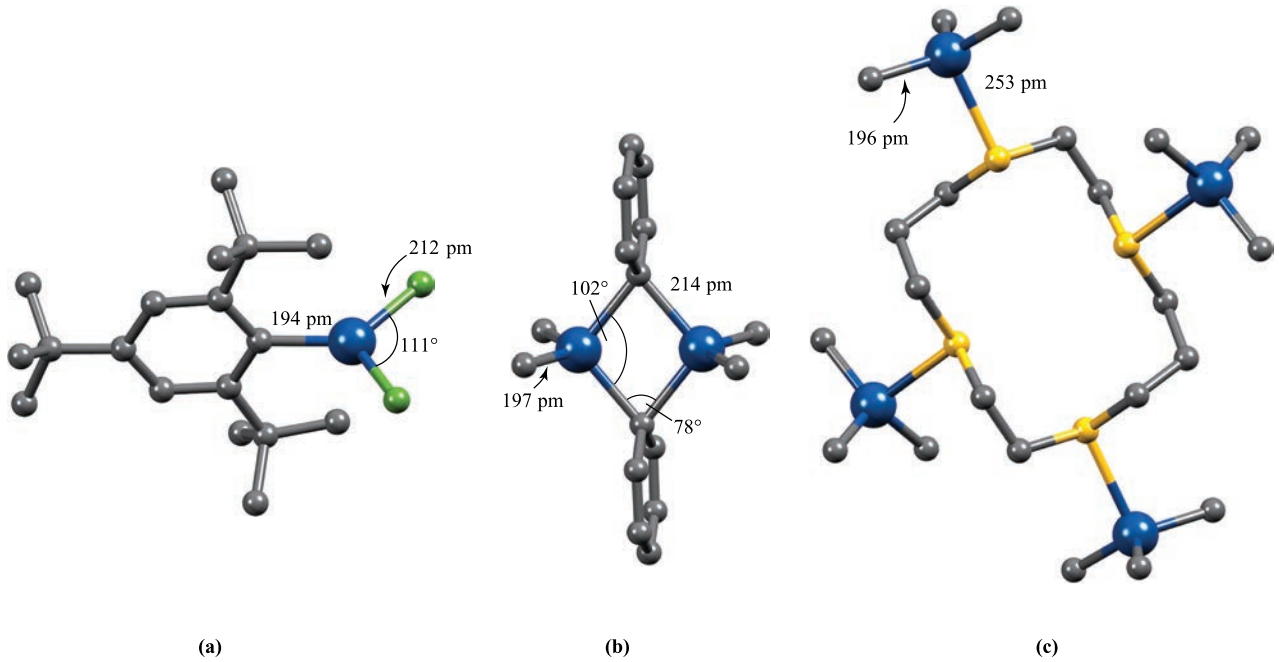


Fig. 23.8 The solid state structures (X-ray diffraction) of (a) (2,4,6-$^{t}Bu_3C_6H_2$)$AlCl_2$ [R.J. Wehmschulte *et al.* (1996) *Inorg. Chem.*, vol. 35, p. 3262], (b) $Me_2Al(\mu\text{-}Ph)_2AlMe_2$ [J.F. Malone *et al.* (1972) *J. Chem. Soc., Dalton Trans.*, p. 2649] and (c) the adduct L·$(AlMe_3)_4$ where L is the sulfur-containing macrocyclic ligand 1,4,8,11-tetrathiacyclotetradecane [G.H. Robinson *et al.* (1987) *Organometallics*, vol. 6, p. 887]. Hydrogen atoms are omitted for clarity; colour code: Al, blue; C, grey; Cl, green; S, yellow.

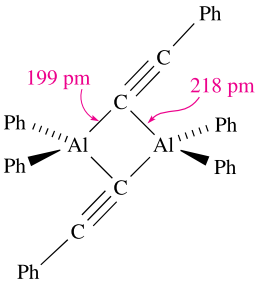
$$2Al + 3RX \longrightarrow \tfrac{1}{2}[R_2AlX]_2 \qquad (23.28)$$

(23.8)

$$Al + \tfrac{3}{2}H_2 + 2R_3Al \longrightarrow 3R_2AlH \qquad (23.29)$$

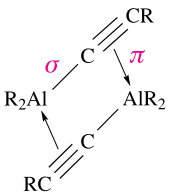
Alkyl aluminium hydrides are obtained by reaction 23.29. These compounds, although unstable to both air and water, are important catalysts for the polymerization of alkenes and other unsaturated organic compounds. We describe the commercially important role of alkyl aluminium derivatives as co-catalysts in Ziegler–Natta alkene polymerization in Section 25.8.[†]

(23.9)



Earlier we noted that R_3B compounds are monomeric. In contrast, aluminium trialkyls form dimers. Although this resembles the behaviour of the halides discussed in Section 13.6, there are differences in bonding. Trimethylaluminium (mp 313 K) possesses structure **23.9** and a bonding description similar to that in B_2H_6 is appropriate. The fact that $Al{-}C_{bridge} > Al{-}C_{terminal}$ is consistent with 3c-2e bonding in the Al−C−Al bridges, but with 2c-2e terminal bonds. Equilibria between dimer and monomer exist in solution, with the monomer becoming more favoured as the steric demands of the alkyl group increase. Mixed alkyl halides also dimerize as exemplified in structure **23.8**, but with particularly bulky R groups, the monomer (with trigonal planar Al) is favoured, e.g. (2,4,6-$^{t}Bu_3C_6H_2$)$AlCl_2$ (Fig. 23.8a). Triphenylaluminium also exists as a dimer, but in the mesityl derivative (mesityl = 2,4,6-$Me_3C_6H_2$), the steric demands of the substituents stabilize the monomer. Figure 23.8b shows the structure of $Me_2Al(\mu\text{-}Ph)_2AlMe_2$, and the orientations of the bridging phenyl groups are the same as in $Ph_2Al(\mu\text{-}Ph)_2AlPh_2$. This orientation is sterically favoured and places each *ipso*-carbon atom in an approximately tetrahedral environment.

The ***ipso***-carbon atom of a phenyl ring is the one to which the substituent is attached; e.g. in PPh_3, the *ipso*-C of each Ph ring is bonded to P.



In dimers containing RC≡C-bridges, a different type of bonding operates. The structure of $Ph_2Al(PhC{\equiv}C)_2AlPh_2$

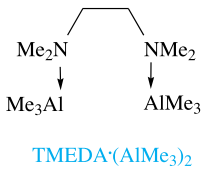
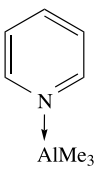
(**23.10**) shows that the alkynyl bridges lean over towards one of the Al centres. This is interpreted in terms of their behaving as σ,π-ligands: each forms one Al–C σ-bond and interacts with the second Al centre by using the C≡C π-bond. Thus, each alkynyl group is able to provide three electrons (one σ- and two π-electrons) for bridge bonding in contrast to one electron being supplied by an alkyl or aryl group; the bonding is shown schematically in **23.11**.

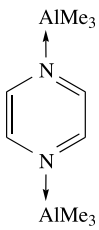


(23.10)

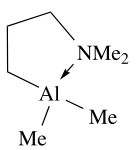


(23.11)

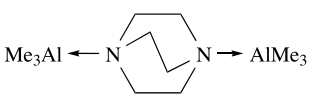
Trialkylaluminium derivatives behave as Lewis acids, forming a range of adducts, e.g. $R_3N{\cdot}AlR_3$, $K[AlR_3F]$, $Ph_3P{\cdot}AlMe_3$ and more exotic complexes such as that shown in Fig. 23.8c. Each adduct contains a tetrahedrally sited Al atom. Trialkylaluminium compounds are stronger Lewis acids than either R_3B or R_3Ga, and the sequence for group 13 follows the trend $R_3B < R_3Al > R_3Ga > R_3In > R_3Tl$. Most adducts of $AlMe_3$ with nitrogen donors (e.g. $Me_3N{\cdot}AlMe_3$, **23.12**, **23.13** and **23.14**) are air- and moisture-sensitive, and must be handled under inert atmospheres. One way of stabilizing the system is by the use of an internal amine as in **23.15**. Alternatively, complex **23.16** (containing a bicyclic diamine) can be handled in air, having a hydrolytic stability comparable to that of $LiBH_4$.



TMEDA·$(AlMe_3)_2$

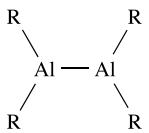


(23.12)

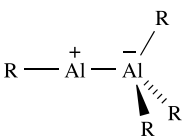


(23.13)

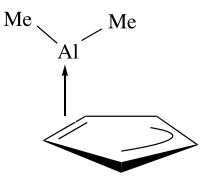
(23.14)



(23.15)



(23.16)



The first $R_2Al{-}AlR_2$ derivative (reported in 1988) was prepared by potassium reduction of the sterically hindered $\{(Me_3Si)_2CH\}_2AlCl$. The Al–Al bond distance in $\{(Me_3Si)_2CH\}_4Al_2$ is 266 pm (compare r_{cov} = 130 pm) and the Al_2C_4 framework is *planar*, despite this being a singly bonded compound. A related compound is $(2,4,6\text{-}^{i}Pr_3C_6H_2)_4Al_2$ (Al–Al = 265 pm) but here the Al_2C_4 framework is non-planar (angle between the two AlC_2 planes = 45°). One-electron reduction of Al_2R_4 ($R = 2,4,6\text{-}^{i}Pr_3C_6H_2$) gives the radical anion $[Al_2R_4]^-$ with a formal Al–Al bond order of 1.5. Consistent with the presence of a π-contribution, the Al–Al bond is shortened upon reduction to 253 pm for $R = (Me_3Si)_2CH$, and 247 pm for $R = 2,4,6\text{-}^{i}Pr_3C_6H_2$. In both anions, the Al_2R_4 frameworks are essentially planar. In theory, a dialane $R_2Al{-}AlR_2$, **23.17**, possesses an isomer, **23.18**, and such a species is exemplified by $(\eta^5\text{-}C_5Me_5)Al{-}Al(C_6F_5)_3$. The Al–Al bond (259 pm) in this compound is shorter than in compounds of type $R_2Al{-}AlR_2$ and this is consistent with the ionic contribution made to the Al–Al interaction in isomer **23.18**.

(23.17)

(23.18)

(23.19)

The reaction between cyclopentadiene and Al_2Me_6 gives $CpAlMe_2$ which is a volatile solid. In the gas phase, it is monomeric with an η^2-Cp bonding mode (**23.19**). This effectively partitions the cyclopentadienyl ring into alkene and allyl parts, since only two of the five π-electrons are donated to the metal centre. In the solid state, the molecules interact to form polymeric chains (Fig. 23.9a). The related compound Cp_2AlMe is monomeric with an η^2-mode in the solid state (Fig. 23.9b). In solution, Cp_2AlMe and $CpAlMe_2$ are highly fluxional. A small energy difference between the different modes of bonding of the cyclopentadienyl ligand is also observed in the compounds $(C_5H_5)_3Al$ (i.e. Cp_3Al), $(1,2,4\text{-}Me_3C_5H_2)_3Al$ and $(Me_4C_5H)_3Al$. In solution, even at low temperature, these are stereochemically non-rigid, with negligible energy

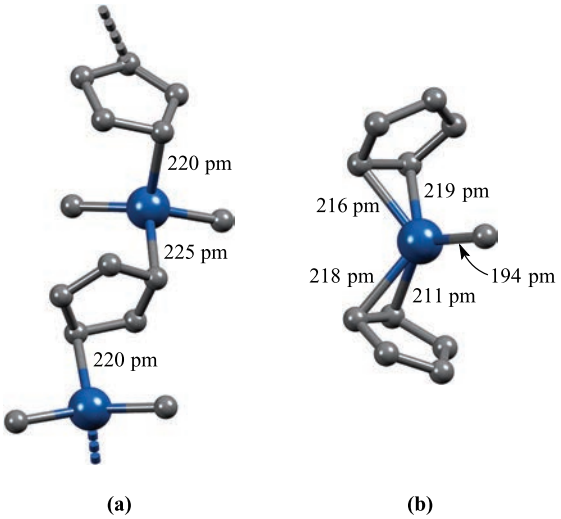


Fig. 23.9 The solid state structures (X-ray diffraction) of (a) polymeric $CpAlMe_2$ [B. Tecle *et al.* (1982) *Inorg. Chem.*, vol. 21, p. 458] and (b) monomeric $(\eta^2\text{-Cp})_2AlMe$ [J.D. Fisher *et al.* (1994) *Organometallics*, vol. 13, p. 3324]. Hydrogen atoms are omitted; colour code: Al, blue; C, grey.

differences between κC^1-, η^2-, η^3- and η^5-modes of bonding. In the solid state, the structural parameters are consistent with the descriptions:

- $(\eta^2\text{-}C_5H_5)(\eta^{1.5}\text{-}C_5H_5)(\kappa C^1\text{-}C_5H_5)Al$ and $(\eta^2\text{-}C_5H_5)(\eta^{1.5}\text{-}C_5H_5)_2Al$ for the two independent molecules present in the crystal lattice;
- $(\eta^5\text{-}1,2,4\text{-}Me_3C_5H_2)(\kappa C^1\text{-}1,2,4\text{-}Me_3C_5H_2)_2Al$;
- $(\kappa C^1\text{-}Me_4C_5H)_3Al$.

These examples illustrate the non-predictable nature of these systems.

Compounds of the type R_3Al contain aluminium in oxidation state +3, while Al_2R_4 formally contains Al(II). The reduction of $[(\eta^5\text{-}C_5Me_5)XAl(\mu\text{-}X)]_2$ (X = Cl, Br, I) by Na/K alloy gives $[(\eta^5\text{-}C_5Me_5)Al]_4$, with the yield being the highest for X = I, corresponding to the lowest Al–X bond enthalpy. $[(\eta^5\text{-}C_5Me_5)Al]_4$ contains a tetrahedral cluster of Al atoms (Fig. 23.10) and is formally an aluminium(I) compound. Stabilization of this and related compounds requires the presence of bulky cyclopentadienyl ligands. It has not been possible to isolate monomeric $(\eta^5\text{-}C_5R_5)Al$.[†]

Gallium, indium and thallium

Since 1980, interest in organometallic compounds of Ga, In and Tl has grown, mainly because of their potential use as precursors to semiconducting materials such as GaAs and InP. Volatile compounds can be used in the growth of thin films by MOCVD (*metal organic chemical vapour deposition*) or MOVPE (*metal organic vapour phase epitaxy*) techniques (see Section 28.6). Precursors include Lewis base adducts of metal alkyls, e.g. $Me_3Ga{\cdot}NMe_3$ and $Me_3In{\cdot}PEt_3$. Reaction 23.30 is an example of the thermal decomposition of gaseous precursors to form a semiconductor which can be deposited in thin films (see Box 23.3).

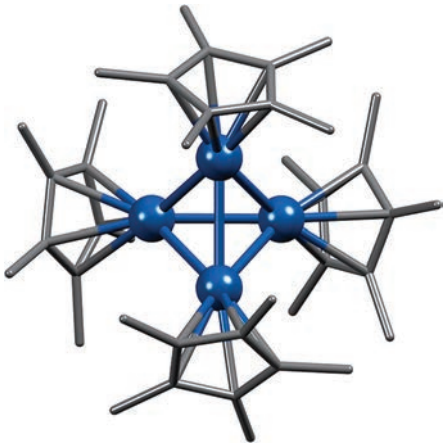

Fig. 23.10 The structure of $[(\eta^5\text{-}C_5Me_5)Al]_4$ (determined by X-ray diffraction at 200 K); Al–Al = 277 pm, and average Al–C = 234 pm [Q. Yu *et al.* (1999) *J. Organomet. Chem.*, vol. 584, p. 94]. Hydrogen atoms are omitted; colour code: Al, blue; C, grey. The C_5Me_5 ligands are shown in stick-representation for clarity.

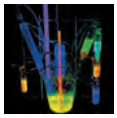
$$Me_3Ga(g) + AsH_3(g) \xrightarrow{1000-1150\,K} GaAs(s) + 3CH_4(g) \quad (23.30)$$

Gallium, indium and thallium trialkyls, R_3M, can be made by use of Grignard reagents (reaction 23.31), RLi (eq. 23.32) or R_2Hg (eq. 23.33), although a variation in strategy is usually needed to prepare triorganothallium derivatives (e.g. reaction 23.34) since R_2TlX is favoured in reactions 23.31 or 23.32. The Grignard route is valuable for the synthesis of triaryl derivatives. A disadvantage of the Grignard route is that $R_3M{\cdot}OEt_2$ may be the isolated product.

$$MBr_3 + 3RMgBr \xrightarrow{Et_2O} R_3M + 3MgBr_2 \quad (23.31)$$

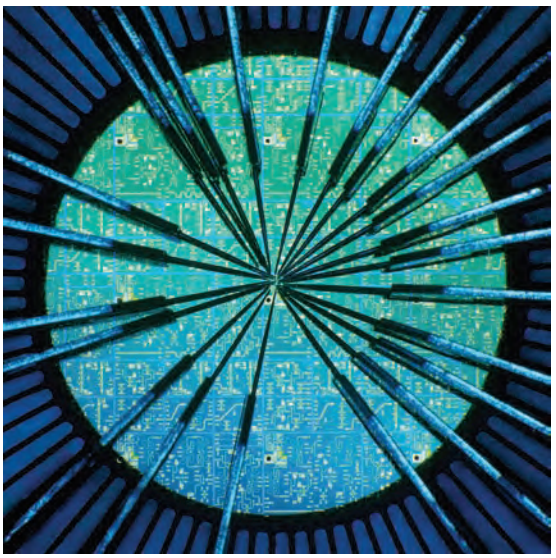


$$MCl_3 + 3RLi \xrightarrow{\text{hydrocarbon solvent}} R_3M + 3LiCl \quad (23.32)$$

$$2M + 3R_2Hg \longrightarrow 2R_3M + 3Hg \quad (\textit{not} \text{ for } M = Tl) \quad (23.33)$$

$$2MeLi + MeI + TlI \longrightarrow Me_3Tl + 2LiI \quad (23.34)$$

Trialkyls and triaryls of Ga, In and Tl are monomeric (trigonal planar metal centres) in solution and the gas phase. In the solid state, monomers are essentially present, but close intermolecular contacts are important in most



[†] For insight into the development of organoaluminium(I) compounds, see: H.W. Roesky (2004) *Inorg. Chem.*, vol. 43, p. 7284 – 'The renaissance of aluminum chemistry'; H.W. Roesky and S.S. Kumar (2005) *Chem. Commun.*, p. 4027 – 'Chemistry of aluminium(I)'.

APPLICATIONS

Box 23.3 III–V semiconductors

The so-called III–V semiconductors derive their name from the old group numbers for groups 13 and 15, and include AlAs, AlSb, GaP, GaAs, GaSb, InP, InAs and InSb. Of these, GaAs is of the greatest commercial interest. Although Si is probably the most important commercial semiconductor, a major advantage of GaAs over Si is that the charge carrier mobility is much greater. This makes GaAs suitable for high-speed electronic devices. Another important difference is that GaAs exhibits a fully allowed electronic transition between valence and conduction bands (i.e. it is a *direct* band gap semiconductor) whereas Si is an *indirect* band gap semiconductor. The consequence of this difference is that GaAs (and, similarly, the other III–V semiconductors) are more suited than Si for use in optoelectronic devices, since light is emitted more efficiently. The III–Vs have important applications in light-emitting diodes (LEDs). III–V semiconductors are discussed in detail in Section 28.6.

structures. In trimethylindium, the formation of long In····C interactions (Fig. 23.11a) means that the structure can be described in terms of cyclic tetramers. Each In centre also forms an additional weak In····C interaction (356 pm) with the C atom of an adjacent tetramer to give an infinite network. The solid state structures of Me_3Ga and Me_3Tl resemble that of Me_3In. Within the planar Me_3Ga and Me_3Tl molecules, the average Ga−C and Tl−C bond distances are 196 and 230 pm, respectively. Within the tetrameric units, the Ga····C and Tl····C separations are 315 and

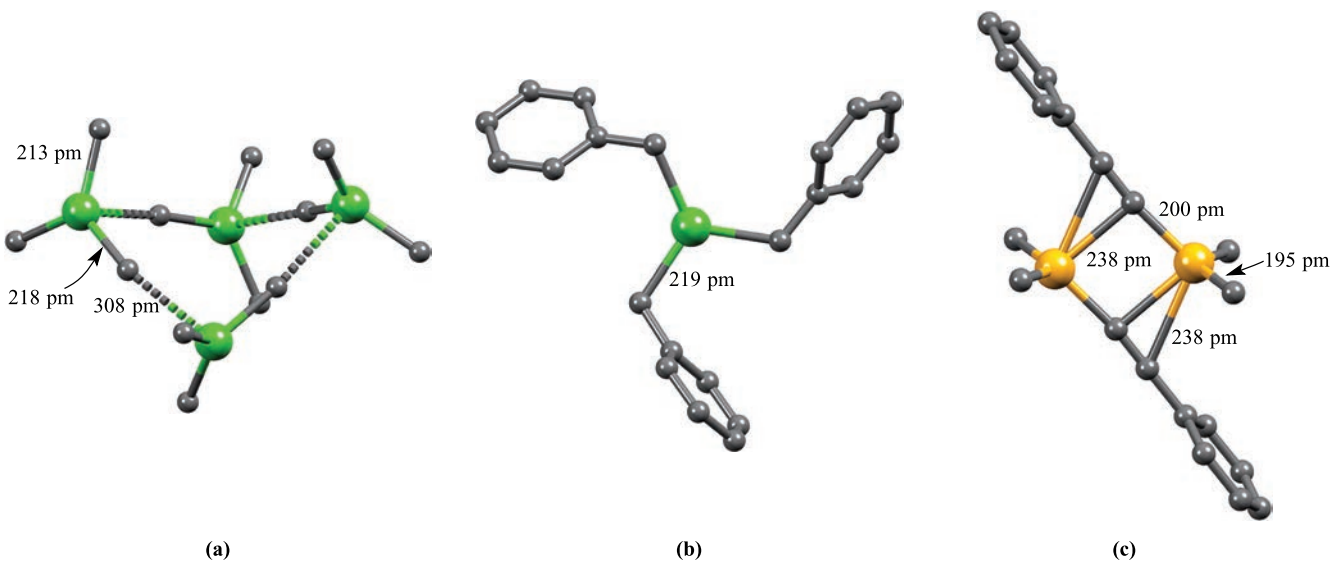

Fig. 23.11 The solid state structures (X-ray diffraction) of (a) Me_3In for which one of the tetrameric units (see text) is shown [A.J. Blake *et al*. (1990) *J. Chem. Soc., Dalton Trans.*, p. 2393], (b) $(PhCH_2)_3In$ [B. Neumuller (1991) *Z. Anorg. Allg. Chem.*, vol. 592, p. 42] and (c) $Me_2Ga(\mu\text{-}C{\equiv}CPh)_2GaMe_2$ [B. Tecle *et al*. (1981) *Inorg. Chem.*, vol. 20, p. 2335]. Hydrogen atoms are omitted for clarity; colour code: In, green; Ga, yellow; C, grey.

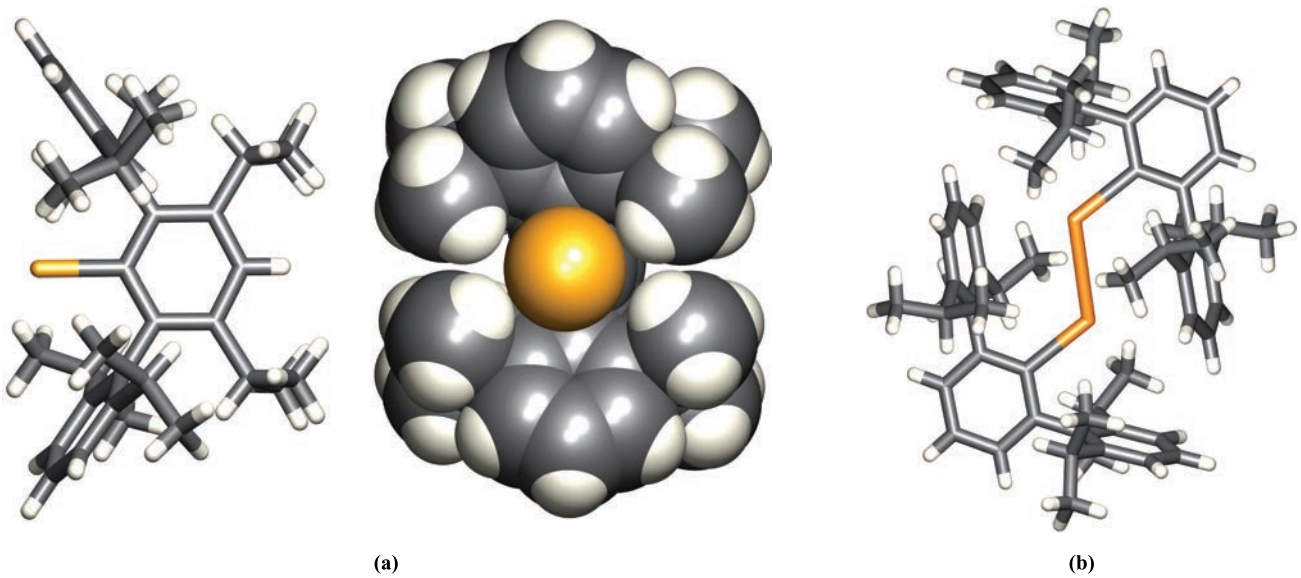

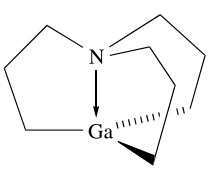

Fig. 23.12 (a) Two views of the structure (X-ray diffraction) of $\{C_6H\text{-}2,6\text{-}(C_6H_3\text{-}2,6\text{-}^iPr_2)_2\text{-}3,5\text{-}^iPr_2\}Ga$ in stick and space-filling representations [Z. Zhu *et al*. (2009) *Chem. Eur. J*., vol. 15, p. 5263]. Colour code: Ga, yellow; C, grey; H, white. (b) The structure of $\{C_6H_3\text{-}2,6\text{-}(C_6H_3\text{-}2,6\text{-}^iPr_2)_2\}_2Tl_2$ determined by X-ray diffraction [R.J. Wright *et al*. (2005) *J. Am. Chem. Soc*., vol. 127, p. 4794]. The figure illustrates the steric crowding of the organic substituents around the central Tl_2 core; Tl–Tl = 309 pm, and angle C–Tl–Tl = 119.7°. Colour code: Tl, orange; C, grey; H, white.

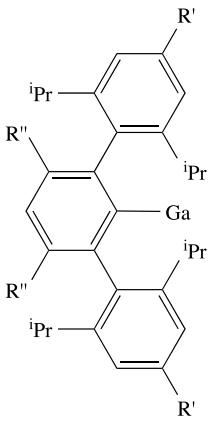
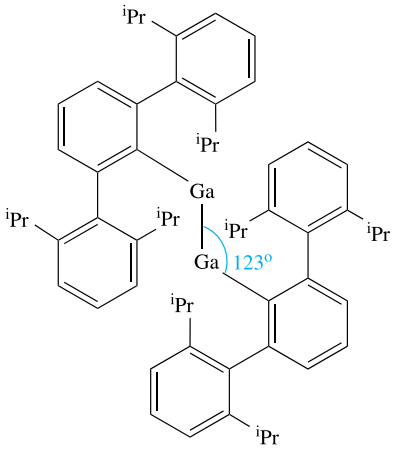


316 pm, respectively. Intermolecular interactions are also observed in, for example, crystalline Ph_3Ga, Ph_3In and $(PhCH_2)_3In$. Figure 23.11b shows one molecule of $(PhCH_2)_3In$, but each In atom interacts weakly with carbon atoms of phenyl rings of adjacent molecules. Dimer formation is observed in $Me_2Ga(\mu\text{-}C{\equiv}CPh)_2GaMe_2$ (Fig. 23.11c), and the same bonding description that we outlined for $R_2Al(\mu\text{-}C{\equiv}CPh)_2AlR_2$ (**23.10** and **23.11**) is appropriate.

Triorganogallium, indium and thallium compounds are air- and moisture-sensitive. Hydrolysis initially yields the linear $[R_2M]^+$ ion (which can be further hydrolysed), in contrast to the inertness of R_3B towards water and the formation of $Al(OH)_3$) from R_3Al. The $[R_2Tl]^+$ cation is also present in R_2TlX (X = halide), and the ionic nature of this compound differs from the covalent character of R_2MX for the earlier group 13 elements. Numerous adducts $R_3M{\cdot}L$ (L = Lewis base) are known in which the metal centre is tetrahedrally sited, e.g. $Me_3Ga{\cdot}NMe_3$, $Me_3Ga{\cdot}NCPh$, $Me_3In{\cdot}OEt_2$, $Me_3In{\cdot}SMe_2$, $Me_3Tl{\cdot}PMe_3$, $[Me_4Tl]^-$. In compound **23.20**, donation of the lone pair comes from within the organic moiety; the GaC_3-unit is planar since the ligand is not flexible enough for the usual tetrahedral geometry to be adopted.



(23.20)

Species of type $[E_2R_4]$ (single E–E bond) and $[E_2R_4]^-$ (E–E bond order 1.5) can be prepared for Ga and In provided that R is especially bulky (e.g. R = $(Me_3Si)_2CH$, 2,4,6-$^iPr_3C_6H_2$), and reduction of $[(2,4,6\text{-}^iPr_3C_6H_2)_4Ga_2]$ to $[(2,4,6\text{-}^iPr_3C_6H_2)_4Ga_2]^-$ is accompanied by a shortening of the Ga–Ga bond from 252 to 234 pm, consistent with an increase in bond order (1 to 1.5). By using even bulkier substituents, it is possible to prepare gallium(I) compounds RGa (**23.21**) starting from gallium(I) iodide. Monomeric structures have been confirmed for compound **23.21** with R' = R" = ^{i}Pr, and with R' = H, R" = ^{i}Pr. The latter structure is shown in Fig. 23.12a. The space-filling representation emphasizes how the sterically demanding substituents protect the Ga atom. Compound **23.21** with R' = R" = H crystallizes as the weakly bound dimer **23.22**, reverting to a monomer when dissolved in cyclohexane. The Ga–Ga bond in **23.22** possesses a bond order of less than 1. Reduction of **23.22** by Na leads to $Na_2[RGaGaR]$, in which the dianion retains the *trans*-bent geometry of **23.22**. The Ga–Ga bond length is 235 pm, significantly shorter than in **23.22**. The salt $Na_2[RGaGaR]$ was first prepared from the reaction of $RGaCl_2$ and Na in Et_2O, and it has been proposed that $[RGaGaR]^{2-}$ contains a gallium–gallium triple bond. The nature of this bonding has been the subject of intense theoretical interest. On the one hand, there is support for a Ga≡Ga formulation, while on the other, it is concluded that factors such as $Ga{-}Na^+{-}Ga$ interactions contribute to the short Ga–Ga distance. More recent experimental observations indicate that the Ga–Ga interaction in $Na_2[RGaGaR]$ is best

R' = ^{i}Pr, ^{t}Bu or H
R'' = H or ^{i}Pr

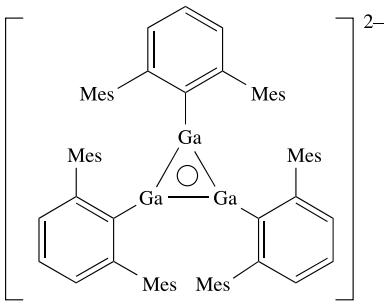
(23.21)

Ga–Ga = 263 pm

(23.22)

described as consisting of a single bond, augmented both by Ga–Na^{+}–Ga interactions and by the weak interaction that is present in the precursor **23.22**.[†]

The Ga(I) chemistry described above must be compared with the following observations for In and Tl, in which the nature of the organic group R plays a critical role. The reaction of InCl with LiR when R = C_6H_3-2,6-(C_6H_2-2,4,6-$^{i}Pr_3$)$_2$ yields RIn, an analogue of compound **23.21** with R' = ^{i}Pr. The monomeric nature of RIn in the solid state has been confirmed by X-ray diffraction data. However, when R = C_6H_3-2,6-(C_6H_3-2,6-$^{i}Pr_2$)$_2$, monomeric RIn exists in cyclohexane solutions, but dimeric RInInR is present in the solid state. The thallium analogue of compound **23.22** is prepared by reaction 23.35. Dimeric RTlTlR (Fig. 23.12b) has the same *trans*-bent structure as its gallium and indium analogues. In hydrocarbon solvents, the dimer dissociates into monomers, consistent with a weak Tl–Tl bond. The monomer can be stabilized by formation of the adduct RTl·B(C_6F_5)$_3$. If R is C_6H_3-2,6-(C_6H_3-2,6-Me_2)$_2$, reaction of LiR with TlCl produces RTl in solution, but this crystallizes as a trimer containing a triangular Tl_3 unit. Overall, these data illustrate how subtle changes in the organic group can lead to (not readily predictable) structural variations of the organometallic species in solution and the solid state.



$$2\mathrm{LiR} + 2\mathrm{TlCl} \xrightarrow[-\mathrm{LiCl}]{\mathrm{Et_2O,\ 195\ K}} 2\mathrm{RTl} \longrightarrow \mathrm{RTlTlR}$$

R = C_6H_3-2,6-(C_6H_3-2,6-$^{i}Pr_2$)$_2$ — in solid state

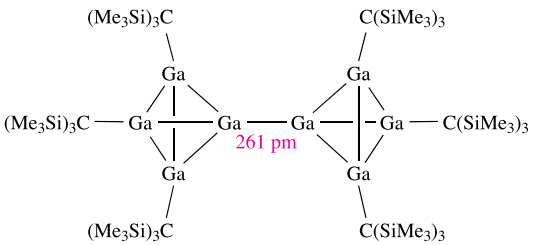
[†] For further details, see: J. Su, X.-W. Li, R.C. Crittendon and G.H. Robinson (1997) *J. Am. Chem. Soc.*, vol. 119, p. 5471; G.H. Robinson (1999) *Acc. Chem. Res.*, vol. 32, p. 773; N.J. Hardman, R.J. Wright, A.D. Phillips and P.P. Power (2003) *J. Am. Chem. Soc.*, vol. 125, p. 2667.

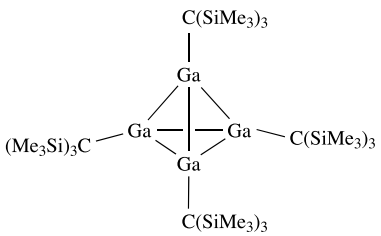


The 2,6-dimesitylphenyl substituent is also extremely sterically demanding, and reduction of (2,6-$Mes_2C_6H_3$)$GaCl_2$ with Na yields Na_2[(2,6-$Mes_2C_6H_3$)$_3Ga_3$]. The [(2,6-$Mes_2C_6H_3$)$_3Ga_3$]$^{2-}$ anion possesses the cyclic structure (**23.23**) and is a 2π-electron aromatic system.

Mes = 2,4,6-$Me_3C_6H_2$

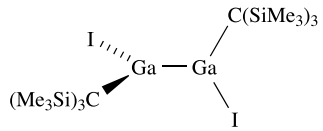
(23.23)

In eq. 13.51, we illustrated the use of the metastable GaBr as a precursor to multinuclear Ga-containing species. Gallium(I) bromide has also been used as a precursor to a number of organogallium clusters. For example, one of the products of the reaction of GaBr with $(Me_3Si)_3CLi$ in toluene at 195 K is **23.24**.



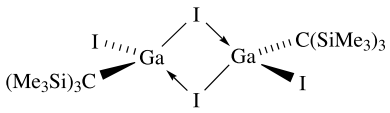
average Ga–Ga in tetrahedral cluster = 263 pm

(23.24)



Worked example 23.3 Reactions of {$(Me_3Si)_3C$}$_4E_4$ (E = Ga or In)

The reaction of the tetrahedral cluster {$(Me_3Si)_3C$}$_4Ga_4$ with I_2 in boiling hexane results in the formation of {$(Me_3Si)_3CGaI$}$_2$ and {$(Me_3Si)_3CGaI_2$}$_2$. In each compound there is only one Ga environment. Suggest structures for these compounds and state the oxidation state of Ga in the starting material and products.



The starting cluster is a gallium(I) compound:

I_2 oxidizes this compound and possible oxidation states are Ga(II) (e.g. in a compound of type $R_2Ga{-}GaR_2$) and Ga(III). $\{(Me_3Si)_3CGaI\}_2$ is related to compounds of type $R_2Ga{-}GaR_2$; steric factors may contribute towards a non-planar conformation:

Further oxidation by I_2 results in the formation of the Ga(III) compound $\{(Me_3Si)_3CGaI_2\}_2$ and a structure consistent with equivalent Ga centres is:

Self-study exercises

1. The Br_2 oxidation of $\{(Me_3Si)_3C\}_4In_4$ leads to the formation of the In(II) compound $\{(Me_3Si)_3C\}_4In_4Br_4$ in which each In atom retains a tetrahedral environment. Suggest a structure for the product.
2. $\{(Me_3Si)_3CGaI\}_2$ represents a Ga(II) compound of type $R_2Ga_2I_2$. However, 'Ga_2I_4', which may appear to be a related compound, is ionic. Comment on this difference.
3. A staggered conformation is observed in the solid state for $\{(Me_3Si)_3CGaI\}_2$. It has been suggested that a contributing factor may be hyperconjugation involving Ga–I bonding electrons. What acceptor orbital is available for hyperconjugation, and how does this interaction operate?

[*Ans.* W. Uhl *et al.* (2003) *Dalton Trans.*, p. 1360.]

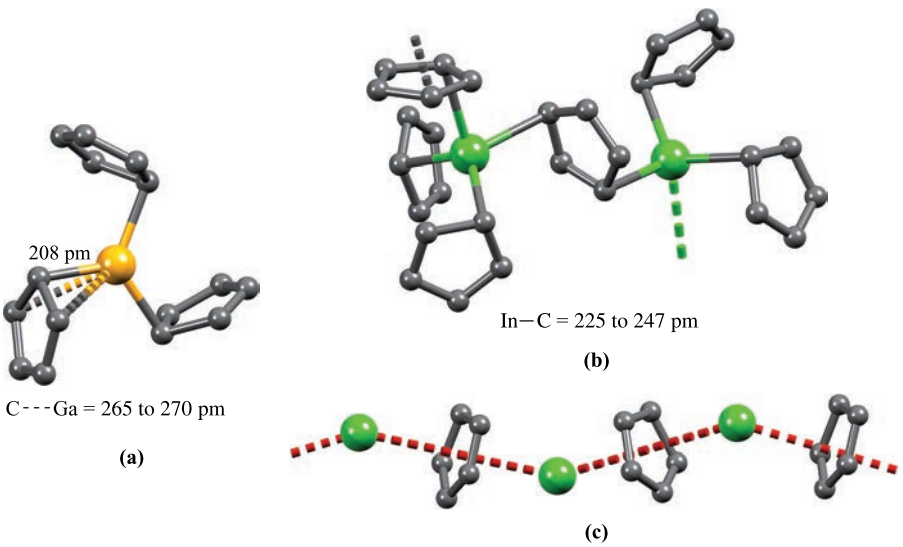
Cyclopentadienyl complexes illustrate the increase in stability of the M(I) oxidation state as group 13 is descended, a consequence of the thermodynamic 6*s* inert pair effect (see Box 13.4). Cyclopentadienyl derivatives of Ga(III) which have been prepared (eqs. 23.36 and 23.37) and structurally characterized include Cp_3Ga and $CpGaMe_2$.

$$GaCl_3 + 3Li[Cp] \longrightarrow Cp_3Ga + 3LiCl \qquad (23.36)$$

$$Me_2GaCl + Na[Cp] \longrightarrow CpGaMe_2 + NaCl \qquad (23.37)$$

The structure of $CpGaMe_2$ resembles that of $CpAlMe_2$ (Fig. 23.9a), and Cp_3Ga is monomeric with three κC^1-Cp groups bonded to trigonal planar Ga (Fig. 23.13a). The In(III) compound Cp_3In is prepared from NaCp and $InCl_3$, but is structurally different from Cp_3Ga. Solid Cp_3In contains polymeric chains in which each In atom is distorted tetrahedral (Fig. 23.13b).

The reaction of $(\eta^5\text{-}C_5Me_5)_3Ga$ with HBF_4 results in the formation of $[(C_5Me_5)_2Ga]^+[BF_4]^-$. In solution, the C_5Me_5 groups are fluxional down to 203 K, but in the solid state the complex is a dimer (**23.25**) containing $[(\kappa C^1\text{-}C_5Me_5)(\eta^3\text{-}C_5Me_5)Ga]^+$ ions. The structure of $[(C_5Me_5)_2Ga]^+$



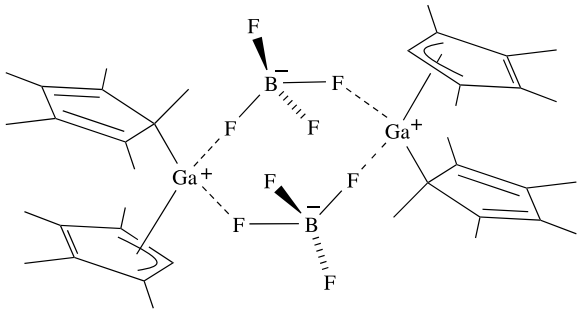


Fig. 23.13 The solid state structures (X-ray diffraction) of (a) monomeric $(\kappa C^1\text{-Cp})_3Ga$ [O.T. Beachley *et al.* (1985) *Organometallics*, vol. 4, p. 751], (b) polymeric Cp_3In [F.W.B. Einstein *et al.* (1972) *Inorg. Chem.*, vol. 11, p. 2832] and (c) polymeric CpIn [O.T. Beachley *et al.* (1988) *Organometallics*, vol. 7, p. 1051]; the zigzag chain is emphasized by the red hashed line. Hydrogen atoms are omitted for clarity; colour code: Ga, yellow; In, green; C, grey.

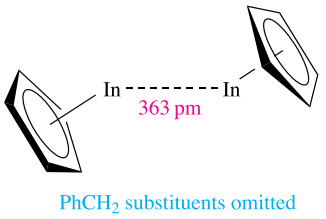
contrasts with that of $[(C_5Me_5)_2Al]^+$, in which the C_5-rings are coparallel.



(23.25)

We saw earlier that gallium(I) halides can be used to synthesize RGa compounds (**23.21**). Similarly, metastable solutions of GaCl have been used to prepare $(C_5Me_5)Ga$ by reactions with $(C_5Me_5)Li$ or $(C_5Me_5)_2Mg$. An alternative route is the reductive dehalogenation of $(C_5Me_5)GaI_2$ using potassium with ultrasonic activation. In the gas phase and in solution, $(C_5Me_5)Ga$ is monomeric, but in the solid state, hexamers are present.

On moving down group 13, the number of M(I) cyclopentadienyl derivatives increases, with a wide range being known for Tl(I). The condensation of In vapour (at 77 K) onto C_5H_6 gives CpIn, and CpTl is readily prepared by reaction 23.38.

$$C_5H_6 + TlX \xrightarrow{KOH/H_2O} CpTl + KX \qquad \text{e.g. X = halide} \qquad (23.38)$$

Both CpIn and CpTl are monomeric in the gas phase, but in the solid, they possess the polymeric chain structure shown in Fig. 23.13c. The cyclopentadienyl derivatives $(C_5R_5)M$ (M = In, Tl) are structurally diverse in the solid state, e.g. for $R = PhCH_2$ and M = In or Tl, 'quasi-dimers' **23.26** are present (there may or may not be a meaningful metal–metal interaction), and $(\eta^5\text{-}C_5Me_5)In$ forms hexameric clusters. An important reaction of $(\eta^5\text{-}C_5Me_5)In$ is with CF_3SO_3H which gives the triflate salt of In^+. The salt $In[O_2SCF_3]$ is air-sensitive and hygroscopic but is, nonetheless, a convenient source of indium(I) as an alternative to In(I) halides.

(23.26)

One use of CpTl is as a cyclopentadienyl transfer reagent to *d*-block metal ions, but it can also act as an acceptor of Cp^-, reacting with Cp_2Mg to give $[Cp_2Tl]^-$. This can be isolated as the salt $[CpMgL][Cp_2Tl]$ upon the addition of the chelating ligand $L = Me_2NCH_2CH_2NMeCH_2CH_2NMe_2$. The anion $[Cp_2Tl]^-$ is isoelectronic with Cp_2Sn and possesses a structure in which the η^5-Cp rings are mutually tilted. The tilt angle (defined in Fig. 23.14c for the structurally related Cp_2Si) is 157°. Although this ring orientation implies the presence of a stereochemically active lone pair, it has been shown theoretically that there is only a small energy difference ($3.5\,kJ\,mol^{-1}$) between this structure and one in which the η^5-Cp rings are parallel (i.e. as in Fig. 23.14a). We return to this point at the end of the next section.

23.5 Group 14

Organo-compounds of the group 14 elements include some important commercial products, including polysiloxanes (*silicones*) discussed in Section 14.10 and Box 14.12. Organotin compounds are employed as polyvinylchloride (PVC) stabilizers (against degradation by light and heat), antifouling paints on ships, wood preservatives and agricultural pesticides (see Box 23.4). Leaded motor fuels contain the anti-knock agent Et_4Pb, although this use

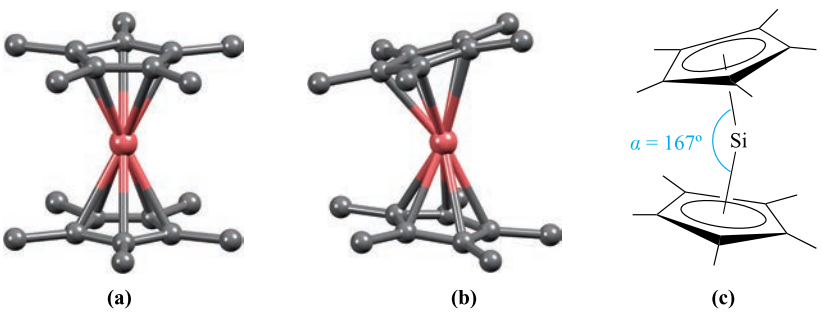


Fig. 23.14 The solid state structure of $(\eta^5\text{-}C_5Me_5)_2Si$ contains two independent molecules. (a) In the first molecule, the cyclopentadienyl rings are co-parallel, while (b) in the other molecule they are mutually tilted; (c) the tilt angle is measured as angle α [P. Jutzi *et al.* (1986) *Angew. Chem. Int. Ed.*, vol. 25, p. 164]. Hydrogen atoms are omitted for clarity; colour code: Si, pink; C, grey.

has declined on environmental grounds (see Fig. 14.3). Several general properties of the organo-derivatives of the group 14 elements, E, are as follows:

- in most compounds, the group 14 element is tetravalent;
- the E−C bonds are generally of low polarity;
- their stability towards all reagents decreases from Si to Pb;
- in contrast to the group 13 organometallics, derivatives of the group 14 elements are less susceptible to nucleophilic attack.

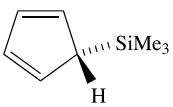
Silicon

Silicon tetraalkyl and tetraaryl derivatives (R_4Si), as well as alkyl or aryl silicon halides (R_nSiCl_{4-n}, $n = 1$–3) can be prepared by reaction types 23.39–23.43. Note that variation in stoichiometry provides flexibility in synthesis, although the product specificity may be influenced by steric requirements of the organic substituents. Reaction 23.39 is used industrially (the *Rochow* or *Direct process*).

$$n\text{MeCl} + \underset{\text{alloy}}{\text{Si/Cu}} \xrightarrow{573\text{ K}} \text{Me}_n\text{SiCl}_{4-n} \qquad (23.39)$$

$$\text{SiCl}_4 + 4\text{RLi} \longrightarrow \text{R}_4\text{Si} + 4\text{LiCl} \qquad (23.40)$$

$$\text{SiCl}_4 + \text{RLi} \longrightarrow \text{RSiCl}_3 + \text{LiCl} \qquad (23.41)$$



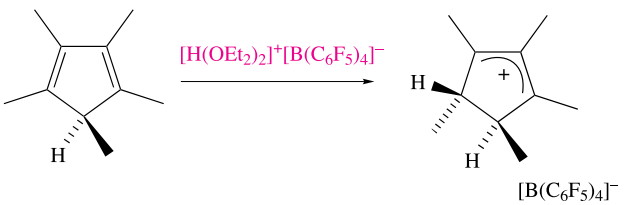
$$\text{SiCl}_4 + 2\text{RMgCl} \xrightarrow{\text{Et}_2\text{O}} \text{R}_2\text{SiCl}_2 + 2\text{MgCl}_2 \qquad (23.42)$$

$$\text{Me}_2\text{SiCl}_2 + {}^t\text{BuLi} \longrightarrow {}^t\text{BuMe}_2\text{SiCl} + \text{LiCl} \qquad (23.43)$$

The structures of the products of reactions 23.39–23.43 are all similar: monomeric, with tetrahedrally sited Si and resembling their C analogues.

Silicon−carbon single bonds are relatively strong (318 kJ mol^{-1}) and R_4Si derivatives possess high thermal stabilities. The stability of the Si−C bond is further illustrated by the fact that chlorination of Et_4Si gives $(ClCH_2CH_2)_4Si$, in contrast to the chlorination of R_4Ge or R_4Sn which yields R_nGeCl_{4-n} or R_nSnCl_{4-n} (see eq. 23.53). An important reaction of Me_nSiCl_{4-n} ($n = 1$–3) is hydrolysis to produce polysiloxanes (e.g. eq. 23.44 and see Section 14.10 and Box 14.12).

$$\left.\begin{aligned}\text{Me}_3\text{SiCl} + \text{H}_2\text{O} &\longrightarrow \text{Me}_3\text{SiOH} + \text{HCl}\\ 2\text{Me}_3\text{SiOH} &\longrightarrow \text{Me}_3\text{SiOSiMe}_3 + \text{H}_2\text{O}\end{aligned}\right\} \qquad (23.44)$$



(23.27)

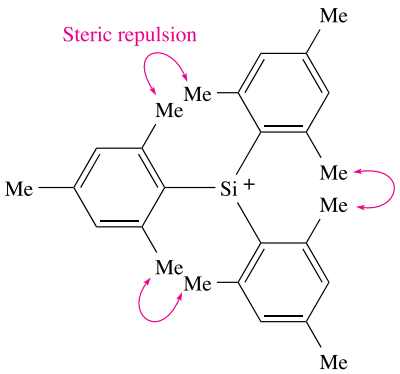
The reaction of Me_3SiCl with NaCp leads to **23.27**, in which the cyclopentadienyl group is κC^1. Related κC^1-complexes include $(\kappa C^1\text{-}C_5Me_5)_2SiBr_2$ which reacts with anthracene/potassium to give the diamagnetic *silylene*

Fig. 23.15 The structure of the $[(\eta^5\text{-}C_5Me_5)Si]^+$ cation present in the compound $[(\eta^5\text{-}C_5Me_5)Si][B(C_6F_5)_4]$, determined by X-ray diffraction [P. Jutzi *et al.* (2004) *Science*, vol. 305, p. 849]. Hydrogen atoms are omitted; colour code: Si, pink; C, grey.

$(\eta^5\text{-}C_5Me_5)_2Si$. In the solid state, two independent molecules are present (Fig. 23.14) which differ in the relative orientations of the cyclopentadienyl rings. In one molecule, the two C_5-rings are parallel and staggered (compare Cp_2Mg) whereas in the other, they are tilted. We return to this at the end of Section 23.5. Reaction 23.45 shows the formation of the proton-transfer agent $[C_5Me_5H_2]^+[B(C_6F_5)_4]^-$. This reagent removes one of the $[\eta^5\text{-}C_5Me_5]^-$ ligands from $(\eta^5\text{-}C_5Me_5)_2Si$ (reaction 23.46) to give the $[(\eta^5\text{-}C_5Me_5)Si]^+$ cation (Fig. 23.15).[†] This and the related $[(\eta^5\text{-}C_5{}^i\text{Pr}_5)Si]^+$ cation are important in being the only stable derivatives of the $[HSi]^+$ ion which has been observed in the solar spectrum, and is thought to be present in interstellar space.

(23.45)

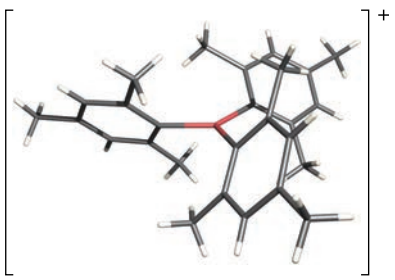
$$[C_5Me_5H_2]^+[B(C_6F_5)_4]^- + (\eta^5\text{-}C_5Me_5)_2Si \xrightarrow{CH_2Cl_2} [(\eta^5\text{-}C_5Me_5)Si]^+[B(C_6F_5)_4]^- + 2Me_5C_5H \qquad (23.46)$$



The reactions between R_2SiCl_2 and alkali metals or alkali metal naphthalides give *cyclo*-$(R_2Si)_n$ by loss of Cl^- and Si−Si bond formation. Bulky R groups favour small rings (e.g. $(2,6\text{-}Me_2C_6H_3)_6Si_3$ and $^t\text{Bu}_6Si_3$) while smaller R substituents encourage the formation of large rings (e.g. $Me_{12}Si_6$, $Me_{14}Si_7$ and $Me_{32}Si_{16}$). Reaction 23.47 is designed to provide a specific route to a particular ring size.

$$Ph_2SiCl_2 + Li(SiPh_2)_5Li \longrightarrow \textit{cyclo}\text{-}Ph_{12}Si_6 + 2LiCl \qquad (23.47)$$

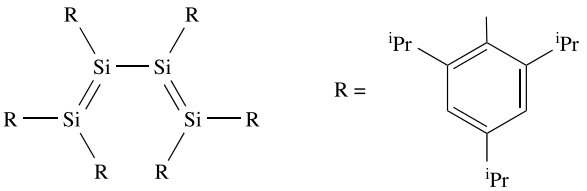
In Section 9.9, we introduced the weakly coordinating carbaborane anions $[CHB_{11}R_5X_6]^-$ (R = H, Me, Cl and



[†] P. Jutzi (2014) *Chem. Eur. J.*, vol. 20, p. 9192 – 'The pentamethylcyclopentadienylsilicon(II) cation: synthesis, characterization and reactivity'.

X = Cl, Br, I), and Fig. 9.6c showed the structure of $^{i}Pr_3Si(CHB_{11}H_5Cl_6)$ which approaches that of the ion-pair $[^{i}Pr_3Si]^+[CHB_{11}H_5Cl_6]^-$. The reaction of the strong electrophile $Et_3Si(CHB_{11}Me_5Br_6)$ with $Mes_3Si(CH_2CH{=}CH_2)$ (Mes = mesityl) gives $[Mes_3Si][CHB_{11}Me_5Br_6]$. In the solid state, this contains well-separated $[Mes_3Si]^+$ and $[CHB_{11}Me_5Br_6]^-$ ions, giving the first example of a free silylium ion. The trigonal planar Si centre is consistent with sp^2 hybridization, but steric hindrance between the mesityl groups leads to a deviation from the overall planarity that would be needed to maximize C 2*p*–Si 3*p* π-overlap (diagram **23.28**). The actual arrangement of the mesityl groups (**23.29**) balances steric and electronic requirements.

Planar arrangement of aryl groups would optimize π-bonding



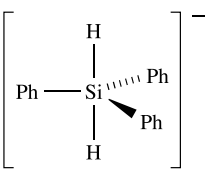
(23.28)

(23.29)

Silylenes, R_2Si (analogues of carbenes), can be formed by a variety of methods, for example, the photolysis of cyclic or linear organopolysilanes. As expected, R_2Si species are highly reactive, undergoing many reactions analogous to those typical of carbenes. Stabilization of R_2Si can be achieved by using sufficiently bulky substituents, and electron diffraction data confirm the bent structure of $\{(Me_3Si)_2HC\}_2Si$ ($\angle C{-}Si{-}C = 97°$).

In Section 14.3, we discussed the use of bulky substituents to stabilize $R_2Si{=}SiR_2$ and $RSi{\equiv}SiR$ compounds. The sterically demanding 2,4,6-$^{i}Pr_3C_6H_2$ group has been used to stabilize **23.30**, the first example of a compound containing conjugated Si=Si bonds. An unusual feature of **23.30** is the preference for the s-*cis* conformation in both solution and the solid state.

(23.30)



The spatial arrangement of two conjugated double bonds about the central single bond is described as being **s-*cis*** and **s-*trans***, defined as follows:

Worked example 23.4 Organosilicon hydrides

The reaction of Ph_2SiH_2 with potassium metal in 1,2-dimethoxyethane (DME) in the presence of 18-crown-6 yields a salt of $[Ph_3SiH_2]^-$ in which the hydride ligands are *trans* to each other. The salt has the formula [X][Ph_3SiH_2]. The solution ^{29}Si NMR spectrum shows a triplet (J = 130 Hz) at δ −74 ppm. Explain the origin of the triplet. What signals arising from the anion would you expect to observe in the solution ^{1}H NMR spectrum of [X][Ph_3SiH_2]?

First, draw the expected structure of $[Ph_3SiH_2]^-$. The question states that the hydride ligands are *trans*, and a trigonal bipyramidal structure is consistent with the VSEPR model:

In the ^{29}Si NMR spectrum, the triplet arises from coupling of the ^{29}Si nucleus to two equivalent ^{1}H ($I = \frac{1}{2}$) nuclei.

Signals in the ^{1}H NMR spectrum that can be assigned to $[Ph_3SiH_2]^-$ arise from the phenyl and hydride groups. The three Ph groups are equivalent (all equatorial) and, in theory, give rise to three multiplets (δ 7–8 ppm) for

ortho-, *meta*- and *para*-H atoms. In practice, these signals may overlap. The equivalent hydride ligands give rise to one signal. Silicon has one isotope that is NMR active: ^{29}Si, 4.7%, $I = \frac{1}{2}$ (see Table 14.1). We know from the ^{29}Si NMR spectrum that there is spin–spin coupling between the directly bonded ^{29}Si and ^{1}H nuclei. Considering these protons in the ^{1}H NMR spectrum, 95.3% of the protons are attached to non-spin active Si and give rise to a singlet; 4.7% are attached to ^{29}Si and give rise to a doublet ($J = 130$ Hz). The signal will appear as a small doublet superimposed on a singlet (see Fig. 4.24).

Self-study exercises

These questions refer to the experiment described in the worked example.

1. Suggest how you might prepare Ph_2SiH_2 starting from a suitable organosilicon halide.
   [*Ans.* Start from Ph_2SiCl_2; use method of eq. 10.39]
2. Draw the structure of 18-crown-6. What is its role in this reaction? Suggest an identity for cation $[\mathbf{X}]^+$.
   [*Ans.* See Fig. 11.9 and discussion]

[For the original literature, see: M.J. Bearpark *et al.* (2001) *J. Am. Chem. Soc.*, vol. 123, p. 7736.]

Germanium

There are similarities between the methods of preparation of compounds with Ge−C and Si−C bonds: compare reaction 23.48 with 23.39, 23.49 with 23.41, 23.50 with 23.42, and 23.51 with the synthesis of $Me_3Si(\kappa C^1\text{-Cp})$.

$$n\text{RCl} + \text{Ge/Cu} \xrightarrow{\Delta} \text{R}_n\text{GeCl}_{4-n} \quad \text{R = alkyl or aryl} \tag{23.48}$$

$$\text{GeCl}_4 + \text{RLi} \longrightarrow \text{RGeCl}_3 + \text{LiCl} \tag{23.49}$$

$$\text{GeCl}_4 + 4\text{RMgCl} \xrightarrow{\text{Et}_2\text{O}} \text{R}_4\text{Ge} + 4\text{MgCl}_2 \tag{23.50}$$

$$\text{R}_3\text{GeCl} + \text{Li[Cp]} \longrightarrow \text{R}_3\text{Ge}(\kappa C^1\text{-Cp}) + \text{LiCl} \tag{23.51}$$

Tetraalkyl and tetraaryl germanium compounds possess monomeric structures with tetrahedrally sited germanium. They are thermally stable and tend to be chemically inert. Halogenation requires a catalyst (eqs. 23.52 and 23.53). Chlorides can be obtained from the corresponding bromides or iodides by halogen exchange (eq. 23.54). The presence of halo-substituents increases reactivity (e.g. eq. 23.55) and makes the halo-derivatives synthetically more useful than R_4Ge compounds.

$$2\text{Me}_4\text{Ge} + \text{SnCl}_4 \xrightarrow{\text{AlCl}_3} 2\text{Me}_3\text{GeCl} + \text{Me}_2\text{SnCl}_2 \tag{23.52}$$

$$\text{R}_4\text{Ge} + \text{X}_2 \xrightarrow{\text{AlX}_3} \text{R}_3\text{GeX} + \text{RX} \quad (\text{X = Br, I}) \tag{23.53}$$

$$\text{R}_3\text{GeBr} + \text{AgCl} \longrightarrow \text{R}_3\text{GeCl} + \text{AgBr} \tag{23.54}$$

$$\text{R}_3\text{GeX} \xrightarrow{\text{KOH/EtOH, H}_2\text{O}} \text{R}_3\text{GeOH} \tag{23.55}$$

A simple method of preparing $RGeCl_3$ (R = alkyl or alkenyl) is by the passage of $GeCl_4$ and RCl vapours over grains of Ge heated at 650–800 K. The reaction proceeds by intermediate carbene-like $GeCl_2$ which inserts into a C–Cl bond (eq. 23.56).

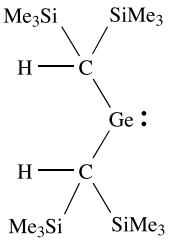
$$\text{Ge} + \text{GeCl}_4 \longrightarrow 2\{\text{Cl}_2\text{Ge:}\} \xrightarrow{2\text{RCl}} 2\text{RGeCl}_3 \tag{23.56}$$

The availability of Ge(II) halides (see Section 14.8) means that the synthesis of $(\eta^5\text{-}C_5R_5)_2Ge$ derivatives does not require a reduction step as was the case for the silicon analogues described above. Reaction 23.57 is a general route to $(\eta^5\text{-}C_5R_5)_2Ge$, which exist as monomers in the solid, solution and vapour states.

$$\text{GeX}_2 + 2\text{Na}[\text{C}_5\text{R}_5] \longrightarrow (\eta^5\text{-}\text{C}_5\text{R}_5)_2\text{Ge} + 2\text{NaX} \quad (\text{X = Cl, Br}) \tag{23.57}$$

X-ray diffraction studies for Cp_2Ge and $\{\eta^5\text{-}C_5(CH_2Ph)_5\}_2Ge$ confirm the bent structure type illustrated in Figs. 23.14b and c for $(\eta^5\text{-}C_5Me_5)_2Si$. However, in $\{\eta^5\text{-}C_5Me_4(SiMe_2{}^tBu)\}_2Ge$, the two C_5-rings are coparallel and mutually staggered. The preferences for tilted versus coparallel rings are discussed further at the end of Section 23.5. Reaction 23.58 generates $[(\eta^5\text{-}C_5Me_5)Ge]^+$ which is structurally analogous to $[(\eta^5\text{-}C_5Me_5)Si]^+$ (Fig. 23.15). However, $[(\eta^5\text{-}C_5Me_5)Ge]^+$ (like $[(\eta^5\text{-}C_5Me_5)Sn]^+$ and $[(\eta^5\text{-}C_5Me_5)Pb]^+$) exists in the presence of more nucleophilic counter-ions than does $[(\eta^5\text{-}C_5Me_5)Si]^+$, consistent with the increasing stability of the +2 oxidation state on descending group 14.

$$(\eta^5\text{-}\text{C}_5\text{Me}_5)_2\text{Ge} + \text{HBF}_4\cdot\text{Et}_2\text{O} \longrightarrow [(\eta^5\text{-}\text{C}_5\text{Me}_5)\text{Ge}][\text{BF}_4] + \text{C}_5\text{Me}_5\text{H} + \text{Et}_2\text{O} \tag{23.58}$$



Organogermanium(II) compounds are a growing family. Germylenes (R_2Ge) include the highly reactive Me_2Ge which can be prepared by reaction 23.59. Photolysis reaction 23.60 shows a general strategy to form R_2Ge.

$$\text{Me}_2\text{GeCl}_2 + 2\text{Li} \xrightarrow{\text{THF}} \text{Me}_2\text{Ge} + 2\text{LiCl} \tag{23.59}$$

$$\text{Me}(\text{GeR}_2)_{n+1}\text{Me} \xrightarrow{h\nu} \text{R}_2\text{Ge} + \text{Me}(\text{GeR}_2)_n\text{Me} \tag{23.60}$$

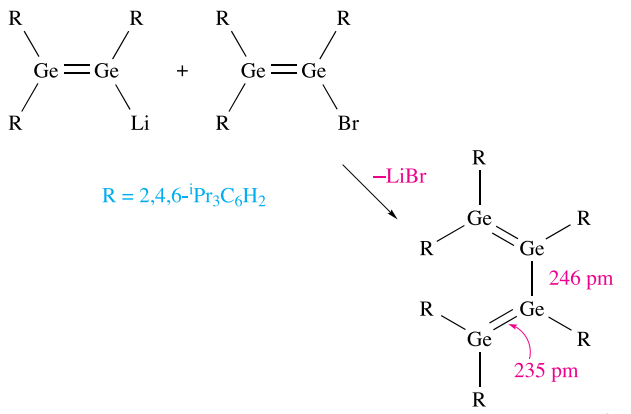
Using very sterically demanding R groups can stabilize the R_2Ge species. Thus, compound **23.31** is stable at room

temperature. The bent structure of $\{(Me_3Si)_2HC\}_2Ge$ has been confirmed by electron diffraction ($\angle C-Ge-C = 107°$).

(23.31)

Double bond formation between C and Ge was mentioned in Section 14.3, and the formation of Ge=Ge bonds to give digermenes can be achieved (eqs. 23.61 and 23.62) if particularly bulky substituents (e.g. 2,4,6-$Me_3C_6H_2$, 2,6-$Et_2C_6H_3$, 2,6-$^iPr_2C_6H_3$) are used to stabilize the system.

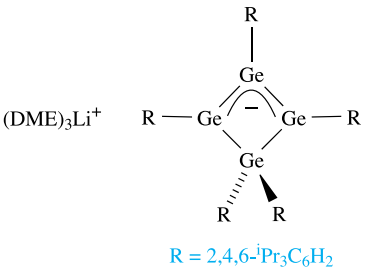
$$2RR'GeCl_2 \xrightarrow{LiC_{10}H_8,\ DME} RR'Ge{=}GeRR' + 4LiCl \qquad (23.61)$$



$LiC_{10}H_8$ = lithium naphthalide

$$2R_2Ge\{C(SiMe_3)_3\}_2 \xrightarrow{h\nu} 2\{R_2Ge{:}\} + (Me_3Si)_3CC(SiMe_3)_3$$

$$\downarrow$$



$$R_2Ge{=}GeR_2 \qquad (23.62)$$

Data for several structurally characterized digermenes confirm a non-planar Ge_2C_4-framework analogous to that observed for distannenes discussed in the next section (see Fig. 23.19). Digermenes are stable in the solid state in the absence of air and moisture, but in solution they show a tendency to dissociate into R_2Ge, the extent of dissociation depending on R. With 2,4,6-$^iPr_3C_6H_2$ as substituent, $R_2Ge{=}GeR_2$ remains as a dimer in solution and can be used to generate a tetragermabuta-1,3-diene (scheme 23.63). The precursors are made *in situ* from $R_2Ge{=}GeR_2$ by treatment with Li or with Li followed by 2,4,6-$Me_3C_6H_2Br$.

(23.63)

Conditions are critical in the above reaction because prolonged reaction of $R_2Ge{=}GeR_2$ (R = 2,4,6-$^iPr_3C_6H_2$) with Li in 1,2-dimethoxyethane (DME) results in the formation of **23.32**.

(23.32)

The reduction of R_2GeGeR_2 to $[R_2GeGeR_2]^{2-}$ is more difficult than conversion of RGeGeR to $[RGeGeR]^{2-}$ (see below), but it can be achieved with careful choice of substituents and reaction conditions (eq. 23.64). The solid state structures of these salts illustrate the influential role of the metal ions. Not only do the ions interact with the Ge_2 unit (shown for the K^+ salt in Fig. 23.16), but the geometry of the central $Ge_2H_2C_2$-unit varies with M^+. The Li^+ salt contains a planar $Ge_2H_2C_2$-unit, whereas it is *trans*-trigonal pyramidal in the K^+ salt (Fig. 23.16). In the Na^+ salt, the H atoms bridge the Ge–Ge bond.

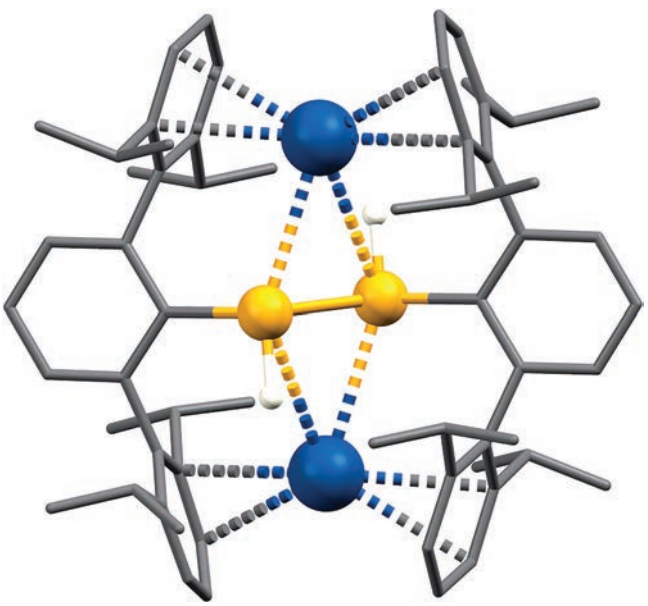


Fig. 23.16 The solid state structure (determined by X-ray diffraction) of $K_2[Ge_2H_2\{C_6H_3\text{-}2,6\text{-}(C_6H_3\text{-}2,6\text{-}^iPr_2)_2\}_2]$ with H atoms omitted except for those attached to the Ge atoms [A.F. Richards *et al.* (2004) *J. Am. Chem. Soc.*, vol. 126, p. 10530]. Hashed lines highlight the stabilizing influence of the K^+ ions. The organic framework is shown in stick-representation for clarity. Colour code: Ge, orange; K, blue; C, grey; H, white.

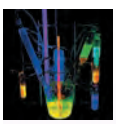
$$\mathrm{RHGeGeHR} \xrightarrow[\mathrm{M = Na\ or\ K\ in\ toluene}]{\mathrm{M = Li\ in\ Et_2O/THF}} \mathrm{M_2[RHGeGeHR]} \quad (23.64)$$

$\mathrm{R = C_6H_3\text{-}2,6\text{-}(C_6H_3\text{-}2,6\text{-}{}^{i}Pr_2)_2}$

The formation of RGeGeR has been achieved by using the extremely bulky substituent $\mathrm{R = 2,6\text{-}(2,6\text{-}{}^{i}Pr_2C_6H_3)_2C_6H_3}$. The solid state structure of RGeGeR shows a *trans*-bent conformation with a C–Ge–Ge bond angle of 129° and Ge–Ge bond length of 228.5 pm. Theoretical studies suggest a Ge–Ge bond order of ≈2.5. RGeGeR is formed by reduction of RGeCl using Li, Na or K. However, the conditions must be carefully controlled, otherwise the predominant products are the singly and doubly reduced derivatives $[\mathrm{RGeGeR}]^-$ (a radical anion) and $[\mathrm{RGeGeR}]^{2-}$. Analogous reactions occur when RSnCl is reduced. In both K[RGeGeR] and $\mathrm{Li_2}$[RGeGeR], a *trans*-bent geometry is observed, as in RGeGeR. Each cation is involved in significant interactions with the anion (i.e. as in Fig. 23.16).



Tin

Some features that set organotin chemistry apart from organosilicon or organogermanium chemistries are the:

- greater accessibility of the +2 oxidation state;
- greater range of possible coordination numbers;
- presence of halide bridges (see Section 14.8).

Reactions 23.65–23.67 illustrate synthetic approaches to $\mathrm{R_4Sn}$ compounds, and organotin halides can be prepared by routes equivalent to reactions 23.39 and 23.48, redistribution reactions from anhydrous $\mathrm{SnCl_4}$ (eq. 23.68), or from Sn(II) halides (eq. 23.69). Using $\mathrm{R_4Sn}$ in excess in reaction 23.68 gives a route to $\mathrm{R_3SnCl}$. Reaction 23.66 is used industrially for the preparation of tetrabutyltin and tetraoctyltin. Commercial applications of organotin compounds are highlighted in Box 23.4.

$$4\mathrm{RMgBr} + \mathrm{SnCl_4} \longrightarrow \mathrm{R_4Sn} + 4\mathrm{MgBrCl} \quad (23.65)$$

APPLICATIONS

Box 23.4 Commercial uses and environmental problems of organotin compounds

Organotin(IV) compounds have a wide range of applications, with catalytic and biocidal properties being of particular importance. There is an emerging interest in potential medicinal uses. The compounds below are selected examples:

- $\mathrm{{}^{n}Bu_3Sn(OAc)}$ (produced by reacting $\mathrm{{}^{n}Bu_3SnCl}$ and NaOAc) is an effective fungicide and bactericide; it also has applications as a polymerization catalyst.
- $\mathrm{{}^{n}Bu_2Sn(OAc)_2}$ (from $\mathrm{{}^{n}Bu_2SnCl_2}$ and NaOAc) is used as a polymerization catalyst and a stabilizer for PVC.
- $(\mathit{cyclo}\text{-}\mathrm{C_6H_{11}})_3\mathrm{SnOH}$ (formed by alkaline hydrolysis of the corresponding chloride) and $(\mathit{cyclo}\text{-}\mathrm{C_6H_{11}})_3\mathrm{Sn(OAc)}$ (produced by treating $(\mathit{cyclo}\text{-}\mathrm{C_6H_{11}})_3\mathrm{SnOH}$ with AcOH) are used widely as insecticides in fruit orchards and vineyards.
- $\mathrm{{}^{n}Bu_3SnO{}^{n}Sn{}^{n}Bu_3}$ (formed by aqueous NaOH hydrolysis of $\mathrm{{}^{n}Bu_3SnCl}$) has uses as an algicide, fungicide and wood-preserving agent.
- $\mathrm{{}^{n}Bu_3SnCl}$ (a product of the reaction of $\mathrm{{}^{n}Bu_4Sn}$ and $\mathrm{SnCl_4}$) is a bactericide and fungicide.
- $\mathrm{Ph_3SnOH}$ (formed by base hydrolysis of $\mathrm{Ph_3SnCl}$) is used as an agricultural fungicide for crops such as potatoes, sugar beet and peanuts.
- The cyclic compound $(\mathrm{{}^{n}Bu_2SnS})_3$ (formed by reacting $\mathrm{{}^{n}Bu_2SnCl_2}$ with $\mathrm{Na_2S}$) is used as a stabilizer for PVC.

Tributyltin derivatives have been used as antifouling agents, applied to the underside of ships' hulls to prevent the build-up of, for example, barnacles. Global legislation now bans or greatly restricts the use of organotin-based antifouling agents on environmental grounds. Environmental risks associated with the uses of organotin compounds as pesticides, fungicides and PVC stabilizers are also a cause for concern and are the subject of regular assessments. The toxicity of organotin compounds to aquatic life follows the order triorganotin > diorganotin > monoorganotin species.

$$SnCl_2 + Ph_2Hg \longrightarrow Ph_2SnCl_2 + Hg \quad (23.69)$$

Tetraorganotin compounds tend to be colourless liquids or solids which are quite stable to attack by water and air. The ease of cleavage of the Sn–C bonds depends upon the R group, with Bu_4Sn being relatively stable. In moving to the organotin halides, reactivity increases and the chlorides are useful as precursors to a range of organotin derivatives. Figure 23.17 gives selected reactions of R_3SnCl. The structures of R_4Sn compounds are all similar and contain tetrahedral Sn. However, the presence of halide groups leads to significant variation in solid state structure owing to the possibility of Sn–X–Sn bridge formation. In the solid state, Me_3SnF molecules are connected into zigzag chains by asymmetric, bent Sn–F–Sn bridges (**23.33**), each Sn being in a trigonal bipyramidal arrangement. The presence of bulky substituents may result in either a straightening of the ···Sn–F–Sn–F··· backbone (e.g. in Ph_3SnF) or in a monomeric structure (e.g. in $\{(Me_3Si)_3C\}Ph_2SnF$). In $(Me_3SiCH_2)_3SnF$ (Fig. 23.18a), the Me_3SiCH_2 substituents are very bulky, and the Sn–F distances are much

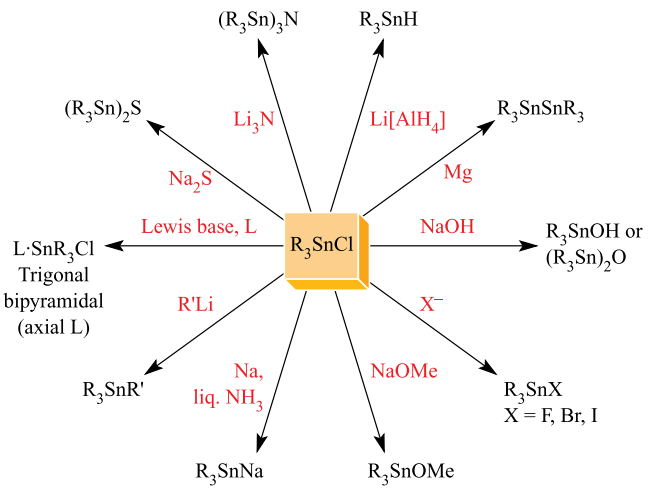

Fig. 23.17 Selected reactions of R_3SnCl; products such as R_3SnH, R_3SnNa and R_3SnSnR_3 are useful starting materials in organotin chemistry.

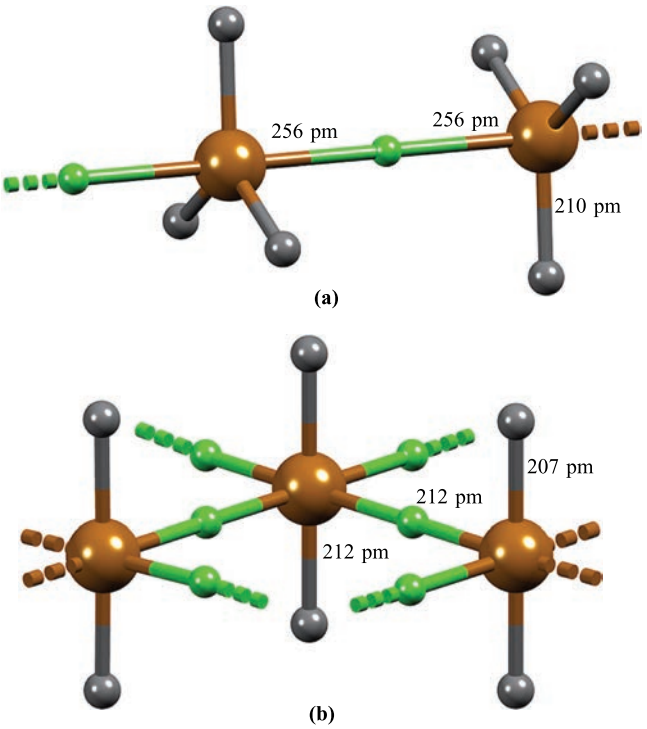

Fig. 23.18 The structures (X-ray diffraction) of (a) $(Me_3SiCH_2)_3SnF$ (only the methylene C atom of each Me_3SiCH_2 group is shown) in which the Sn–F distances are long and indicate the presence of $[(Me_3SiCH_2)_3Sn]^+$ cations interacting with F^- anions to give chains [L.N. Zakharov *et al.* (1983) *Kristallografiya*, vol. 28, p. 271], and (b) Me_2SnF_2 in which Sn–F–Sn bridge formation leads to the generation of sheets [E.O. Schlemper *et al.* (1966) *Inorg. Chem.*, vol. 5, p. 995]. Hydrogen atoms are omitted for clarity; colour code: Sn, brown; C, grey; F, green.

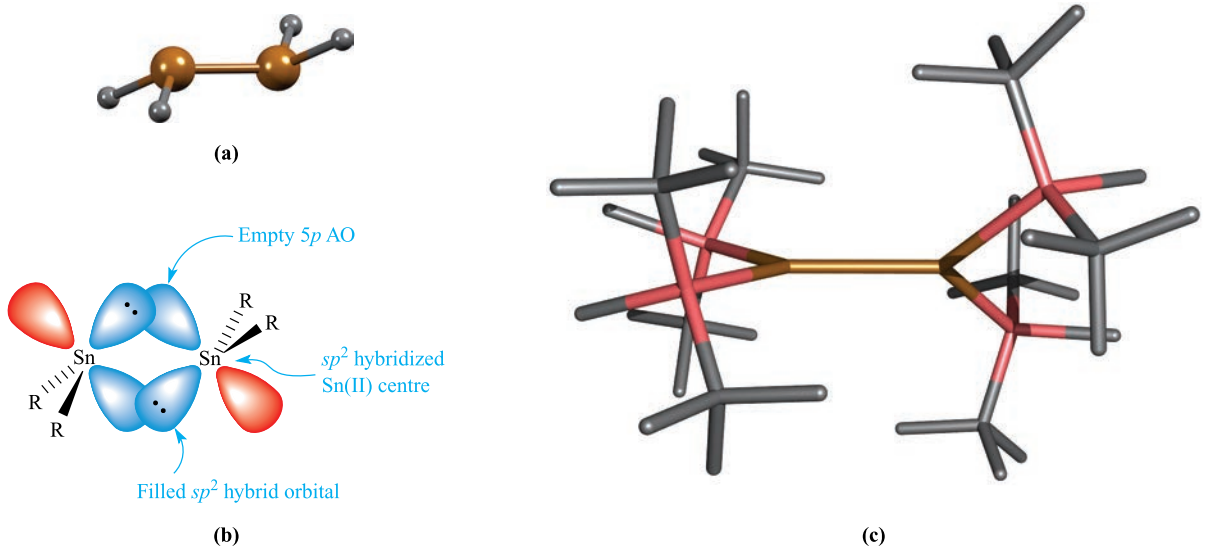
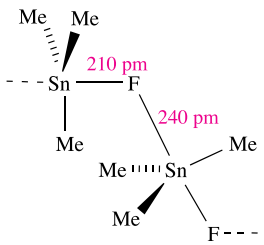
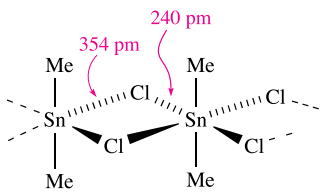
longer than the sum of the covalent radii. Solid state ^{119}Sn NMR spectroscopy and measurements of the ^{119}Sn–^{19}F spin–spin coupling constants provide a useful means of deducing the extent of molecular association in the absence of crystallographic data. Difluoro derivatives R_2SnF_2 tend to contain octahedral Sn in the solid state. In Me_2SnF_2, sheets of interconnected molecules are present (Fig. 23.18b). The tendency for association is less for the later halogens (F > Cl > Br > I). Thus, $MeSnBr_3$ and $MeSnI_3$ are monomeric, and, in contrast to Me_2SnF_2, Me_2SnCl_2 forms chains of the type shown in **23.34**. It has also been noted that the structure may be temperature dependent. Thus, at 108 K, crystalline $(cyclo\text{-}C_6H_{11})_3SnCl$ consists of chains with asymmetrical bridges; between 108 and 298 K, changes in the Sn–Cl bond length and the intermolecular separation (structures **23.35**) suggest a transition to a structure containing discrete molecules. Figure 23.17 illustrates the ability of R_3SnCl to act as a Lewis acid. Similarly, salts of, for example, $[Me_2SnF_4]^{2-}$ may be prepared and contain discrete octahedral anions.







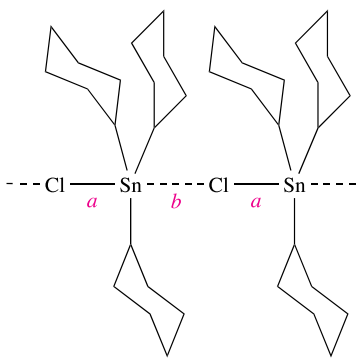


Fig. 23.19 (a) Representation of the structure of an R_2SnSnR_2 compound which possesses a non-planar Sn_2C_4 framework, and (b) proposed bonding scheme involving sp^2 hybridized tin, and overlap of occupied sp^2 hybrid orbitals with empty 5*p* atomic orbitals to give a weak Sn=Sn double bond. (c) The structure of the distannene $\{^tBu_2MeSi\}_4Sn_2$ (determined by X-ray diraction) [T. Fukawa *et al.* (2004) *J. Am. Chem. Soc.*, vol. 126, p. 11758]. For clarity, the structure is shown in a tube representation with H atoms omitted; colour code: Sn, brown; Si, pink; C, grey.

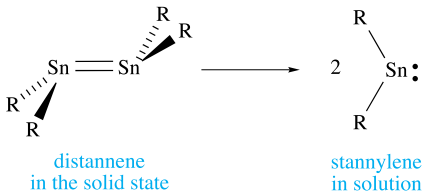
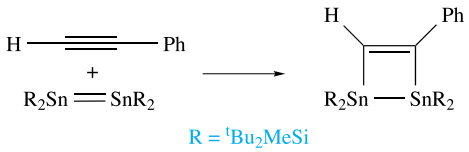
(23.34)

At 108 K: a = 246.6 pm
b = 300.8 pm



At 298 K: a = 241.5 pm
b = 329.8 pm

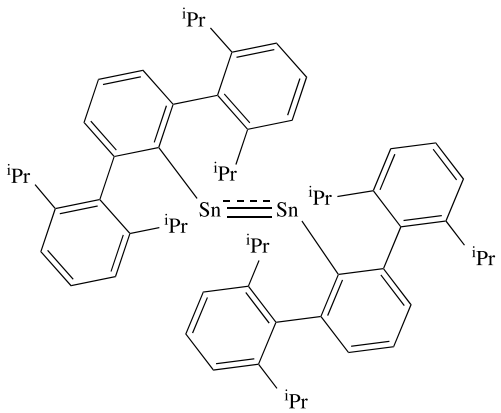
(23.35)



The reaction of $(2,4,6\text{-}^iPr_3C_6H_2)_3SnCH_2CH{=}CH_2$ with a strong electrophile in the presence of the weakly coordinating anion $[B(C_6F_5)_4]^-$ is a successful method of preparing a stannylium cation, $[R_3Sn]^+$. The approach parallels that used to prepare $[Mes_3Si]^+$, but stabilization of the stannylium ion requires more sterically demanding aryl groups. The structure of $[(2,4,6\text{-}^iPr_3C_6H_2)_3Sn]^+$ is similar to that of $[Mes_3Si]^+$ (**23.29**).

Tin(II) organometallics of the type R_2Sn, which contain Sn−C σ-bonds, are stabilized only if R is sterically demanding. For example, reaction of $SnCl_2$ with $Li[(Me_3Si)_2CH]$ gives $\{(Me_3Si)_2CH\}_2Sn$ which is monomeric in solution and dimeric in the solid state. The dimer (Fig. 23.19a) does not possess a planar Sn_2C_4 framework (i.e. it is *not* analogous to an alkene) and the Sn−Sn bond distance (276 pm) is too great to be consistent with a normal double bond. A bonding model involving overlap of filled sp^2 hybrids and vacant 5*p* atomic orbitals (Fig. 23.19b) has been suggested. Distannenes typically exist as dimers in the solid state, but dissociate into monomeric stannylenes in solution (eq. 23.70). However, $\{^tBu_2MeSi\}_4Sn_2$ (Fig. 23.19c) is an exception. The Sn–Sn bond is particularly short (267 pm), and each Sn centre is trigonal planar (sp^2 hybridized). The Sn_2Si_4-unit is twisted, and the deviation from planarity probably arises from steric factors. The presence of Sn=Sn double bond character in the solution species is exemplified by the cycloaddition reaction 23.71. The bonding scheme used for most distannenes (Fig. 23.19b) is not appropriate for $\{^tBu_2MeSi\}_4Sn_2$ and, instead, the bonding is viewed in terms of a σ-interaction supplemented by an out-of-plane *p*–*p* π-interaction; dispersion forces are also considered to be important.†

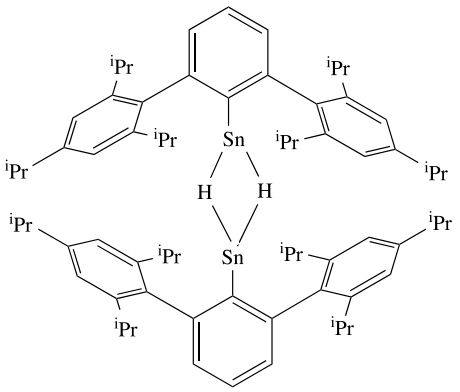
† For comments on bonding schemes in distannenes, see: V.Ya. Lee *et al.* (2006) *J. Am. Chem. Soc.*, vol. 126, p. 11643; J.-D. Guo, D.J. Liptrot, S. Nagese and P.P. Power (2015) *Chem. Sci.*, vol. 6, p. 6235.



(23.70)

(23.71)

The formation of the *trans*-bent RSnSnR (**23.36**) is achieved by using extremely bulky R groups. The Sn–Sn bond length is 267 pm and angle C–Sn–Sn is 125° and, as for the Ge analogue, theoretical results indicate that the bond order is ≈2.5.



(23.36)

Cyclopentadienyl Sn(II) derivatives $(\eta^5\text{-}C_5R_5)_2Sn$ can be prepared by reaction 23.72.

$$2Na[Cp] + SnCl_2 \longrightarrow (\eta^5\text{-}Cp)_2Sn + 2NaCl \qquad (23.72)$$

The structures of $(\eta^5\text{-}C_5R_5)_2Sn$ with various R groups form a series in which the tilt angle α (defined in Fig. 23.14 for $(\eta^5\text{-}C_5R_5)_2Si$) increases as the steric demands of R increase: $\alpha = 125°$ for R = H, 144° for R = Me, 180° for R = Ph. We consider the structures of group 14 metallocenes again at the end of Section 23.5. Under appropriate conditions, Cp_2Sn reacts with Cp^- to yield $[(\eta^5\text{-}Cp)_3Sn]^-$. This last reaction shows that Cp_2Sn can function as a Lewis *acid*.

Organotin(IV) hydrides such as $^nBu_3SnH$ (prepared by $LiAlH_4$ reduction of the corresponding $^nBu_3SnCl$) are widely used as reducing agents in organic synthesis. In contrast, the first organotin(II) hydride, RSnH, was reported only in 2000. It is made by reacting $^iBu_2AlH$ with RSnCl where R is the sterically demanding substituent shown in **23.37**. In the solid state, dimers (**23.37**) supported by hydride bridges (Sn···Sn = 312 pm) are present. The orange solid dissolves in Et_2O, hexane or toluene to give blue solutions, indicating that RSnH monomers exist in solution. This conclusion is based on the electronic spectroscopic properties ($\lambda_{max} = 608$ nm) which are similar to those of monomeric R_2Sn compounds.

(23.37)

Worked example 23.5 Organotin compounds

The reaction of $\{(Me_3Si)_3C\}Me_2SnCl$ with one equivalent of ICl gives compound A. Use the mass spectrometric and ^1H NMR spectroscopic data below to suggest an identity for A. Suggest what product might be obtained if an excess of ICl is used in the reaction.

A: δ 0.37 ppm (27H, s, $J(^{29}Si–^1H) = 6.4$ Hz); δ 1.23 ppm (3H, s, $J(^{117}Sn–^1H)$, $J(^{119}Sn–^1H) = 60, 62$ Hz). No parent peak observed in the mass spectrum; highest mass peak $m/z = 421$.

The ^1H NMR spectroscopic data show the presence of two proton environments in a ratio of 27 : 3. These integrals, along with the coupling constants, suggest the retention of an $(Me_3Si)_3C$ group and *one* Me substituent bonded directly to Sn. Iodine monochloride acts as a chlorinating agent, and one Me group is replaced by Cl. The mass spectrometric data are consistent with a molecular formula of $\{(Me_3Si)_3C\}MeSnCl_2$, with the peak at $m/z = 421$ arising from the ion $[\{(Me_3Si)_3C\}SnCl_2]^+$, i.e. the parent ion with loss of Me.

With an excess of ICl, the expected product is $\{(Me_3Si)_3C\}SnCl_3$.

Self-study exercises

These questions refer to the experiment described above. Additional data: see Table 14.1.

1. Use Appendix 5 to deduce how the peak at $m/z = 421$ in the mass spectrum confirms the presence of *two* Cl atoms in **A**. [*Hint*: Refer to Section 1.3]

2. Sketch the appearance of the ^{1}H NMR signal at δ 1.23 ppm in the spectrum of **A** and indicate where you would measure $J(^{117}\text{Sn}–^1\text{H})$ and $J(^{119}\text{Sn}–^1\text{H})$.
[*Hint*: Refer to Fig. 4.24]

3. In what coordination geometry do you expect the Sn atom to be sited in compound **A**? [*Ans*. Tetrahedral]

[For further information, see S.S. Al-Juaid *et al.* (1998) *J. Organomet. Chem.*, vol. 564, p. 215.]

Lead

Tetraethyllead (made by reaction 23.73 or by electrolysis of $NaAlEt_4$ or EtMgCl using a Pb anode) was formerly widely used as an anti-knock agent in motor fuels. However, for environmental reasons, the use of leaded fuels has declined (see Fig. 14.3).

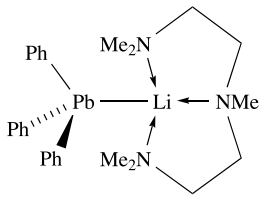
$$\underset{\text{alloy}}{4\text{NaPb}} + 4\text{EtCl} \xrightarrow{\approx 373\text{ K in an autoclave}} \text{Et}_4\text{Pb} + 3\text{Pb} + 4\text{NaCl} \qquad (23.73)$$

Laboratory syntheses of R_4Pb compounds include the use of Grignard reagents (eqs. 23.74 and 23.75) or organolithium compounds (eqs. 23.76 and 23.77). High-yield routes to $R_3Pb{-}PbR_3$ involve the reactions of R_3PbLi (see below) with R_3PbCl.

$$2\text{PbCl}_2 + 4\text{RMgBr} \xrightarrow{\text{Et}_2\text{O}} 2\{\text{R}_2\text{Pb}\} + 4\text{MgBrCl}$$
$$\downarrow$$
$$\text{R}_4\text{Pb} + \text{Pb} \qquad (23.74)$$

$$3\text{PbCl}_2 + 6\text{RMgBr} \xrightarrow{\text{Et}_2\text{O, 253 K}} \text{R}_3\text{Pb}{-}\text{PbR}_3 + \text{Pb} + 6\text{MgBrCl} \qquad (23.75)$$

$$2\text{PbCl}_2 + 4\text{RLi} \xrightarrow{\text{Et}_2\text{O}} \text{R}_4\text{Pb} + 4\text{LiCl} + \text{Pb} \qquad (23.76)$$



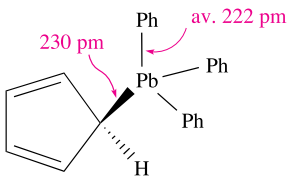
$$\text{R}_3\text{PbCl} + \text{R'Li} \longrightarrow \text{R}_3\text{R'Pb} + \text{LiCl} \qquad (23.77)$$

Alkyllead chlorides can be prepared by reactions 23.78 and 23.79, and these routes are favoured over treatment of R_4Pb with X_2, the outcome of which is hard to control.

$$\text{R}_4\text{Pb} + \text{HCl} \longrightarrow \text{R}_3\text{PbCl} + \text{RH} \qquad (23.78)$$

$$\text{R}_3\text{PbCl} + \text{HCl} \longrightarrow \text{R}_2\text{PbCl}_2 + \text{RH} \qquad (23.79)$$

Compounds of the R_4Pb and R_6Pb_2 families possess monomeric structures with tetrahedral Pb centres as exemplified by the cyclohexyl derivative in Fig. 23.20a. The number of Pb derivatives that have been structurally studied is less than for the corresponding Sn-containing compounds. For the organolead halides, the presence of bridging halides is again a common feature giving rise to increased coordination numbers at the metal centre, e.g. in Me_3PbCl (Fig. 23.20b). Monomers are favoured if the organic substituents are sterically demanding as in $(2,4,6\text{-Me}_3\text{C}_6\text{H}_2)_3\text{PbCl}$. We mentioned above the use of R_3PbLi reagents. The first structurally characterized member of this group was 'Ph_3PbLi', isolated as the monomeric complex **23.38**.



(23.38)

Tetraalkyl and tetraaryl lead compounds are inert with respect to attack by air and water at room temperature. Thermolysis leads to radical reactions such as those shown in scheme 23.80, which will be followed by further radical reaction steps.

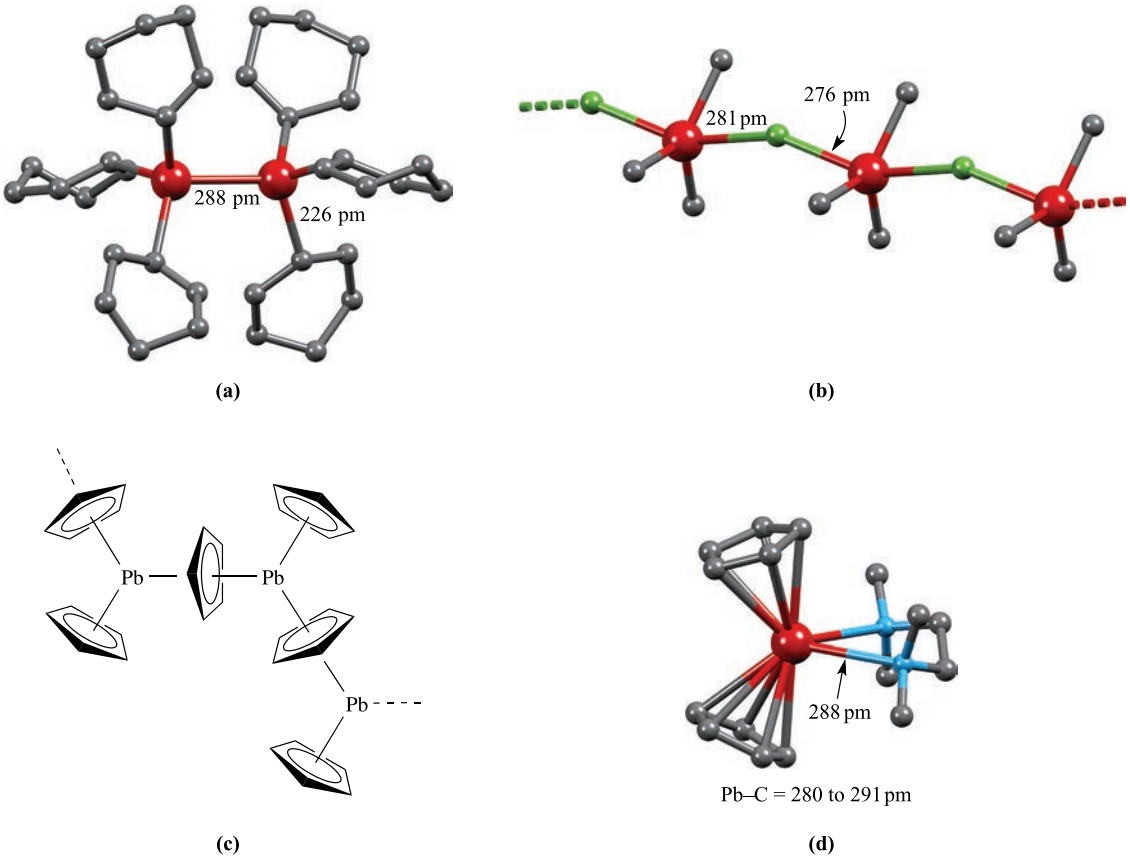
$$\left.\begin{aligned} &\text{Et}_4\text{Pb} \longrightarrow \text{Et}_3\text{Pb}^{\bullet} + \text{Et}^{\bullet} \\ &2\text{Et}^{\bullet} \longrightarrow n\text{-C}_4\text{H}_{10} \\ &\text{Et}_3\text{Pb}^{\bullet} + \text{Et}^{\bullet} \longrightarrow \text{C}_2\text{H}_4 + \text{Et}_3\text{PbH} \\ &\text{Et}_3\text{PbH} + \text{Et}_4\text{Pb} \longrightarrow \text{H}_2 + \text{Et}_3\text{Pb}^{\bullet} \\ &\qquad\qquad + \text{Et}_3\text{PbCH}_2\text{CH}_2^{\bullet} \end{aligned}\right\} \qquad (23.80)$$

The chloride group in R_3PbCl can be replaced to give a range of R_3PbX species (e.g. $X^- = [N_3]^-$, $[NCS]^-$, $[CN]^-$, $[OR']^-$). Where X^- has the ability to bridge, polymeric structures are observed in the solid state. Both R_3PbN_3 and R_3PbNCS are strong Lewis acids and form adducts such as $[R_3Pb(N_3)_2]^-$. The reaction of Ph_3PbCl with Na[Cp] gives $Ph_3Pb(\kappa C^1\text{-Cp})$; structure **23.39** has been confirmed by X-ray diffraction and it is significant that the distance $Pb{-}C_{Cp} > Pb{-}C_{Ph}$. This is consistent with a weaker $Pb{-}C_{Cp}$ bond, and preferential bond cleavage is observed, e.g. in scheme 23.81.

$$\text{Ph}_3\text{PbO}_2\text{CMe} \xleftarrow{\text{MeCO}_2\text{H}} \text{Ph}_3\text{Pb}(\kappa C^1\text{-Cp}) \xrightarrow{\text{PhSH}} \text{Ph}_3\text{PbSH} \qquad (23.81)$$

(23.39)

Cyclopentadienyl derivatives of Pb(II), $(\eta^5\text{-C}_5\text{R}_5)_2\text{Pb}$, can be prepared by reactions of a Pb(II) salt (e.g. acetate or chloride) with $Na[C_5R_5]$ or $Li[C_5R_5]$. The $(\eta^5\text{-C}_5\text{R}_5)_2\text{Pb}$



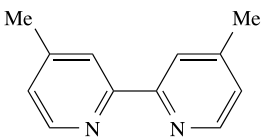


Fig. 23.20 The solid state structures of (a) $Pb_2(C_6H_{11})_6$ [X-ray diffraction: N. Kleiner *et al.* (1985) *Z. Naturforsch., Teil B*, vol. 40, p. 477], (b) Me_3PbCl [X-ray diffraction: D. Zhang *et al.* (1991) *Z. Naturforsch., Teil A*, vol. 46, p. 337], (c) Cp_2Pb (schematic diagram), and (d) $(\eta^5\text{-Cp})_2Pb(Me_2NCH_2CH_2NMe_2)$ [X-ray diffraction: M.A. Beswick *et al.* (1996) *J. Chem. Soc., Chem. Commun.*, p. 1977]. Hydrogen atoms are omitted for clarity; colour code: Pb, red; C, grey; Cl, green; N, blue.

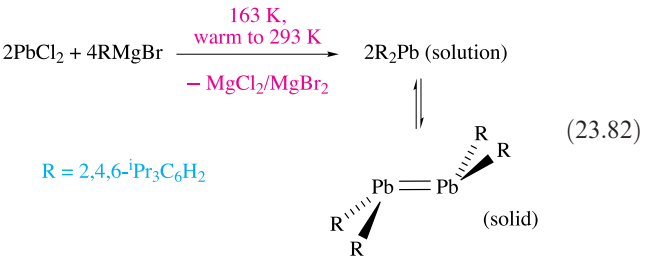
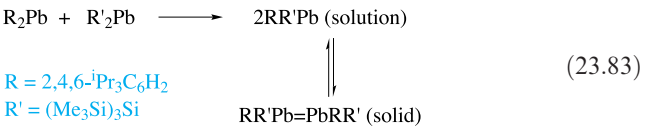


compounds are generally sensitive to air, but the presence of bulky R groups increases their stability. The solid state structure of Cp_2Pb consists of polymeric chains (Fig. 23.20c), but in the gas phase, discrete $(\eta^5\text{-Cp})_2Pb$ molecules are present which possess the bent structure shown for $(\eta^5\text{-}C_5Me_5)_2Si$ in Fig. 23.14b. Other $(\eta^5\text{-}C_5R_5)_2Pb$ compounds which have been studied in the solid state are monomers. Bent structures (as in Fig. 23.14b) are observed for R = Me or $PhCH_2$ for example, but in $\{\eta^5\text{-}C_5Me_4(Si^tBuMe_2)\}_2Pb$ where the organic groups are especially bulky, the C_5-rings are coparallel (see the end of Section 23.5). Cp_2Pb (like Cp_2Sn) can act as a Lewis *acid*. It reacts with the Lewis bases $Me_2NCH_2CH_2NMe_2$ and 4,4'-Me_2bpy (**23.40**) to form the adducts $(\eta^5\text{-Cp})_2Pb{\cdot}L$ where L is the Lewis base. Figure 23.20d shows the solid state structure of $(\eta^5\text{-Cp})_2Pb{\cdot}Me_2NCH_2CH_2NMe_2$, and the structure of $(\eta^5\text{-Cp})_2Pb{\cdot}$(4,4'-$Me_2$bpy) is similar. Further evidence for Lewis acid behaviour comes from the reaction of $(\eta^5\text{-Cp})_2Pb$ with Li[Cp] in the presence of the crown ether 12-crown-4, which gives $[Li(12\text{-crown-}4)]_2[Cp_9Pb_4][Cp_5Pb_2]$. The structures of $[Cp_9Pb_4]^-$ and $[Cp_5Pb_2]^-$ consist of fragments of the polymeric chain of Cp_2Pb (see Fig. 23.20c), e. g. in $[Cp_5Pb_2]^-$, one Cp^- ligand bridges between the two Pb(II) centres and the remaining four Cp^- ligands are bonded in an η^5-mode, two to each Pb atom.



(23.40)

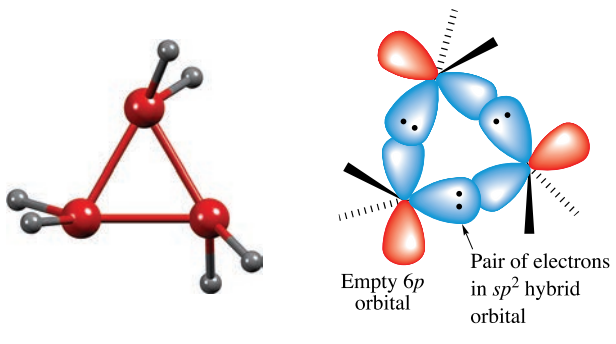
Diarylplumbylenes, R_2Pb, in which the Pb atom carries a lone pair of electrons, can be prepared by the reaction of $PbCl_2$ with RLi provided that R is suitably sterically demanding. The presence of monomers in the solid state has been confirmed for R = 2,4,6-$(CF_3)_3C_6H_2$ and 2,6-(2,4,6-$Me_3C_6H_2)_2C_6H_3$. Dialkyl derivatives are represented by $\{(Me_3Si)_2CH\}_2Pb$. The association of R_2Pb units to form $R_2Pb{=}PbR_2$ depends critically on R as the following examples illustrate. Crystalline $\{(Me_3Si)_3Si\}RPb$ with R = 2,3,4-Me_3-6-^{t}BuC$_6$H and 2,4,6-$(CF_3)_3C_6H_2$, contain dimers in which the Pb···Pb distances are 337 and 354 pm,

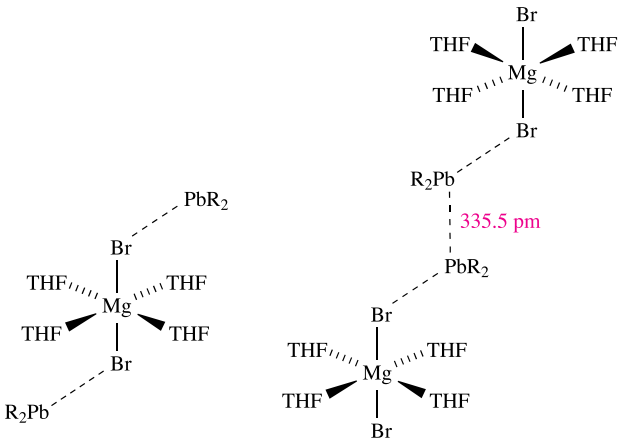
respectively. These separations are too long to be consistent with the presence of Pb=Pb bonds. The product in scheme 23.82 is monomeric in the gas phase and solution. In the solid, it is dimeric with a Pb–Pb bond length of 305 pm, indicative of a Pb=Pb bond. The ligand-exchange reaction 23.83 leads to a product with an even shorter Pb–Pb bond (299 pm). The bonding in $R_2Pb{=}PbR_2$ can be described in an analogous manner to that shown for $R_2Sn{=}SnR_2$ in Fig. 23.19.

(23.82)

(23.83)

When the Grignard reagent in scheme 23.82 is changed to 2,4,6-$Et_3C_6H_2MgBr$, the crystalline product is **23.41**, whereas with 2,4,6-$Me_3C_6H_2MgBr$, **23.42** is isolated. The formation of **23.41** can be suppressed by carrying out the reaction in the presence of dioxane. In this case, $(2,4,6\text{-}Et_3C_6H_2)_2Pb$ trimerizes to **23.43**, in which the Pb–Pb bond distances are 318 ppm. These rather long bonds, along with the orientations of the R groups (Fig. 23.21a), lead to a bonding description involving donation of the lone pair from one R_2Pb: unit into the empty 6*p* orbital of the adjacent unit (Fig. 23.21b). These reaction systems are complicated, and changes in the R group and in the ratio of starting materials may result in disproportionation of PbX_2 (eq. 23.84), or give salts of $[Pb(PbR_3)_3]^-$ (**23.44**).





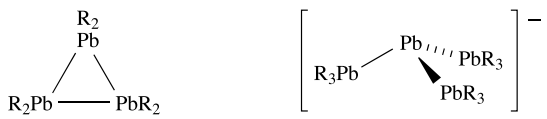


Fig. 23.21 (a) The structure of the Pb_3C_6 core in $\{(2,4,6\text{-}Et_3C_6H_2)_2Pb\}_3$, determined by X-ray diffraction [F. Stabenow *et al.* (2003) *J. Am. Chem. Soc.*, vol. 125, p. 10172]. Colour code: Pb, red; C, grey. (b) A bonding description for the Pb–Pb interactions in $\{(2,4,6\text{-}Et_3C_6H_2)_2Pb\}_3$.

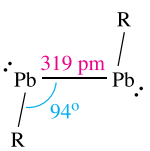
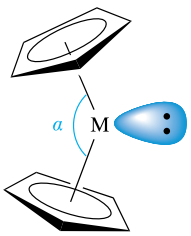


$$3PbCl_2 + 6RMgBr \longrightarrow R_3Pb{-}PbR_3 + Pb + 6MgBrCl \quad (23.84)$$

The reaction of RPbBr ($R = 2,6\text{-}(2,6\text{-}{}^{i}Pr_2C_6H_3)_2C_6H_3$) with $LiAlH_4$ leads to RPbPbR (**23.45**) (eq. 23.85). This is not analogous, either in structure or bonding, to RGeGeR and RSnSnR (see structure **23.36**). In RPbPbR, the Pb–Pb distance is consistent with a single bond, and each Pb atom is considered to have a sextet of electrons (one lone and two bonding pairs). The Pb–Pb bond length is close to that in trimer **23.43**.

$$2RPbBr \xrightarrow{LiAlH_4} 2RPbH \xrightarrow{-H_2} RPbPbR \quad (23.85)$$



R = 2,6-(2,6-$^{i}Pr_2C_6H_3)_2C_6H_3$

(23.45)

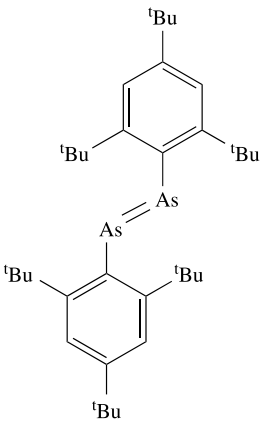
Coparallel and tilted C_5-rings in group 14 metallocenes

The first group 14 metallocenes to be characterized were $(\eta^5\text{-}C_5H_5)_2Sn$ and $(\eta^5\text{-}C_5H_5)_2Pb$, and in both compounds, the C_5-rings are mutually tilted. This observation was

originally interpreted in terms of the presence of a stereochemically active lone pair of electrons as shown in structure **23.46**.

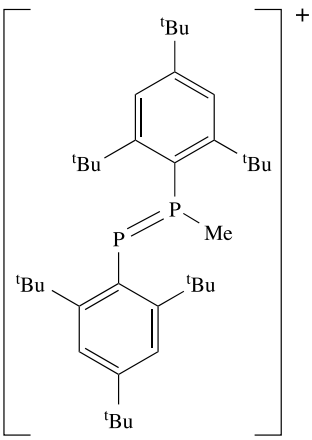
(23.46)

However, as the examples in Section 23.5 have shown, not all group 14 metallocenes exhibit structures with tilted C_5-rings. For example, in each of $(\eta^5\text{-}C_5Ph_5)_2Sn$, $\{\eta^5\text{-}C_5Me_4(SiMe_2{}^tBu)\}_2Ge$ and $(\eta^5\text{-}C_5{}^iPr_3H_2)_2Pb$, the two C_5-rings are coparallel. Trends such as that along the series $(\eta^5\text{-}C_5H_5)_2Sn$ (tilt angle $\alpha = 125°$), $(\eta^5\text{-}C_5Me_5)_2Sn$ ($\alpha = 144°$) and $(\eta^5\text{-}C_5Ph_5)_2Sn$ (coparallel rings) have been explained in terms of steric factors: as the inter-ring steric repulsions increase, angle α in **23.46** increases, and the final result is a rehybridization of the metal orbitals, rendering the lone pair stereochemically inactive. It is, however, difficult to rationalize the occurrence of *both* tilted and coparallel forms of $(\eta^5\text{-}C_5Me_5)_2Si$ (Fig. 23.14) using steric arguments. Furthermore, the preference for coparallel rings in the solid state for $\{\eta^5\text{-}C_5Me_4(SiMe_2{}^tBu)\}_2Pb$ and $(\eta^5\text{-}C_5{}^iPr_3H_2)_2Pb$, in contrast to a tilted structure for $(\eta^5\text{-}C_5{}^iPr_5)_2Pb$ ($\alpha = 170°$), cannot be rationalized in terms of inter-ring steric interactions. The situation is further complicated by the fact that as one descends group 14, there is an increased tendency for the lone pair of electrons to be accommodated in an *ns* orbital and to become stereochemically inactive. A final point for consideration is that, although polymeric, the group 2 metallocenes $(\eta^5\text{-Cp})_2M$ (M = Ca, Sr, Ba) exhibit bent C_5–M–C_5 units: here, there is no lone pair of electrons to affect the structure. Taking all current data into consideration, it is necessary to reassess (i) the stereochemical role of the lone pair of electrons in $(\eta^5\text{-}C_5R_5)_2M$ compounds (M = group 14 metal) and (ii) the role of inter-ring steric interactions as factors that contribute to the preference for coparallel or tilted C_5-rings. Theoretical studies indicate that the difference in energy between the two structures for a given molecule is small: $\approx$1–12 kJ mol^{-1} depending on ring substituents. Crystal-packing forces have been suggested as a contributing factor, but further studies are required to provide a definitive explanation.[†]



[†] For further discussion, see: S.P. Constantine, H. Cox, P.B. Hitchcock and G.A. Lawless (2000) *Organometallics*, vol. 19, p. 317; J.D. Smith and T.P. Hanusa (2001) *Organometallics*, vol. 20, p. 3056; V.M. Rayón and G. Frenking (2002) *Chem. Eur. J.*, vol. 8, p. 4693.

23.6 Group 15



Bonding aspects and E=E bond formation

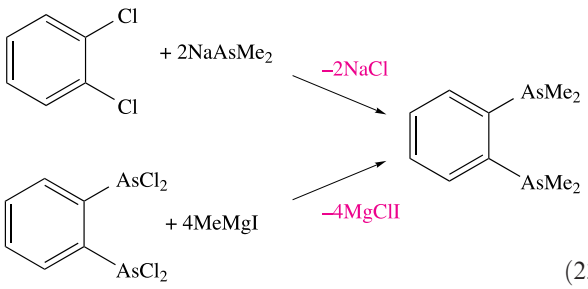
Our discussion of organometallic compounds of group 15 covers As, Sb and Bi. There is an extensive chemistry of compounds with N–C or P–C bonds, but much of this belongs within the remit of organic chemistry, although amines and phosphanes (e.g. R_3E, $R_2E(CH_2)_nER_2$ where E = N or P) are important ligands in inorganic complexes. In both cases, the group 15 element acts as a σ-donor, and in the case of phosphorus, also as a π-acceptor (see Section 20.4).

On descending group 15, the E–E and E–C bond enthalpy terms both decrease (e.g. see Table 15.3). In Section 15.3, we emphasized differences in bonding between nitrogen and the later elements, and illustrated that $(p\text{–}p)\pi$-bonding is important for nitrogen but not for the heavier elements. Thus, nitrogen chemistry provides many compounds of type $R_2N{=}NR_2$, but for most R groups the analogous $R_2E{=}ER_2$ compounds (E = P, As, Sb or Bi) are unstable with respect to oligomerization to give cyclic compounds such as Ph_6P_6. Only by the use of especially bulky substituents is double bond formation for the later elements made possible, with the steric hindrance preventing oligomerization. Thus, several compounds with P=P, P=As, As=As, P=Sb, Sb=Sb, Bi=Bi and P=Bi are known and possess *trans*-configurations as shown in structure **23.47**. The bulky substituents that have played a major role in enabling RE=ER compounds to be stabilized are 2,4,6-^{t}Bu$_3$C$_6$H$_2$, 2,6-(2,4,6-Me$_3$C$_6$H$_2$)$_2$C$_6$H$_3$ and 2,6-(2,4,6-^{i}Pr$_3$C$_6$H$_2$)$_2$C$_6$H$_3$. Along the series RE=ER for E = P, As, Sb and Bi and R = 2,6-(2,4,6-Me$_3$C$_6$H$_2$)$_2$C$_6$H$_3$, the E=E bond length increases (198.5 pm, E = P; 228 pm, E = As; 266 pm, E = Sb; 283 pm, E = Bi) and the E–E–C bond angle decreases (110°, E = P; 98.5°, E = As; 94°, E = Sb; 92.5°, E = Bi). Methylation of RP=PR (R = 2,4,6-^{t}Bu$_3$C$_6$H$_2$) to give **23.48** can be achieved, but only if a 35-fold excess of methyl trifluoromethanesulfonate is used. We return to single bond formation between As, Sb and Bi atoms later.

(23.47)

(23.48)

Arsenic, antimony and bismuth



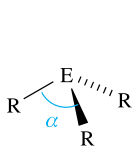
Organometallic compounds of As(III), Sb(III) and Bi(III) can be prepared from the respective element and organo halides (reaction 23.86) or by use of Grignard reagents (eq. 23.87) or organolithium compounds. Treatment of organo halides (e.g. those from reaction 23.86) with R'Li gives RER'_2 or R_2ER' (e.g. eq. 23.88).

$$2As + 3RBr \xrightarrow{\text{in presence of Cu, } \Delta} RAsBr_2 + R_2AsBr \quad (23.86)$$

$$EX_3 + 3RMgX \xrightarrow{\text{ether solvent}} R_3E + 3MgX_2 \quad (23.87)$$

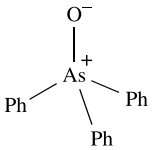
$$R_2AsBr + R'Li \longrightarrow R_2AsR' + LiBr \quad (23.88)$$

Scheme 23.89 shows the formation of an organoarsane that is commonly used as a chelating ligand for heavy metals, the soft As donors being compatible with soft metal centres (see Table 7.10).



(23.89)

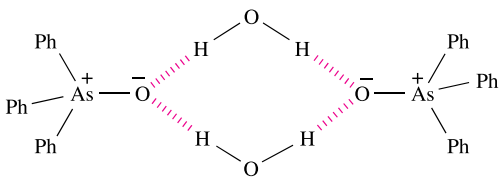
Metal(V) derivatives, R_5E, cannot be prepared from the corresponding pentahalides, but may be obtained by oxidation of R_3E followed by treatment with RLi (e.g. eq. 23.90). The same strategy can be used to form, for example, Me_2Ph_3Sb (reaction 23.91).



$$R_3As + Cl_2 \longrightarrow R_3AsCl_2 \xrightarrow[-2LiCl]{2RLi} R_5As \quad (23.90)$$

$$Ph_3SbCl_2 + 2MeLi \xrightarrow{Et_2O,\ 195\,K} Me_2Ph_3Sb + 2LiCl \quad (23.91)$$

The oxidative addition of R'X (R = alkyl) to R_3E produces $R_3R'EX$, with the tendency of R_3E to undergo this reaction decreasing in the order As > Sb ≫ Bi, and I > Br > Cl. Further, conversion of R_3X to $R_3R'EX$ by this route works for R = alkyl or aryl when E = As, but not for R = aryl when E = Sb. Compounds of the type R_3EX_2 are readily prepared as shown in eq. 23.90, and R_2EX_3 derivatives can be made by addition of X_2 to R_2EX (E = As, Sb; X = Cl, Br).



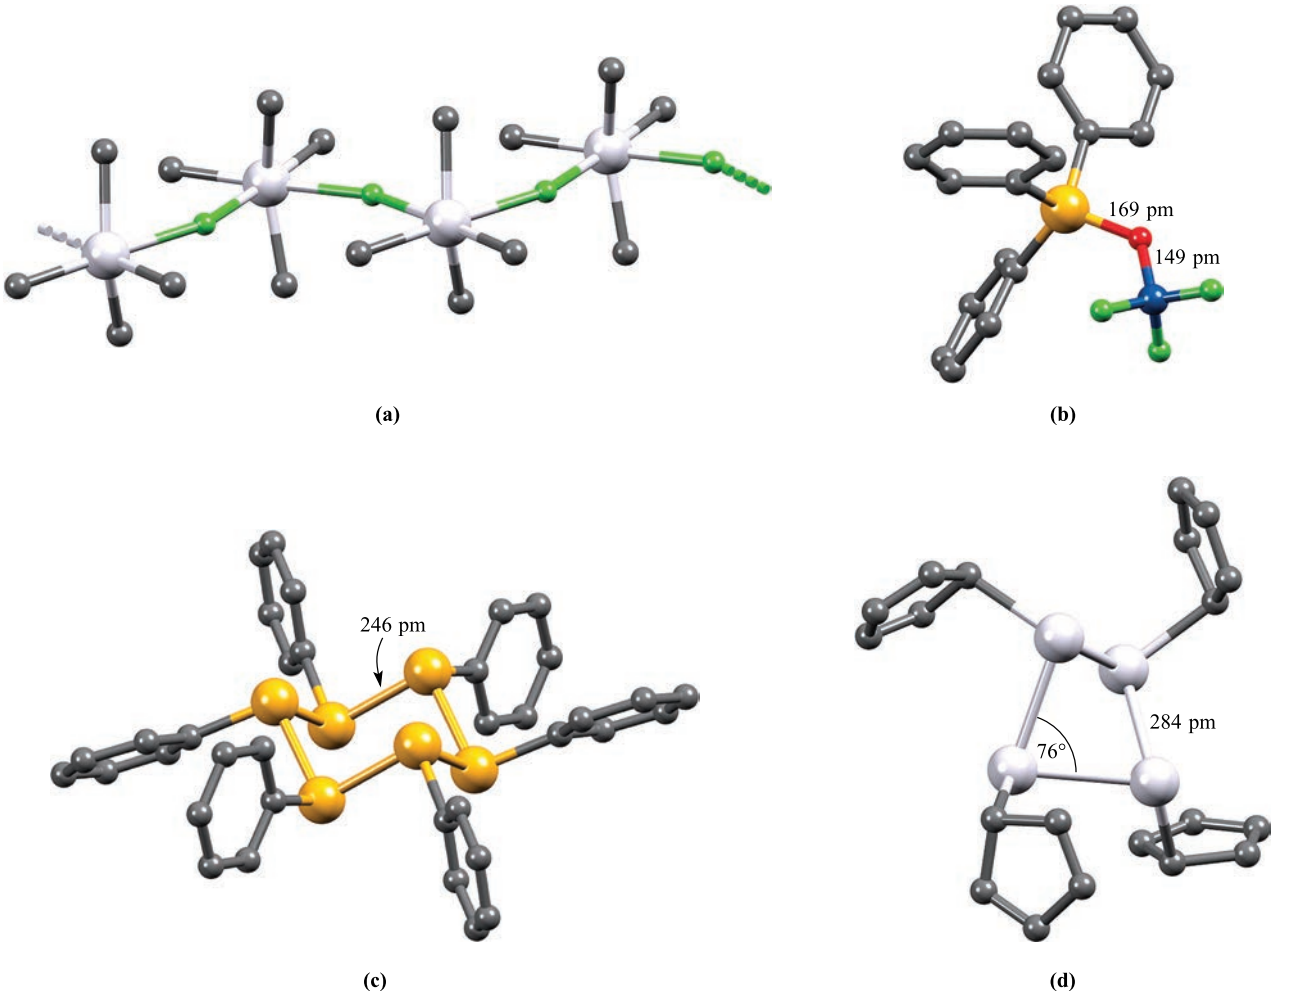
(23.49)

(23.50)

Compounds of the type R_3E are sensitive to oxidation by air but resist attack by water. They are more stable when R = aryl (compared to alkyl), and stability for a given series of triaryl derivatives decreases in the order $R_3As > R_3Sb > R_3Bi$. All R_3E compounds structurally characterized to date are trigonal pyramidal, and the C–E–C angle α in **23.49** decreases for a given R group in the order As > Sb > Bi. Hydrogen peroxide oxidizes Ph_3As to Ph_3AsO, for which **23.50** is a bonding representation. Ph_3SbO is similarly prepared or can be obtained by heating $Ph_3Sb(OH)_2$. Triphenylbismuth oxide is made by oxidation of Ph_3Bi or hydrolysis of Ph_3BiCl_2. The ready formation of these oxides should be compared with the relative stability of Ph_3P with respect to oxidation, the ready oxidation of Me_3P, and the use of Me_3NO as an oxidizing agent. (See Section 15.3 for a discussion of the bonding in hypervalent compounds of the group 15 elements.) Triphenylarsenic oxide forms a monohydrate which exists as a hydrogen-bonded dimer (**23.51**) in the solid state. Ph_3SbO crystallizes in several modifications which contain either monomers or polymers, and has a range of catalytic uses in organic chemistry, e.g. oxirane polymerization, and reactions between amines and acids to give amides. The reaction of Ph_3AsO with PhMgX leads to the salts $[Ph_4As]X$ (X=Cl, Br, I). These salts are commercially available and are widely used to provide a large cation for the stabilization of salts containing large anions (see Box 24.1).

(23.51)

The ability of R_3E to act as a Lewis base decreases down group 15. *d*-Block metal complexes involving R_3P ligands are far more numerous than those containing R_3As and R_3Sb (see Section 24.2), and only a few complexes containing R_3Bi ligands have been structurally characterized, e.g. $Cr(CO)_5(BiPh_3)$ (**23.52**) and $[(\eta^5\text{-Cp})Fe(CO)_2(BiPh_3)]^+$. Adducts are also formed between R_3E or R_3EO (E = As, Sb) and Lewis acids such as boron trifluoride (Fig. 23.22b), and in Section 17.4, we described complexes formed between Ph_3E (E = P, As, Sb) and halogens.



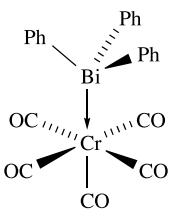


Fig. 23.22 The solid state structures (X-ray diffraction) of (a) polymeric Me_4SbF in which each Sb(V) centre is distorted octahedral [W. Schwarz *et al.* (1978) *Z. Anorg. Allg. Chem.*, vol. 444, p. 105], (b) $Ph_3AsO{\cdot}BF_3$ [N. Burford *et al.* (1990) *Acta Crystallogr., Sect. C*, vol. 46, p. 92], (c) Ph_6As_6 in which the As_6 adopts a chair conformation [A.L. Rheingold *et al.* (1983) *Organometallics*, vol. 2, p. 327] and (d) $(\kappa C^1\text{-}C_5Me_5)_4Sb_4$ with methyl groups omitted for clarity [O.M. Kekia *et al.* (1996) *Organometallics*, vol. 15, p. 4104]. Hydrogen atoms are omitted for clarity; colour code: Sb, silver; As, yellow; C, grey; F, green; B, blue; O, red.

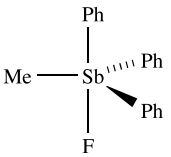
(23.52)

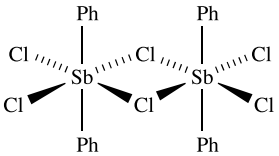
Compounds of type R_5E (E = As, Sb, Bi) adopt either a trigonal bipyramidal or square-based pyramidal structure. In the solid state, Me_5Sb, Me_5Bi, $(4\text{-}MeC_6H_4)_5Sb$ and the solvated compound $Ph_5Sb{\cdot}\frac{1}{2}C_6H_{12}$ are trigonal bipyramidal, while unsolvated Ph_5Sb and Ph_5Bi are square-based pyramidal. Electron diffraction studies on gaseous Me_5As and Me_5Sb confirm trigonal bipyramidal structures. In solution, the compounds are highly fluxional on the NMR timescale, even at low temperatures. The fluxional process involves ligand exchange via the interconversion of trigonal bipyramidal and square-based pyramidal structures (see Fig. 4.25). For $(4\text{-}MeC_6H_4)_5Sb$ in $CHFCl_2$ solvent, a barrier of $\approx$6.5 kJ mol^{-1} to ligand exchange has been determined from ^{1}H NMR spectroscopic data.

On heating, R_5E compounds decompose, with the thermal stability decreasing down the group, e.g. Ph_5As is more thermally stable than Ph_5Sb than Ph_5Bi. The decomposition products vary and, for example, Ph_5Sb decomposes to Ph_3Sb and PhPh, while Me_5As gives Me_3As, CH_4 and C_2H_4. Cleavage of an E–C bond in R_5E compounds occurs upon treatment with halogens, Brønsted acids or Ph_3B (eqs. 23.92–23.94). Both Me_5Sb and Me_5Bi react with MeLi in THF (eq. 23.95) to give salts containing the octahedral ions $[Me_6E]^-$.



$$Ph_5E + Cl_2 \longrightarrow Ph_4ECl + PhCl \qquad (23.92)$$

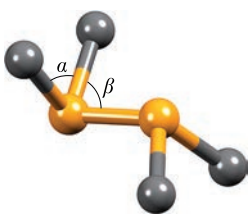
$$Ph_5E + HCl \longrightarrow Ph_4ECl + PhH \quad (23.93)$$



$$Ph_5E + Ph_3B \longrightarrow [Ph_4E]^+[BPh_4]^- \quad (23.94)$$

$$Me_5Sb + MeLi \xrightarrow{Et_2O,\ THF} [Li(THF)_4]^+[Me_6Sb]^- \quad (23.95)$$

The monohalides R_4EX tend to be ionic for X = Cl, Br or I, i.e. $[R_4E]^+X^-$, but among the exceptions is Ph_4SbCl which crystallizes as discrete trigonal bipyramidal molecules. The fluorides possess covalent structures. In the solid state, Me_4SbF forms polymeric chains (Fig. 23.22a) while $MePh_3SbF$ exists as trigonal bipyramidal molecules **23.53**. For the di- and trihalides there is also structural variation, and ionic, discrete molecular and oligomeric structures in the solid state are all exemplified, e.g. Me_3AsBr_2 is ionic and contains the tetrahedral $[Me_3AsBr]^+$ ion, Ph_3BiCl_2 and Ph_3SbX_2 (X = F, Cl, Br or I) are trigonal bipyramidal molecules with axial X atoms, Ph_2SbCl_3 is dimeric (**23.54**), while Me_2SbCl_3 exists in two structural forms, one ionic $[Me_4Sb]^+[SbCl_6]^-$ and the other a covalent dimer.

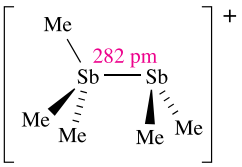


(23.53)

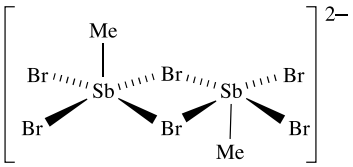
(23.54)

The family of $R_2E{-}ER_2$ compounds is well represented and those structurally characterized by X-ray diffraction include Ph_4As_2, Ph_4Sb_2 and Ph_4Bi_2. All possess the staggered conformation shown in **23.55** for the C_4E_2 core with values of α and β of 103° and 96° for Ph_4As_2, 94° and 94° for Ph_4Sb_2, and 98° and 91° for Ph_4Bi_2. As expected, the E–E bond length increases: 246 pm in Ph_4As_2, 286 pm in Ph_4Sb_2, and 298 pm in Ph_4Bi_2. Equation 23.96 gives a typical preparative route. Some R_4Sb_2 and R_4Bi_2 (but not R_4As_2) derivatives are *thermochromic* (see Section 21.6).

$$2R_2BiCl + 2Na \xrightarrow[2.\ 1,2\text{-dichloroethane}]{1.\ \text{liquid } NH_3} R_4Bi_2 + 2NaCl \quad (23.96)$$



(23.55)



Ligand redistribution in liquid Me_2SbBr (no solvent) leads to the formation of the salt $[Me_3SbSbMe_2]_2[MeBr_2Sb(\mu\text{-}Br)_2SbBr_2Me]$ which contains ions **23.56** and **23.57**. The proposed pathway is given in scheme 23.97. The eclipsed conformation of cation **23.56** is probably determined by close cation–anion interactions in the solid state.

$$2Me_2SbBr \longrightarrow Me_3Sb + MeSbBr_2$$

$$2Me_2SbBr + 2Me_3Sb + 2MeSbBr_2 \rightleftharpoons [\mathbf{23.56}]_2[\mathbf{23.57}] \quad (23.97)$$

(23.56)

(23.57)

Worked example 23.6 Application of the VSEPR model

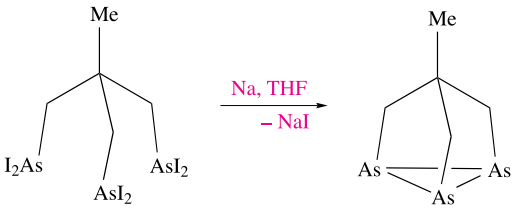
Confirm that the octahedral structure of $[Ph_6Bi]^-$ (formed in a reaction analogous to 23.95) is consistent with the VSEPR model.

Bi has five electrons in its valence shell and the negative charge in $[Ph_6Bi]^-$ supplies one more.

Each Ph group supplies one electron to the valence shell of Bi in $[Ph_6Bi]^-$.

Total valence electron count = 5 + 1 + 6 = 12

The six pairs of electrons correspond to an octahedral structure within the VSEPR model, and this is consistent with the observed structure.



Self-study exercises

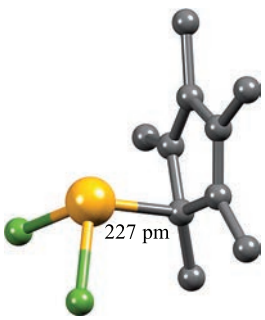
1. Show that the tetrahedral and trigonal pyramidal Sb centres in cation **23.56** are consistent with the VSEPR model. What does this assume about the localization of the positive charge?
2. Confirm that the structure of anion **23.57** is consistent with the VSEPR model. Comment on the preference for this structure over one in which the Me groups are on the same side of the planar Sb_2Br_6-unit.
3. Show that the octahedral centres in $Ph_4Sb_2Cl_6$ (**23.54**) are consistent with the VSEPR model.

Reduction of organometal(III) dihalides (e.g. $RAsCl_2$) with sodium or magnesium in THF, or reduction of $RAs(O)(OH)_2$ acids (reaction 23.98), gives *cyclo*-$(RE)_n$, where n = 3–6. Figure 23.22c shows the structure of

Ph_6As_6 which illustrates the typical trigonal pyramidal environment for the group 15 element. Two crystalline polymorphs of $(\kappa C^1\text{-}C_5Me_5)_4Sb_4$ are known, differing in details of the molecular geometry and crystal packing; one structure is noteworthy for its acute Sb−Sb−Sb bond angles (Fig. 23.22d). Reaction 23.99 is an interesting example of the formation of a *cyclo*-As_3 species, the organic group being tailor-made to encourage the formation of the 3-membered ring. A similar reaction occurs with $MeC(CH_2SbCl_2)_3$.

$$6PhAs(O)(OH)_2 \xrightarrow{H_3PO_2} Ph_6As_6 \qquad (23.98)$$

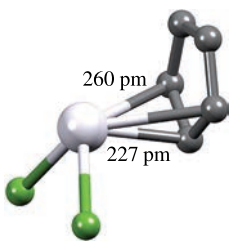
(23.99)



The lithiation (using BuLi) of Ph_2SbH in THF leads to $Ph_2SbLi(THF)_3$ which can be isolated as a crystalline solid. In contrast, lithiation of $PhSbH_2$ in $Me_2NCH_2CH_2NMe_2$ results in Sb–Sb bond formation and the $[Sb_7]^{3-}$ ion. This provides a convenient method of preparing this Zintl ion (see Section 15.6).

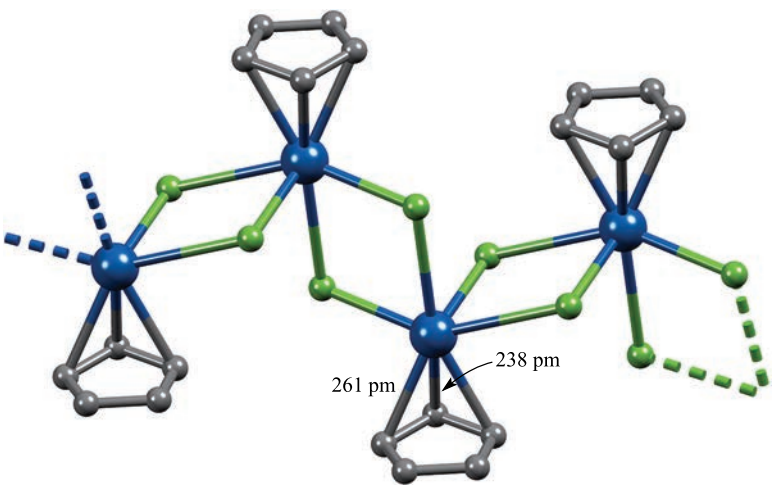
Organometallic chemistry involving cyclopentadienyl ligands is less important in group 15 than for groups 1, 2, 13 and 14. We have already mentioned $(\kappa C^1\text{-}C_5Me_5)_4Sb_4$ (Fig. 23.22d). Other compounds for which solid state structures contain $\kappa C^1\text{-}C_5R_5$ substituents include $(\kappa C^1\text{-}Cp)_3Sb$ (eq. 23.100) and $(\kappa C^1\text{-}C_5Me_5)AsCl_2$ (Fig. 23.23a, prepared by ligand redistribution between $(\kappa C^1\text{-}C_5Me_5)_3As$ and $AsCl_3$). The derivatives Cp_nSbX_{3-n} (X = Cl, Br, I; $n = 1$, 2) are prepared by treating $(\kappa C^1\text{-}Cp)_3Sb$ with SbX_3. $CpBiCl_2$ is made by reaction 23.101.

$$Sb(NMe_2)_3 + 3C_5H_6 \xrightarrow{Et_2O,\ 193\ K} (\kappa C^1\text{-}Cp)_3Sb + 3Me_2NH \qquad (23.100)$$



$$BiCl_3 + Na[Cp] \xrightarrow{Et_2O,\ 203\ K} CpBiCl_2 + NaCl \qquad (23.101)$$

In solution, the cyclopentadienyl rings in this type of compound are fluxional. In the solid state, crystallographic data (where available) reveal significant variation in bonding modes as examples in Fig. 23.23 illustrate. Consideration of the E−C bond distances leads to the designations of κC^1 or η^3. Reaction 23.102 gives one of the few η^5-cyclopentadienyl derivatives of a heavier group 15 element so far prepared. The $[(\eta^5\text{-}C_5Me_5)_2As]^+$ ion is



Four long As - - - C, two at 250 pm and two at 295 pm

(a)

Two long Sb - - - C at 298 pm

(b)

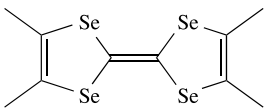
Two long Bi - - - C at 291 pm

(c)

Fig. 23.23 The structures (X-ray diffraction) of (a) monomeric $(\kappa C^1\text{-}C_5Me_5)AsCl_2$ [E.V. Avtomonov *et al.* (1996) *J. Organomet. Chem.*, vol. 524, p. 253], (b) monomeric $(\eta^3\text{-}C_5H_5)SbCl_2$ [W. Frank (1991) *J. Organomet. Chem.*, vol. 406, p. 331] and (c) polymeric $(\eta^3\text{-}C_5H_5)BiCl_2$ [W. Frank (1990) *J. Organomet. Chem.*, vol. 386, p. 177]. Hydrogen atoms are omitted for clarity; colour code: As, yellow; Sb, silver; Bi, blue; C, grey; Cl, green.

isoelectronic with $(\eta^5\text{-}C_5Me_5)_2Ge$ and possesses the same bent structure illustrated for $(\eta^5\text{-}C_5Me_5)_2Si$ in Fig. 23.14b.

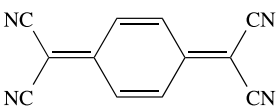
$$(\kappa C^1\text{-}C_5Me_5)_2AsF + BF_3 \longrightarrow [(\eta^5\text{-}C_5Me_5)_2As]^+[BF_4]^- \quad (23.102)$$



23.7 Group 16

Our discussion of organo-compounds of group 16 elements is confined to selenium and tellurium. There are also vast numbers of organic compounds containing C–O or C–S bonds, and some relevant inorganic topics already covered are:

- oxides and oxoacids of carbon (Section 14.9);
- sulfides of carbon (Section 14.11).



Selenium and tellurium

The organic chemistry of selenium and tellurium is an expanding area of research, and one area of active interest is that of 'organic metals'.[†] For example, the tetraselenafulvalene **23.58** acts as an electron donor to the tetracyano derivative **23.59** and 1:1 complexes formed between these, and between related molecules, crystallize with stacked structures and exhibit high electrical conductivities.

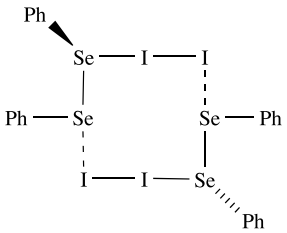
TMTSeF
(tetramethyltetraselenafulvalene)

(23.58)

TCNQ
(tetracyanoquinodimethane)

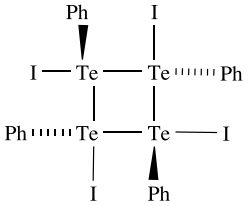
(23.59)

Organic derivatives of Se(II) include R_2Se (prepared by reaction 23.103) and RSeX (X = Cl or Br, prepared by reaction 23.104). Routes to R_2Te and R_2Te_2 compounds are shown in schemes 23.105 and 23.106. It is harder to isolate RTeX compounds than their Se analogues, but they can be stabilized by coordination to a Lewis base.



$$Na_2Se + 2RCl \longrightarrow R_2Se + 2NaCl \quad (23.103)$$

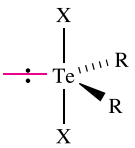
$$R_2Se_2 + X_2 \longrightarrow 2RSeX \qquad (X = Cl, Br) \quad (23.104)$$



$$Te + RLi \longrightarrow RTeLi \xrightarrow{RBr} R_2Te \quad (23.105)$$

$$Na_2Te_2 + 2RX \longrightarrow R_2Te_2 + 2NaX \quad (23.106)$$

Diselenides R_2Se_2 are readily made by treating Na_2Se_2 with RX, and have non-planar structures, e.g. for Ph_2Se_2 in the solid state, the dihedral angle (see Fig. 16.11) is 82° and the Se–Se bond length is 229 pm. The reaction of Ph_2Se_2 with I_2 leads, not to RSeI, but to the charge transfer complex **23.60** (see Section 17.4). In contrast, the reaction with Ph_2Te_2 leads to the tetramer $(PhTeI)_4$ (**23.61**).



(23.60)

(23.61)

Dimethylselenide and telluride react with Cl_2, Br_2 and I_2 to give Me_2SeX_2 and Me_2TeX_2. The solid state structure of Me_2TeCl_2 is based on a trigonal bipyramid in accord with the VSEPR model and this is typical of R_2TeX_2 (**23.62**) compounds. What was at one time labelled as the β-form of Me_2TeI_2 is now known to be $[Me_3Te]^+[MeTeI_4]^-$, with a trigonal pyramidal cation and square-based pyramidal anion; I–Te···I bridges result in each Te centre being in a distorted octahedral environment in the solid state.

(23.62)

The oxidative addition of X_2 to RSeX (X = Cl or Br) leads to $RSeX_3$. Tellurium analogues such as $MeTeCl_3$ can be prepared by treating Me_2Te_2 with Cl_2 or by reacting $TeCl_4$ with Me_4Sn. Reaction 23.107 yields the pyrophoric compound Me_4Te which can be oxidized to Me_4TeF_2 using XeF_2; Ph_4Te can similarly be converted to *cis*-Ph_4TeF_2. Reaction of Me_4TeF_2 with Me_2Zn yields Me_6Te. The phenyl analogue, Ph_6Te, can be prepared by reaction 23.108, and treatment with Cl_2 converts Ph_6Te to Ph_5TeCl. Abstraction of chloride from the latter compound gives $[Ph_5Te]^+$ (eq. 23.109) which (in the $[B(C_6F_5)_4]^-$ salt) has a square-based pyramidal structure. Ph_6Te is thermally stable, but $[Ph_5Te]^+$ decomposes to $[Ph_3Te]^+$ (eq. 23.110).

$$TeCl_4 + 4MeLi \xrightarrow{Et_2O,\ 195\ K} Me_4Te + 4LiCl \quad (23.107)$$

$$Ph_4TeF_2 + 2PhLi \xrightarrow{298\ K} Ph_6Te + 2LiF \quad (23.108)$$

$$Ph_5TeCl \xrightarrow[2.\ LiB(C_6F_5)_4]{1.\ AgSO_3CF_3} [Ph_5Te]^+[B(C_6F_5)_4]^- \quad (23.109)$$

$$[Ph_5Te]^+[B(C_6F_5)_4]^- \xrightarrow{420\ K} [Ph_3Te]^+[B(C_6F_5)_4]^- + (C_6H_5)_2 \quad (23.110)$$

[†] For an overview of the sulfur analogue, see: N. Martín (2013) *Chem. Commun.*, vol. 49, p. 7025 – 'Tetrathiafulvalene: the advent of organic metals'.

KEY TERMS

The following terms were introduced in this chapter. Do you know what they mean?

- ❑ organometallic compound
- ❑ pyrophoric
- ❑ radical anion
- ❑ regioselective
- ❑ metallocene
- ❑ sandwich complex
- ❑ s-*cis* and s-*trans* conformations

PROBLEMS

23.1 Suggest products of the following reactions:

(a) $MeBr + 2Li \xrightarrow{Et_2O}$

(b) $Na + (C_6H_5)_2 \xrightarrow{THF}$

(c) $^{n}BuLi + H_2O \longrightarrow$

(d) $Na + C_5H_6 \longrightarrow$

23.2 Whether the bonding in lithium alkyls is predominantly ionic or covalent is still a matter for debate. Assuming a covalent model, use a hybrid orbital approach to suggest a bonding scheme for $(MeLi)_4$. Comment on the bonding picture you have described.

23.3 Describe the gas-phase and solid state structures of Me_2Be and discuss the bonding in each case. Compare the bonding with that in BeH_2 and $BeCl_2$.

23.4 Suggest products of the following reactions, which are *not* necessarily balanced on the left-hand side:

(a) $Mg + C_5H_6 \longrightarrow$

(b) $MgCl_2 + LiR \longrightarrow$

(c) $RBeCl \xrightarrow{LiAlH_4}$

23.5 The compound $(Me_3Si)_2C(MgBr)_2{\cdot}n$THF is monomeric. Suggest a value for n and propose a structure for this Grignard reagent.

23.6 (a) For the equilibrium $Al_2R_6 \rightleftharpoons 2AlR_3$, comment on the fact that values of K are 1.52×10^{-8} for R = Me, and 2.3×10^{-4} for $R = Me_2CHCH_2$. (b) Describe the bonding in Al_2Me_6, Al_2Cl_6 and $Al_2Me_4(\mu\text{-}Cl)_2$.

23.7 Suggest products of the following reactions, which are *not* necessarily balanced on the left-hand side:

(a) $Al_2Me_6 + H_2O \longrightarrow$

(b) $AlR_3 + R'NH_2 \longrightarrow$

(c) $Me_3SiCl + Na[C_5H_5] \longrightarrow$

(d) $Me_2SiCl_2 + Li[AlH_4] \longrightarrow$

23.8 (a) Discuss the variation in structure for the group 13 trialkyls and triaryls. (b) Comment on features of interest in the solid state structures of $[Me_2(PhC_2)Ga]_2$ and $[Ph_3Al]_2$.

23.9 The conversion of $(\kappa C^1\text{-}C_5Me_5)_2SiBr_2$ to $(\eta^5\text{-}C_5Me_5)_2Si$ is achieved using anthracene/potassium. Outline the role of this reagent.

23.10 Suggest the nature of the solid state structures of (a) Ph_2PbCl_2, (b) Ph_3PbCl, (c) $(2,4,6\text{-}Me_3C_6H_2)_3PbCl$ and (d) $[PhPbCl_5]^{2-}$. In each case, state the expected coordination environment of the Pb centre.

23.11 Suggest products when Et_3SnCl reacts with the following reagents: (a) H_2O; (b) Na[Cp]; (c) Na_2S; (d) PhLi; (e) Na.

23.12 (a) In what ways do the solid state structures of $(\eta^5\text{-}C_5R_5)_2Sn$ for R = H, Me and Ph differ? (b) In the solid state structure of $(\eta^5\text{-}C_5Me_5)_2Mg$, the two cyclopentadienyl rings are parallel; however, for M = Ca, Sr and Ba, the rings are tilted with respect to one another. Say what you can about this observation.

23.13 The reaction of InBr with an excess of $HCBr_3$ in 1,4-dioxane ($C_4H_8O_2$) leads to compound **A** which is an adduct of 1,4-dioxane and contains 21.4% In. During the reaction, the indium is oxidized. The ^{1}H NMR spectrum of **A** shows signals at δ 5.36 ppm (singlet) and δ 3.6 ppm (multiplet) in a ratio 1:8. Treatment of **A** with two molar equivalents of InBr followed by addition of $[Ph_4P]Br$ yields the salt **B** which contains 16.4% In and 34.2% Br. The ^{1}H NMR spectrum of **B** exhibits signals in the range δ 8.01–7.71 ppm and a singlet at δ 0.20 ppm with relative integrals of 60:1. Suggest identities for **A** and **B**.

23.14 Discuss the bonding between the central *p*-block elements in the following compounds and give the expected arrangements of the organic substituents with respect to the central E_2-unit:

(a) $[(2,4,6\text{-}Me_3C_6H_2)_2BB(2,4,6\text{-}Me_3C_6H_2)Ph]^{2-}$

(b) $[(2,4,6\text{-}^{i}Pr_3C_6H_2)_2GaGa(2,4,6\text{-}^{i}Pr_3C_6H_2)_2]^{-}$

(c) $\{(Me_3Si)_2CH\}_2SnSn\{CH(SiMe_3)_2\}_2$

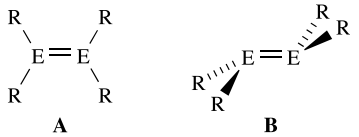
(d) $^{t}Bu_3GeGe^{t}Bu_3$

(e) $(Me_3Si)_3CAsAsC(SiMe_3)_3$

23.15 Suggest products when Me_3Sb reacts with the following reagents: (a) B_2H_6; (b) H_2O_2; (c) Br_2; (d) Cl_2 followed by treatment with MeLi; (e) MeI; (f) Br_2 followed by treatment with Na[OEt].

23.16 Write a brief account of how the changes in available oxidation states for elements, E, in groups 13 to 15 affect the families of organoelement compounds of type R_nE that can be formed.

23.17 Give methods of synthesis for the following families of compound, commenting where appropriate on limitations in the choice of R: (a) R_4Ge; (b) R_3B; (c) $(C_5R_5)_3Ga$; (d) *cyclo*-$(R_2Si)_n$; (e) R_5As; (f) R_4Al_2; (g) R_3Sb.



23.18 Give a short account of the structural variation observed for cyclopentadienyl derivatives Cp_nE of the heavier *p*-block elements.

23.19 Write a brief account of the use of sterically demanding substituents in the stabilization of compounds containing E–E and E=E bonds where E is a *p*-block metal or semi-metal.

23.20 Write a short account describing methods of formation of metal–carbon bonds for metals in the *s*- and *p*-block.

23.21 By using specific examples, illustrate how heteronuclear NMR spectroscopy can be used for the routine characterization of main group organometallic compounds. [Tables 4.3, 11.1, 13.1, 14.1 and 15.2 provide relevant nuclear spin data.]

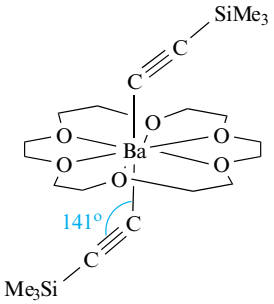
23.22 The structures of $R_2E{=}ER_2$ molecules where E is C, Si, Ge or Sn are usually of type **A** or **B** shown below:

A **B**

The bonding in the E_2-units is described in terms of the interaction of two triplet R_2E centres in **A**, and the interaction of two singlet R_2E centres in **B**. Explain the origins of these descriptions.

23.23 Give examples of the synthetic utility of the $[B(C_6F_5)_4]^-$ and $[CHB_{11}Me_5Br_6]^-$ anions, and rationalize the choice of these anions in the examples that you describe.

OVERVIEW PROBLEMS



23.24 (a) In 1956, it was concluded on the basis of dipole moment measurements that Cp_2Pb did not contain coparallel C_5-rings. Explain how this conclusion follows from such measurements.

(b) X-ray diffraction studies at 113 K show that two cyclopentadienyl complexes of beryllium can be formulated as $(\eta^5\text{-}C_5HMe_4)(\kappa C^1\text{-}C_5HMe_4)Be$ and $(\eta^5\text{-}C_5Me_5)_2Be$ respectively. The solution ^1H NMR spectrum at 298 K of $(C_5HMe_4)_2Be$ exhibits singlets at δ 1.80, 1.83 and 4.39 ppm (relative integrals 6:6:1), whereas that of $(C_5Me_5)_2Be$ shows one singlet at δ 1.83 ppm. Draw diagrams to represent the solid state structures of the compounds and rationalize the solution NMR spectroscopic data.

23.25 Treatment of $(2,4,6\text{-}^tBu_3C_6H_2)P{=}P(2,4,6\text{-}^tBu_3C_6H_2)$ with CF_3SO_3Me gives a salt **A** as the only product. The ^{31}P NMR spectrum of the precursor contains a singlet (δ +495 ppm), while that of the product exhibits two doublets (δ +237 and +332 ppm, $J = 633$ Hz). Compound **A** reacts with MeLi to give two isomers of **B** which are in equilibrium in solution. The solution ^{31}P NMR spectrum of **B** at 298 K shows one broad signal. On cooling to 213 K, two signals at δ −32.4 and −35.8 ppm are observed. From the solid state structures of **A** and one isomer of **B**, the P−P bond lengths are 202 and 222 pm. Suggest identities for **A** and **B**, and draw their structures which show the geometry at each P atom. Comment on the nature of the isomerism in **B**.

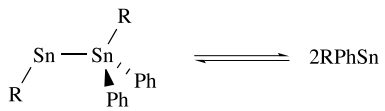
23.26 (a) Suggest how Na will react with $MeC(CH_2SbCl_2)_3$.

(b) Comment on aspects of the bonding in the following compound:

(c) Cp_2Ba and $(C_5Me_5)_2Ba$ both have polymeric structures in the solid state. However, whereas Cp_2Ba is insoluble in common organic solvents, $(C_5Me_5)_2Ba$ is soluble in aromatic solvents. In contrast to $(C_5Me_5)_2Ba$, $(C_5Me_5)_2Be$ is monomeric. Suggest a reason for these observations.

23.27 The reactions of $(\eta^5\text{-}C_5Me_5)GeCl$ with $GeCl_2$ or $SnCl_2$ lead to the compound $[\mathbf{A}]^+[\mathbf{B}]^-$ or $[\mathbf{A}]^+[\mathbf{C}]^-$ respectively. The solution ^1H NMR spectrum of $[\mathbf{A}][\mathbf{C}]$ contains a singlet at δ 2.14 ppm, and the ^{13}C NMR spectrum shows two signals at δ 9.6 and 121.2 ppm. The mass spectra of the compounds exhibit a common peak at $m/z = 209$.

(a) Suggest identities for $[\mathbf{A}][\mathbf{B}]$ and $[\mathbf{A}][\mathbf{C}]$. (b) Assign the ^{13}C NMR spectrum. (c) The peak at $m/z = 209$ is not a single line. Why is this? (d) What structures do you expect $[\mathbf{B}]^-$ and $[\mathbf{C}]^-$ to adopt? (e) Describe the bonding in $[\mathbf{A}]^+$.



23.28 (a) The reaction between $BiCl_3$ and 3 equivalents of EtMgCl yields compound **X** as the organo-product. Two equivalents of BiI_3 react with 1 equivalent of **X** to produce 3 equivalents of compound **Y**. In the solid state, **Y** has a

polymeric structure consisting of chains in which each Bi centre is in a square-based pyramidal environment. Suggest identities for **X** and **Y**, and draw possible structures for part of a chain in crystalline **Y**.

(b) The reaction between $TeCl_4$ and 4 equivalents of LiC_6H_4-4-CF_3 (LiAr) in Et_2O leads to Ar_6Te, Ar_3TeCl and Ar_2Te as the isolated products. Suggest a pathway by which the reaction may take place that accounts for the products.

(c) The reaction of $R'SbCl_2$ with RLi ($R = 2\text{-}Me_2NCH_2C_6H_4$, $R' = CH(SiMe_3)_2$) leads to RR'SbCl. In the solid state, RR'SbCl has a molecular structure in which the Sb centre is 4-coordinate; RR'SbCl is chiral. Suggest a structure for RR'SbCl and draw structures of the two enantiomers.

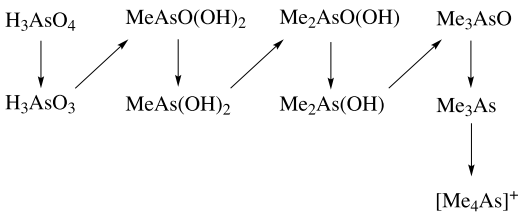
23.29 The following equilibrium has been studied by ^{119}Sn NMR and Mössbauer spectroscopies:

$R = C_6H_3\text{-}2,6\text{-}(C_6H_2\text{-}2,4,6\text{-}^iPr_3)_2$

The ^{119}Sn Mössbauer spectrum of a solid sample of $RSnSnRPh_2$ at 78 K provided evidence for the presence of three different tin environments. When $RSnSnRPh_2$ dissolves in toluene, a red solution is obtained, and at room temperature, the ^{119}Sn NMR spectrum of this solution shows one broad signal at δ 1517 ppm. This chemical shift is similar to that observed for $Sn(C_6H\text{-}2\text{-}^tBu\text{-}4,5,6\text{-}Me_3)_2$. On cooling the solution to 233 K, the signal at δ 1517 ppm gradually sharpens and at the same time, two new signals appear at δ 246 and 2857 ppm. Each of these new signals shows coupling J (^{119}Sn–^{117}Sn/^{119}Sn) = 7237 Hz. Cooling further to 213 K results in the disappearance of the signal at δ 1517 ppm, and at this point, the solution is green in colour. A colour change from green to red is observed when the solution is warmed up to room temperature. Rationalize these observations.

23.30 Experimentally determined analytical data for $PhSeCl_3$ are C, 27.5; H, 1.8; Cl, 39.9%. An X-ray diffraction study of $PhSeCl_3$ shows that it forms polymeric chains in the solid state, with each Se centre in a square-based pyramidal environment with the Ph group in the axial position. (a) To what extent are elemental analytical data useful in characterizing a new compound? (b) Draw part of the polymeric chain from the solid state structure, paying attention to the overall stoichiometry of the compound. (c) Around one Se centre in the solid state structure of $PhSeCl_3$, the observed Se–Cl bond distances are 220, 223, 263 and 273 pm. Comment on these values in the light of your answer to part (b).

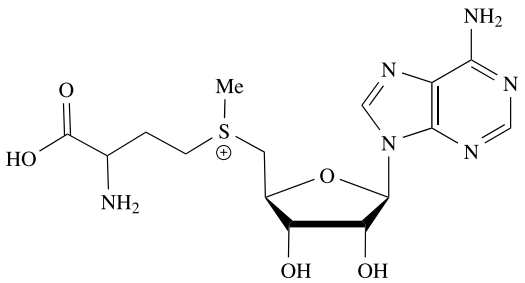
INORGANIC CHEMISTRY MATTERS



23.31 The International Marine Organization is implementing a ban on the use of tributyltin compounds in anti-fouling paints on ships. The $[Bu_3Sn]^+$ cation is leached from paints into the water where it undergoes biodegradation by marine bacteria to $[Bu_2Sn]^{2+}$ and $[BuSn]^{3+}$. Tributyltin compounds (TBT) are more toxic than di- or monobutyltin derivatives (DBT and MBT). The first order rate constants for TBT, DBT and MBT are 0.33, 0.36 and 0.63 y^{-1}, respectively. Determine the half-life of each species in the water.

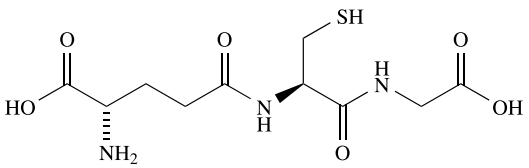
23.32 Comment on:

(a) the use of trimethylorganometallics in the manufacture of III–V semiconductors;



(b) the application of R_3Al compounds as catalysts.

23.33 Yeasts, fungi and bacteria are able to convert inorganic arsenic (arsenous and arsenic acids) to organoarsenic species. The pathway can be represented as follows, although not all species have been isolated:



The source of the methyl group is *S*-adenosylmethionine. Glutathione functions as a

reducing agent and undergoes reversible oxidative coupling to a disulfide.

S-adenosylmethionine

Glutathione

(a) By representing glutathione as RSH, write a half-equation to describe its oxidative coupling, showing how glutathione acts as a reducing agent.

(b) Write a half-equation to decribe the reduction of $Me_2AsO(OH)$.

(c) Discuss the pathway drawn above in terms of redox processes and state in what form the methyl group is transferred from *S*-adenosylmethionine to arsenic.

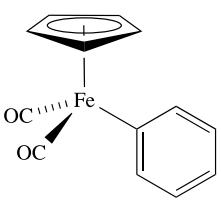
24.1 Introduction

Organometallic chemistry of the *s*- and *p*-block elements was described in Chapter 23, and we now extend the discussion to organometallic compounds containing *d*-block metals from the first, second and third rows. This topic covers a huge area of chemistry, and we can only provide an introduction to it, emphasizing the fundamental families of complexes and reactions.

In the previous chapters, we introduced compounds containing σ-bonds or π-interactions between a metal centre and a cyclopentadienyl ligand. We also introduced examples of 3-electron donor bridging ligands, e.g. halides (**23.8**) and alkynyls (**23.11**), and 2-electron alkene donors, e.g. **23.19**.

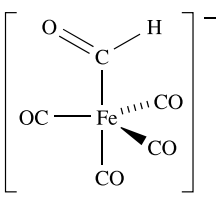
The *hapticity of a ligand* is the number of atoms that are directly bonded to the metal centre (see Box 23.1). Structures **24.1a** and **24.1b** show two representations of an $[\eta^5\text{-}C_5H_5]^-$ (cyclopentadienyl, Cp^-) ligand. For clarity in the diagrams in this chapter, we adopt **24.1b** and similar representations for π-ligands such as $\eta^3\text{-}C_3H_5$ and $\eta^6\text{-}C_6H_6$.

(24.1a)



(24.1b)

24.2 Common types of ligand: bonding and spectroscopy



In this section, we introduce some of the most common ligands found in organometallic complexes. Many other ligands are related to those discussed below, and bonding descriptions can be developed by comparison with the ligands chosen for detailed coverage.

σ-Bonded alkyl, aryl and related ligands

In complexes such as WMe_6, $[MoMe_7]^-$, $TiMe_4$ and $MeMn(CO)_5$, the $M-C_{Me}$ bond can be described as a localized 2c-2e interaction. The same bonding description is applicable to the $Fe-C_{Ph}$ bond in **24.2** and the $Fe-C_{CHO}$ bond in **24.3**.

(24.2)

(24.3)

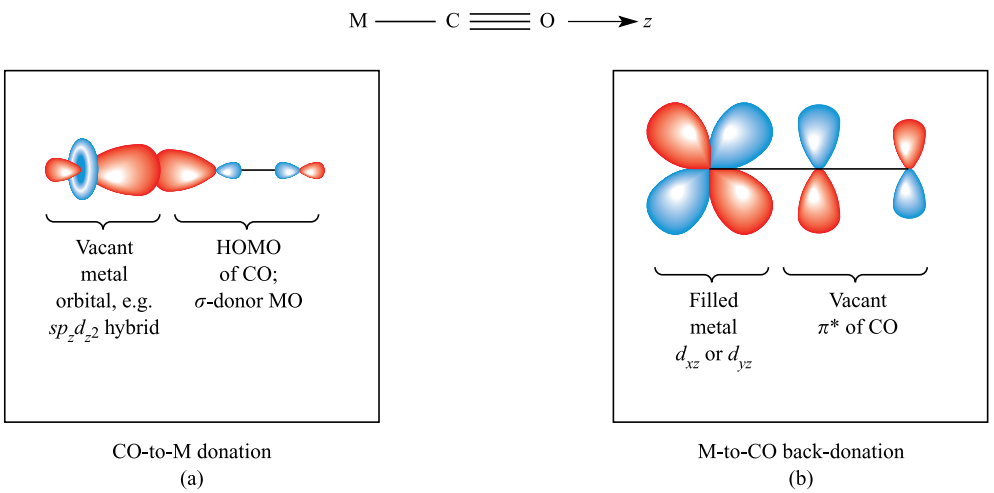


Fig. 24.1. Components of metal–carbonyl bonding: (a) the M−CO σ-bond, and (b) the M−CO π-interaction which leads to back-donation of charge from metal to carbonyl. The orbital labels are examples, and assume that the M, C and O atoms lie on the z axis.

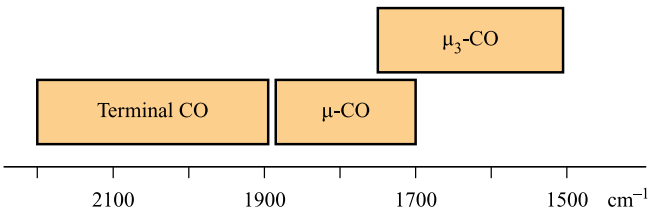
Carbonyl ligands

The bonding in octahedral $M(CO)_6$ complexes was described in Section 20.4 using a molecular orbital approach, but it is also convenient to give a simple picture to describe the bonding in one M−CO interaction. Figure 24.1a shows the σ-interaction between the highest occupied molecular orbital of CO (which has predominantly C character, Fig. 2.15) and a vacant orbital on the metal centre (e.g. an $sp_z d_{z^2}$ hybrid). As a result of this interaction, electronic charge is donated from the CO ligand to the metal. Figure 24.1b shows the π-interaction that leads to *back-donation* of charge from metal to ligand; compare Fig. 24.1b with Fig. 20.14b. This 'donation/back-donation' bonding picture is the *Dewar–Chatt–Duncanson model*. Carbon monoxide is a *weak* σ-*donor* and a *strong* π-*acceptor* (or π-*acid*) and population of the CO π^*-MO weakens and lengthens the C−O bond while also enhancing M−C bonding. Resonance structures **24.4** for the MCO unit also indicate a lowering of the C−O bond order as compared with free CO.[†]

(24.4)

The interplay of donation and back-donation of electronic charge between a metal and π-acceptor ligand is an example of a ***synergic effect***.

[†] For insight from DFT calculations, see: G. Bistoni *et al.* (2016) *Chem. Sci.*, vol. 7, p. 1174 – 'How π back-donation quantitatively controls the CO stretching response in classical and non-classical metal carbonyl complexes'.



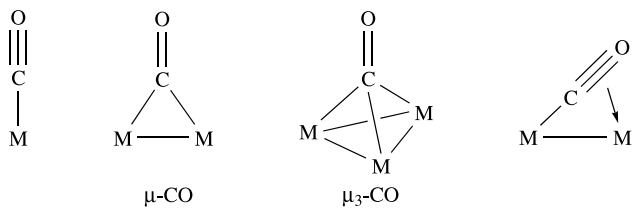


Fig. 24.2. Approximate regions in the IR spectrum in which absorptions assigned to C−O stretches observed for different carbonyl bonding modes; there is often overlap between the regions, e.g. see Table 24.1.

(24.5) **(24.6)** **(24.7)** **(24.8)**

In multinuclear metal species, CO ligands may adopt terminal (**24.5**) or bridging (**24.6** and **24.7**) modes. Other modes are known, e.g. semi-bridging (part way between **24.5** and **24.6**) and mode **24.8**.

Evidence for a lowering of the C−O bond order on coordination comes from structural and spectroscopic data. In the IR spectrum of free CO, an absorption at 2143 cm^{-1} is assigned to the C−O stretching mode and typical changes in vibrational wavenumber, $\bar{\nu}$, on going to metal carbonyl complexes are illustrated in Fig. 24.2. Absorptions due to C−O stretching modes are strong and easily observed. The lower the value of $\bar{\nu}_{CO}$, the weaker the C−O bond and this indicates greater back-donation of charge from metal to CO. Table 24.1 lists data for two

Table 24.1 Infrared spectroscopic data: values of $\bar{\nu}_{CO}$ for isoelectronic sets of tetrahedral $M(CO)_4$ and octahedral $M(CO)_6$ complexes.

Complex	$Ni(CO)_4$	$[Co(CO)_4]^-$	$[Fe(CO)_4]^{2-}$	$[Fe(CO)_6]^{2+}$	$[Mn(CO)_6]^+$	$Cr(CO)_6$	$[V(CO)_6]^-$
$\bar{\nu}_{CO}$ / cm^{-1}	2060	1890	1790	2204	2101	1981	1859

sets of isoelectronic metal carbonyl complexes. On going from $Ni(CO)_4$ to $[Co(CO)_4]^-$ to $[Fe(CO)_4]^{2-}$, the additional negative charge is delocalized onto the ligands, causing a decrease in $\bar{\nu}_{CO}$. A similar effect is seen along the series $[Fe(CO)_6]^{2+}$, $[Mn(CO)_6]^+$, $Cr(CO)_6$ and $[V(CO)_6]^-$. The increased back-donation is also reflected in values of $\bar{\nu}_{MC}$, e.g. 416 cm^{-1} for $[Mn(CO)_6]^+$, and 441 cm^{-1} for $Cr(CO)_6$.[†]

Carbonyl ligand environments can also be investigated using ^{13}C NMR spectroscopy, although systems are often fluxional (e.g. $Fe(CO)_5$, see Fig. 4.25 and discussion) and information about specific CO environments may therefore be masked. Some useful points are that:

- typical ^{13}C NMR shifts for metal carbonyl ^{13}C nuclei are δ +170 to +240 ppm;
- within a series of analogous compounds containing metals from a given triad, the ^{13}C NMR signals for the CO ligands shift to lower frequency, e.g. in the ^{13}C NMR spectra of $Cr(CO)_6$, $Mo(CO)_6$ and $W(CO)_6$, signals are at δ +211, +201 and +191 ppm respectively;
- for a given metal, signals for μ-CO ligands occur at higher frequency (more positive δ value) than those for terminal carbonyls.

In keeping with the typical weakening of the C−O bond on going from free CO to coordinated CO, X-ray diffraction data show a lengthening of the C−O bond. In CO, the C−O bond length is 112.8 pm, whereas typical values in metal carbonyls for terminal and μ-CO are 117 and 120 pm respectively.

The traditional bonding model for an M−CO interaction emphasizes OC ⟶ M σ-donation and significant M ⟶ CO π-back-donation leading to C−O bond weakening and a concomitant lowering of $\bar{\nu}_{CO}$. However, there are a growing number of isolable metal carbonyl complexes in which $\bar{\nu}_{CO}$ is *higher* than in free CO (i.e. >2143 cm^{-1}), the C−O bond distance is shorter than in free CO (i.e. <112.8 pm), and the M−C bonds are relatively long.[‡] Members of this group include the following cations (many are salts of $[SbF_6]^-$ or $[Sb_2F_{11}]^-$, see eqs. 22.78, 22.105 and 24.24) and, in each case, the metal–carbonyl bonding is dominated by the OC ⟶ M σ-component:

- tetrahedral $[Cu(CO)_4]^+$, $\bar{\nu}_{CO} = 2184\ cm^{-1}$, C−O = 111 pm;
- square planar $[Pd(CO)_4]^{2+}$, $\bar{\nu}_{CO} = 2259\ cm^{-1}$, C−O = 111 pm;
- square planar $[Pt(CO)_4]^{2+}$, $\bar{\nu}_{CO} = 2261\ cm^{-1}$, C−O = 111 pm;
- octahedral $[Fe(CO)_6]^{2+}$, $\bar{\nu}_{CO} = 2204\ cm^{-1}$, C−O = 110 pm;
- octahedral $[Ir(CO)_6]^{3+}$, $\bar{\nu}_{CO} = 2268\ cm^{-1}$, C−O = 109 pm.

An analysis of more than 20 000 crystal structures of *d*-block metal carbonyl complexes[*] confirms a clear correlation between C–O and M–C bond distances, i.e. as the M–C bond distance decreases, the C–O bond distance (d_{CO}) increases. Ninety per cent of the structural data fall into a region in which 117.0 pm > d_{CO} > 112.8 pm, and for these M–CO interactions, the M–C σ- and π-bonding contributions are approximately in balance. For 4%, π-bonding dominates and d_{CO} > 117.0 pm, while for 6%, σ-bonding and ionic contributions dominate and d_{CO} < 112.8 pm.

Self-study exercises

Answers to the following problems can be found by reading Section 3.7. Character tables are given in Appendix 3.

1. The vibrational wavenumbers for the ν_{CO} modes in $[V(CO)_6]^-$ are 2020 (A_{1g}), 1894 (E_g) and 1859 (T_{1u}) cm^{-1}. Explain why only one of these modes is IR active.

2. Confirm that $Mn(CO)_5Cl$ belongs to the C_{4v} point group. The vibrational wavenumbers for the ν_{CO} modes in $Mn(CO)_5Cl$ are 2138 (A_1), 2056 (E) and 2000 (A_1) cm^{-1}. Use the C_{4v} character table to confirm that all three modes are IR active.

3. The IR spectrum of a salt of $[Fe(CO)_4]^{2-}$ (T_d) shows an absorption at 1788 cm^{-1}, assigned to the T_2 mode. Sketch a diagram to show the mode of vibration that corresponds to this absorption.

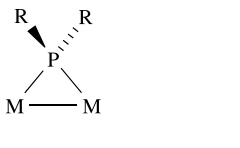
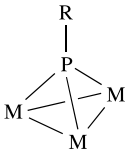
Hydride ligands

The term *hydride ligand* suggests $H^{\delta-}$ and is consistent with the charge distribution expected for an H atom attached to an electropositive metal centre. However, the properties of H ligands depend on environment and in many organometallic complexes, hydrido ligands behave as protons, being removed by base (eq. 24.1) or introduced by treatment with acid (reaction 24.2).



$$HCo(CO)_4 + H_2O \longrightarrow [Co(CO)_4]^- + [H_3O]^+ \quad (24.1)$$

$$[HFe(CO)_4]^- + H^+ \longrightarrow H_2Fe(CO)_4 \quad (24.2)$$



Hydride ligands can adopt terminal, bridging or (in metal clusters) interstitial modes of bonding (**24.9–24.12**). A localized 2c-2e M–H bond is an appropriate description for a terminal hydride, delocalized 3c-2e or 4c-2e interactions describe μ-H and μ_3-H interactions respectively (Figs. 24.3a and 24.3b), and a 7c-2e interaction is appropriate for an interstitial hydride in an octahedral cage (Fig. 24.3c).

can be adopted by $[PR_2]^-$ (**24.15**) or $[PR]^{2-}$ (**24.16**) ligands. Since 1990, examples of *bridging* PR_3 ligands have been known. To date, these typically involve the late *d*-block metals Rh and Pd. An early example is **24.17** which exhibits μ_3-PF_3 in addition to bidentate $R_2PCH_2PR_2$ ligands (see below). A series of dirhodium complexes involving μ-PR_3, μ-Sb^iPr_3 (e.g. **24.18**) or μ-$AsMe_3$ ligands is known.

(24.15)

(24.16)

(24.17)

(24.18)

Phosphanes are σ-donor and π-acceptor ligands (see Section 20.4) and related to them are arsanes (AsR_3), stibanes (SbR_3) and phosphites ($P(OR)_3$). The extent of σ-donation and π-acceptance depends on the substituents, e.g. PR_3 (R = alkyl) is a poor π-acceptor, whereas PF_3 is a poor σ-donor and as strong a π-acceptor as CO. The π-accepting properties of some PR_3 ligands follow the ordering:

$$PF_3 > P(OPh)_3 > P(OMe)_3 > PPh_3 > PMe_3 > P^tBu_3$$

Infrared spectroscopic data can be used to determine this sequence: a ligand *trans* to a CO affects the M ⟶ CO back-donation and, therefore, $\bar{\nu}_{CO}$, e.g. in octahedral $Mo(CO)_3(PF_3)_3$, $\bar{\nu}_{CO} = 2090$ and $2055\,cm^{-1}$, compared with 1937 and $1841\,cm^{-1}$ in $Mo(CO)_3(PPh_3)_3$.

The steric requirements of a PR_3 ligand depend on the R groups. Ligands such as PPh_3 (Fig. 24.4a) or P^tBu_3 are sterically demanding while others such as PMe_3 are less so. The steric requirements are assessed using the *Tolman cone angle*,[†] found by estimating the angle of a cone that has the metal atom at its apex and encompasses the PR_3 ligand taking the van der Waals surfaces of the H atoms as its boundary (Fig. 24.4b). Table 24.2 lists Tolman cone angles for selected ligands.

[†] For a full discussion, see C.A. Tolman (1977) *Chem. Rev.*, vol. 77, p. 313; J.A. Bilbrey and W.D. Allen (2013) *Ann. Rep. Comput. Chem.*, vol. 9, p. 3.

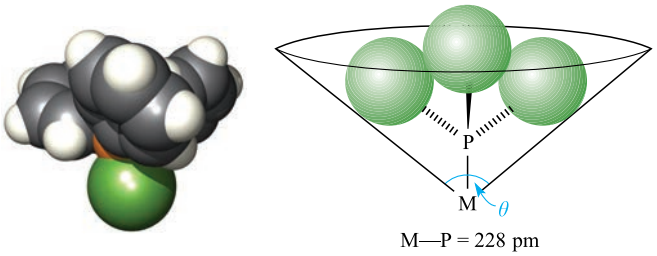

Fig. 24.4. (a) A space-filling diagram of an $FePPh_3$ unit; the phenyl groups adopt a 'paddle-wheel' arrangement; colour code: Fe, green; P, orange; C, grey; H, white. (b) Schematic representation of the measurement of the Tolman cone angle, θ, for a PR_3 ligand; each circle represents the spatial extent of an R group.

Table 24.2 Tolman cone angles for selected phosphane and phosphite ligands.

Ligand	Tolman cone angle / deg	Ligand	Tolman cone angle / deg
$P(OMe)_3$	107	PPh_3	145
PMe_3	118	$P(4\text{-}MeC_6H_4)_3$	145
PMe_2Ph	122	P^iPr_3	160
$PHPh_2$	126	$P(3\text{-}MeC_6H_4)_3$	165
$P(OPh)_3$	128	$P(cyclo\text{-}C_6H_{11})_3$	170
PEt_3	132	P^tBu_3	182
P^nBu_3	132	$P(2\text{-}MeC_6H_4)_3$	194
$PMePh_2$	136	$P(2,4,6\text{-}Me_3C_6H_2)_3$	212

The variation in electronic and steric effects in PR_3 and related ligands can significantly alter the reactivities of complexes in a series in which the only variant is the phosphane ligand. Many polydentate phosphanes are known, two of the more common being **24.19** (dppm) and **24.20** (dppe).[‡] The modes of bonding of polydentate phosphanes depend on the flexibility of the backbone of the ligand. For example, dppm is ideally suited to bridge between two adjacent M centres, whereas dppe is found in chelating and bridging modes, or may act as a monodentate ligand with one P atom uncoordinated. Assigning the bonding mode is aided by ^{31}P NMR spectroscopy. Coordination of a P atom shifts its ^{31}P NMR resonance to higher frequency, e.g. the signal in the ^{31}P NMR spectrum of free PPh_3 is at δ −6 ppm, compared with δ +20.6 ppm for $W(CO)_5(PPh_3)$.

[‡] The abbreviations dppm and dppe originate from the old names bis(diphenylphosphino)methane and bis(diphenylphosphino)ethane, but the IUPAC names are methylenebis(diphenylphosphane) and ethane-1,2-diylbis(diphenylphosphane).

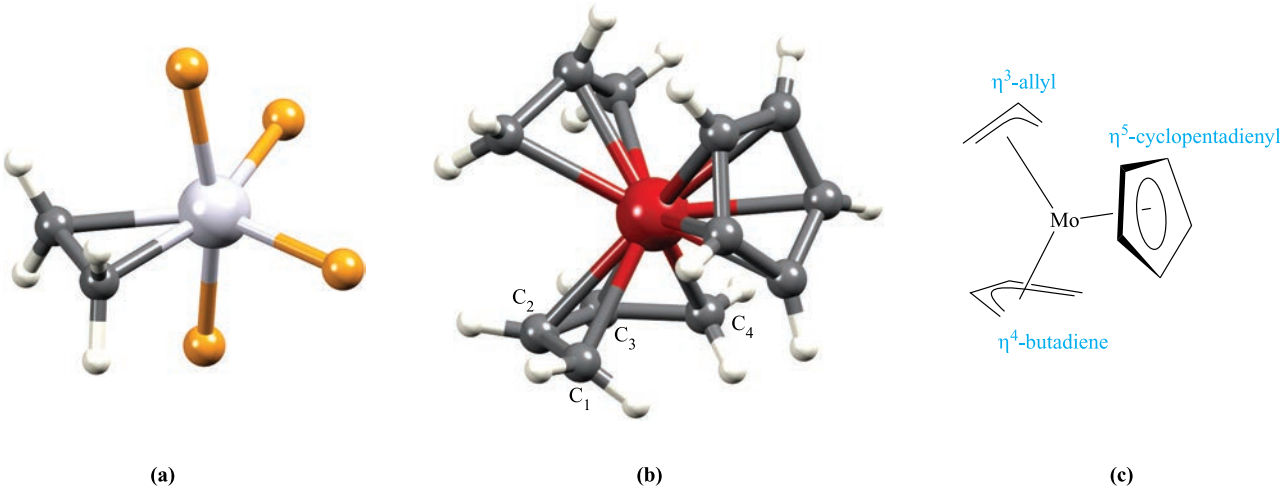
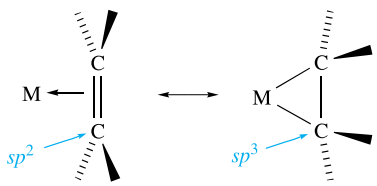
π-Bonded organic ligands

Alkenes, $R_2C{=}CR_2$, tend to bond to metal centres in a 'side-on' (i.e. η^2) manner and behave as 2-electron donors. The metal–ligand bonding can be described in terms of the Dewar–Chatt–Duncanson model (Fig. 24.5). The C=C π-bonding MO acts as an electron donor, while the π^*-MO is an electron acceptor. Populating the π^*-MO leads to:

- C−C bond lengthening, e.g. 133.9 pm in C_2H_4 *vs* 144.5 pm in $(\eta^5\text{-Cp})Rh(\eta^2\text{-}C_2H_4)(PMe_3)$;
- a lowering of the absorption in the vibrational spectrum due to the stretching of the C=C bond, e.g. 1623 cm^{-1} in free C_2H_4 *vs* 1551 cm^{-1} in $Fe(CO)_4(\eta^2\text{-}C_2H_4)$.

The extent of back-donation to $R_2C{=}CR_2$ is influenced by the nature of R, and is enhanced by electron-withdrawing groups such as CN. In the extreme, the π-contribution to the C−C bond is completely removed and the complex becomes a *metallacyclopropane* ring. Structures **24.21a** and **24.21b** show limiting bonding schemes. In **24.21a**, alkene ⟶ M donation of charge is dominant, while in **24.21b**, π-back-donation has fully populated the alkene π^*-MO, reducing the C−C bond order to one. On going from **24.21a** to **24.21b**, the alkene C atoms rehybridize from sp^2 to sp^3, M−C σ-bonds are formed, and





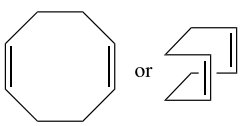


Fig. 24.6. (a) The structure (X-ray diffraction) of $Ru(\eta^2\text{-}C_2H_4)(PMe_3)_4$ illustrating the non-planarity of the coordinated ethene ligand (C−C = 144 pm); only the P atoms of the PMe_3 ligands are shown [W.-K. Wong *et al.* (1984) *Polyhedron*, vol. 3, p. 1255], (b) the structure (X-ray diffraction) of $Mo(\eta^3\text{-}C_3H_5)(\eta^4\text{-}CH_2CHCHCH_2)(\eta^5\text{-}C_5H_5)$ [L.-S. Wang *et al.* (1997) *J. Am. Chem. Soc.*, vol. 119, p. 4453] and (c) a schematic representation of $Mo(\eta^3\text{-}C_3H_5)(\eta^4\text{-}CH_2CHCHCH_2)(\eta^5\text{-}C_5H_5)$. Colour code: Ru, pale grey; Mo, red; C, dark grey; P, orange; H, white.

the alkene substituents bend away from the metal (Fig. 24.6a). Comparisons of X-ray diffraction data for series of complexes provide evidence for these structural changes.

(24.21a) **(24.21b)**

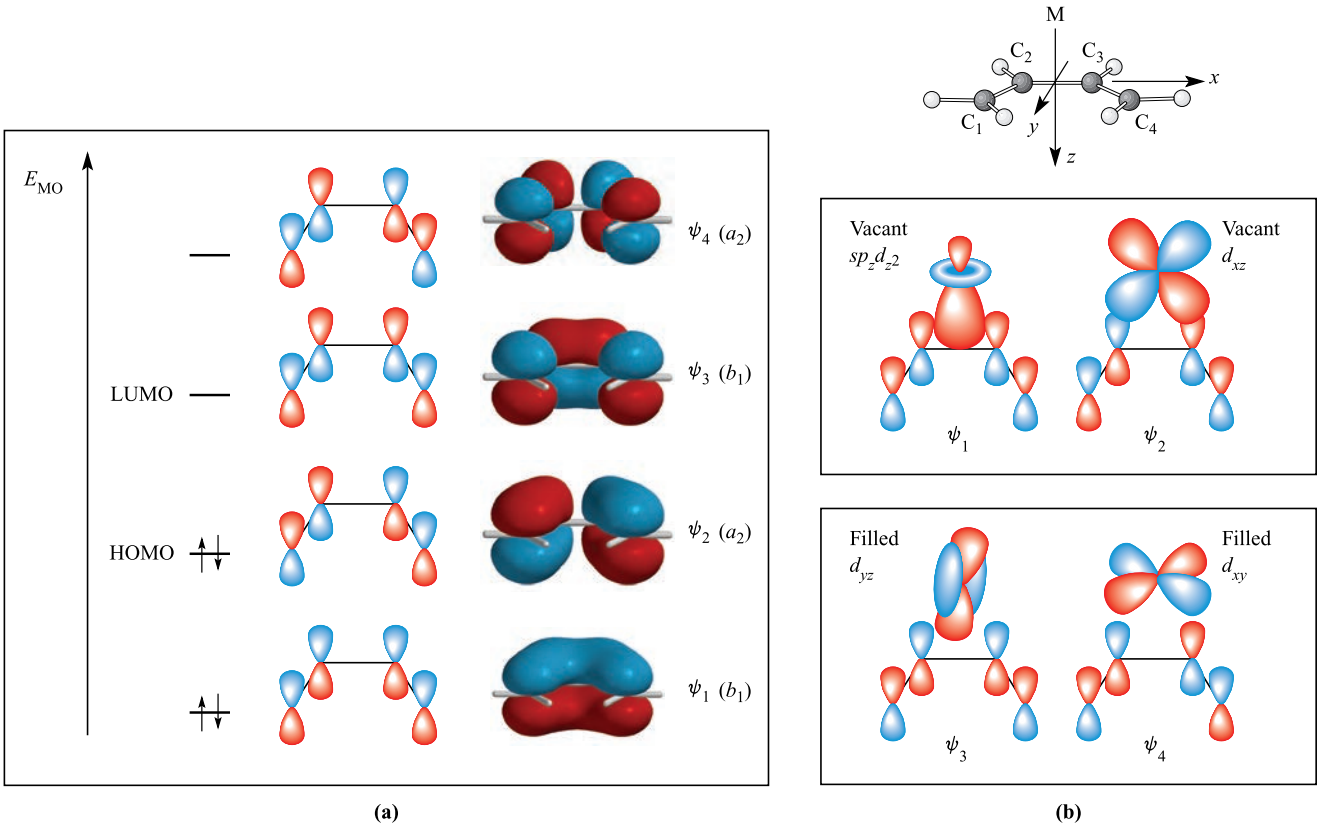
(24.22)

(24.23)

The bonding description for a coordinated alkene can be extended to other unsaturated organic ligands. Polyalkenes may be non-conjugated or conjugated. In complexes of non-conjugated systems (e.g. cycloocta-1,5-diene (cod), **24.22**, or 2,5-norbornadiene (nbd), **24.23**), the metal–ligand bonding is analogous to that for isolated alkene groups. For complexes of conjugated polyenes such as buta-1,3-diene, a delocalized bonding picture is appropriate. Figure 24.7a shows the four π-molecular orbitals of buta-1,3-diene. These MOs can be derived using the procedures described in Section 5.6. *cis*-Buta-1,3-diene (i.e. the *free* ligand) has C_{2v} symmetry. We define the z axis to coincide with the C_2 axis, and the molecule to lie in the yz plane. (This axis set is not that used in Fig. 24.7b. Instead, a convenient axis set is chosen to describe the metal orbitals in the complex.) After C−H and C−C σ-bond formation, each C atom has one $2p$ orbital for π-bonding. The number of these $2p$ orbitals unchanged by each symmetry operation in the C_{2v} point group is given by the following row of characters:

E	C_2	$\sigma_v(xz)$	$\sigma_v'(yz)$
4	0	0	−4

Since there are four $2p$ orbitals, there will be four π-MOs, and from the C_{2v} character table, the row of characters above is reproduced by taking the sum of two A_2 and two B_1 representations. The π-orbitals therefore have a_2 or b_1 symmetry, and schematic representations are shown in Fig. 24.7a. In Fig. 24.7b, their symmetries (see caption to Fig. 24.7) are matched to available metal orbitals. Two combinations lead to ligand ⟶ M donations, and two to M ⟶ ligand back-donation. The interactions involving ψ_2 and ψ_3 weaken bonds C_1−C_2 and C_3−C_4, while strengthening C_2−C_3. The extent of ligand donation or metal back-donation depends on the metal, substituents on the diene, and other ligands present. Structure **24.24** shows the C−C bond lengths in free buta-1,3-diene, and examples of complexes include $Fe(CO)_3(\eta^4\text{-}C_4H_6)$, in which all three C−C bonds in the coordinated diene are 145 pm, and $Mo(\eta^3\text{-}C_3H_5)(\eta^4\text{-}C_4H_6)(\eta^5\text{-}C_5H_5)$ (Fig. 24.6b and c), in which the butadiene ligand has C−C bond lengths of 142 (C_1−C_2), 138 (C_2−C_3) and 141 pm (C_3−C_4). Just as for



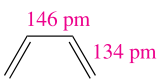


Fig. 24.7. (a) The four π-MOs of buta-1,3-diene (the energy scale is arbitrary); the symmetry labels apply to C_{2v} buta-1,3-diene with the C and H atoms lying in the *yz* plane. These symmetry labels are not applicable to the ligand in a complex of other symmetry. (b) Axis definition for a metal–buta-1,3-diene complex and the combinations of metal and ligand orbitals that lead to transfer of charge from a 1,3-diene to metal (top diagram) and from metal to 1,3-diene (lower diagram). alkene coordination, we can draw two limiting resonance structures (**24.25**) for a buta-1,3-diene (or other 1,3-diene) complex.†

(24.24)

(24.25)

(24.26)

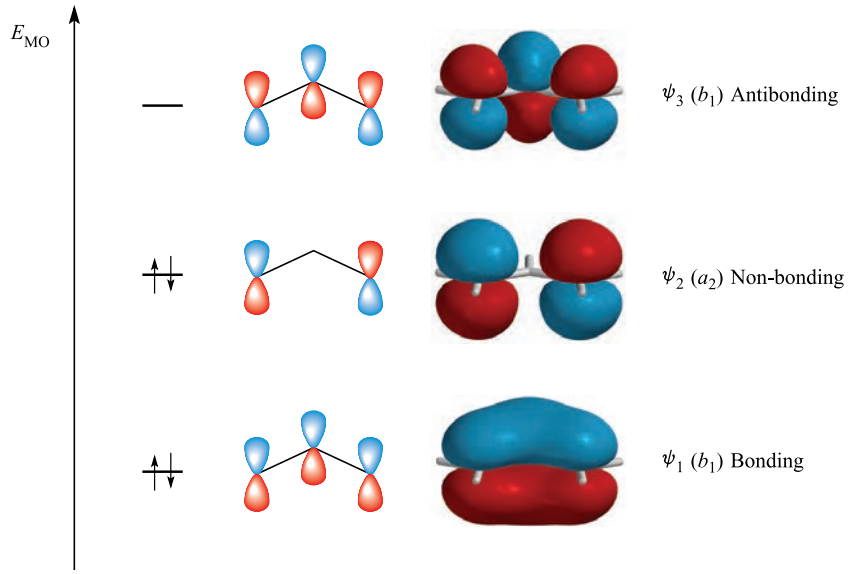
The allyl ligand, $[C_3H_5]^-$ (**24.26**), coordinates in an η^3-mode, using the two occupied π-MOs (bonding and non-bonding) as donors and the π^*-MO as an acceptor (Fig. 24.8). Allyl can also be considered as $[C_3H_5]^\bullet$ (see later). Similar schemes can be developed for cyclobutadiene (η^4-C_4H_4), cyclopentadienyl (η^5-C_5H_5, see Box 23.2), benzene (η^6-C_6H_6) and related ligands as we discuss later in the chapter.

In solution, complexes with π-bonded organic ligands are often fluxional, with rotation of the ligand being a common dynamic process (see structure **24.55**, Fig. 24.22 and scheme 24.98). Variable-temperature NMR spectroscopy is used to study such phenomena.

Nitrogen monoxide

Nitrogen monoxide is a radical (see Section 15.8). Its bonding closely resembles that of CO, and can be represented as in Fig. 2.15 with the addition of one electron into a $\pi^*(2p)$ orbital. The NO molecule can bind to a low oxidation state metal atom in a similar way to CO, and once coordinated NO is known as a *nitrosyl* ligand. However, unlike CO, terminally bound NO can adopt two different bonding modes: linear or bent (see the end of Section 20.4). In the linear mode (**24.27**), NO donates

† For a critical discussion of the C–C bond lengths in Mn(η^4-C_4H_6)$_2$(CO) and related complexes, see: G.J. Reiß and S. Konietzny (2002) *J. Chem. Soc., Dalton Trans.*, p. 862.



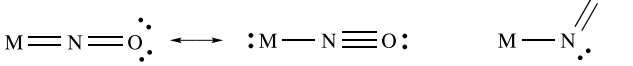


Fig. 24.8. The three π-MOs of the allyl anion, $[C_3H_5]^-$ (the energy scale is arbitrary); the symmetry labels apply to C_{2v} allyl with the C and H atoms lying in the *yz* plane. These symmetry labels are not applicable to the ligand in a complex of other symmetry. The right-hand diagrams were generated computationally using Spartan '04, ©Wavefunction Inc. 2003.

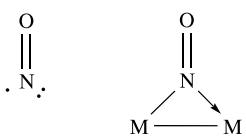
three electrons to the metal centre, and the ligand behaves as a π-acceptor. Experimentally, a 'linear' MNO unit may have M–N–O bond angles in the range 165–180°, and in the IR spectrum, the vibrational wavenumber for the ν_{NO} mode lies in the approximate range 1650–1900 cm^{-1}. In the bent mode (**24.28**), NO donates one electron to the metal centre. Bent nitrosyl ligands are characterized by having M–N–O bond angles in the range 120–140°, and in the IR spectrum, the ν_{NO} absorption typically lies between 1525 and 1690 cm^{-1}.

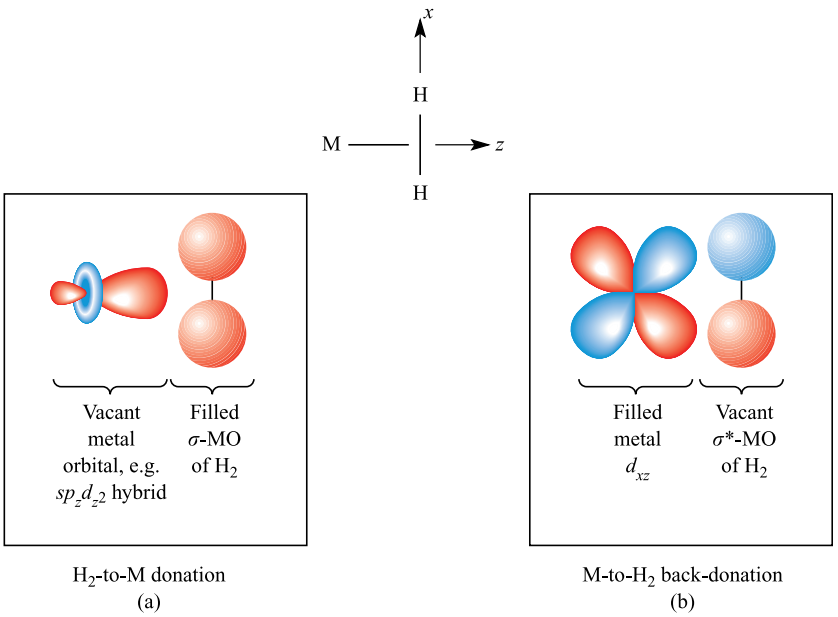


(24.27)

(24.28)

Series of related carbonyl and nitrosyl complexes exist, e.g. $Fe(CO)_5$ and $Fe(CO)_2(NO)_2$, and $Cr(CO)_6$ and $Cr(NO)_4$. The differences in numbers of ligands can be rationalized by applying the 18-electron rule (see the exercises below).

Nitrosyl ligands may also adopt bridging modes, acting as a 3-electron donor (**24.29**).



(24.29)

Self-study exercises

1. Use the 18-electron rule (see Sections 20.4 and 24.3) to explain why Cr(0) binds six CO ligands, i.e. $Cr(CO)_6$, but only four NO ligands, i.e. $Cr(NO)_4$.
2. Show that both $Fe(CO)_5$ and $Fe(CO)_2(NO)_2$ obey the 18-electron rule.
3. Explain why you would expect the Fe–N–O units to be linear in $Fe(NO)_3Cl$.
4. Explain why 'linear NO' may be considered as an NO^+ ligand.
5. The IR spectrum of $Os(NO)_2(PPh_3)_2$ exhibits an absorption at 1600 cm^{-1} assigned to ν_{NO}. This lies on the border between the ranges for bent and linear OsNO units. Suggest why you might conclude that the bonding mode is linear.

Dinitrogen

The molecules N_2 and CO are isoelectronic, and the bonding description in Fig. 24.1 can be qualitatively applied to N_2 complexes (see Section 22.9), although it must be remembered that the MOs of N_2 have equal atomic orbital contributions from each atom. Complexes of N_2 are not as stable as those of CO, and far fewer examples are known. Terminal M–N≡N units are linear (like a terminal M–C≡O), but bridging N_2 ligands do not mimic bridging CO groups (see structure **22.58** and discussion).

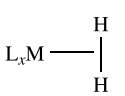
H_2-to-M donation (a)

M-to-H_2 back-donation (b)

Fig. 24.9. Components of metal–dihydrogen bonding: (a) H_2-to-M donation using the H_2 σ-bonding MO and (b) M-to-H_2 back-donation into the H_2 σ^*-MO. The axis set is defined in the top diagram.

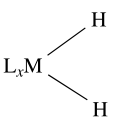
Self-study exercise

The isotopically labelled compound Ni($^{14}N_2$)$_4$ has been formed in an N_2 matrix. The IR spectrum shows an absorption close to 2180 cm^{-1}. This band also appears in the Raman spectrum of Ni($^{14}N_2$)$_4$, along with a band at 2251 cm^{-1}. The latter is absent in the IR spectrum. Both absorptions arise from coordinated N_2 stretching modes. Use these data to deduce the point group of Ni($^{14}N_2$)$_4$. Sketch diagrams to show the modes of vibration and assign symmetry labels to them.



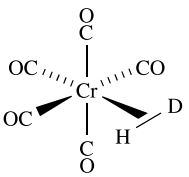
[*Ans.* Refer to Fig. 3.16 and accompanying text]

Dihydrogen



We have already mentioned dihydrogen complexes of Re (e.g. **22.33**) and noted the presence of a 'stretched' H–H bond. Other examples include W(CO)$_3$(η^2-H$_2$)(P^{i}Pr$_3$)$_2$, [OsH(η^2-H$_2$){P(OEt)$_3$}$_4$]$^+$, Cr(CO)$_5$(η^2-H$_2$), W(CO)$_5$(η^2-H$_2$) and [Re(CO)$_5$(η^2-H$_2$)]$^+$. The H_2 molecule only has available a σ-MO (electron donor orbital) and a σ^*-MO (acceptor). Both metal–ligand interactions shown in Fig. 24.9 weaken the H–H bond, and coordination readily leads to H–H cleavage (see Section 24.8). In dihydrogen complexes (**24.30**), the H–H bond distance is usually 80–100 pm. This compares to an H–H separation of $\geq$150 pm in a metal dihydride complex (**24.31**). Complexes containing M(η^2-H$_2$) units but with H–H distances of 110–150 pm (so-called 'stretched' H–H bonds) are also known.[†] Accurate determinations of H–H bond distances require neutron diffraction data. However, by preparing complexes containing HD (e.g. **24.32**), ^{1}H NMR spectroscopic data can be used to confirm the presence of an H–D (or, by analogy, an H–H) bond. The ^{2}H (D) nucleus possesses $I = 1$ and, therefore, ^{1}H–^{2}H coupling is observed. For example, the ^{1}H NMR spectrum of complex **24.32** shows a 1 : 1 : 1 multiplet, with $J_{HD} = 35.8$ Hz. This is smaller than that observed for free HD ($J_{HD} = 43$ Hz), but larger than the value for a metal dihydride complex ($J_{HD} \approx 2$–3 Hz). An estimate of the H–D bond length can be obtained by using the empirical relationship 24.3.

$$d(\text{H–H}) = 144 - (1.68 \times J_{HD}) \qquad (24.3)$$



where: d is in pm, J_{HD} is in Hz

(24.30)

(24.31)

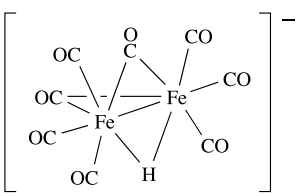
24.3 The 18-electron rule

In Section 20.4, we applied molecular orbital theory to octahedral complexes containing π-acceptor ligands and gave a rationale for the fact that *low oxidation state organometallic complexes tend to obey the 18-electron rule*. This rule often breaks down for early and late *d*-block metals as examples later in the chapter show: 16-electron complexes are common for e.g. Rh(I), Ir(I), Pd(0) and Pt(0). The majority of organometallic compounds with metals from the middle of the *d*-block obey the 18-electron rule and its application is useful, for example, in checking proposed structures. For electron-counting purposes, it is convenient to treat all ligands as *neutral* entities as this avoids the need to assign an oxidation state to the metal centre. However, one must not lose sight of the fact that this is a *formalism*. For example, in the synthesis of cyclopentadienyl derivatives, a common precursor is the salt $Na^+[Cp]^-$. Ferrocene, Cp_2Fe, may be formulated as an Fe(II) compound containing $[Cp]^-$ ligands, but for electron counting, it is convenient to consider the combination of an Fe(0) centre (group 8, 8 valence electrons) and two neutral $Cp^\bullet$ ligands (5-electron donor) giving an 18-electron complex (**24.33**). Of course, the same result is obtained if a formal oxidation state of +2 is assigned to the metal: Fe(II) (6 valence electrons) and two Cp^- ligands (6-electron donor). In this book we count valence electrons in terms of a zero oxidation state metal centre.

Electron count:

Fe(0) = 8 valence electrons
$2Cp^\bullet$ = 2 × 5 valence electrons
Total = 18 electrons

(24.33)

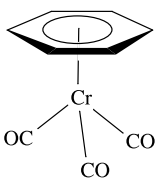


The number of valence electrons for a zero oxidation state metal centre is equal to the group number (e.g. Cr, 6; Fe, 8; Rh, 9). Some commonly encountered ligands† donate the following numbers of valence electrons:

- 1-electron donor: $H^\bullet$ (in any bonding mode), and terminal $Cl^\bullet$, $Br^\bullet$, $I^\bullet$, $R^\bullet$ (e.g. R = alkyl or Ph) or $RO^\bullet$;
- 2-electron donor: CO, PR_3, $P(OR)_3$, $R_2C{=}CR_2$ (η^2-alkene), R_2C**:** (carbene);
- 3-electron donor: η^3-$C_3H_5^\bullet$ (allyl radical), RC (carbyne), μ-$Cl^\bullet$, μ-$Br^\bullet$, μ-$I^\bullet$, μ-$R_2P^\bullet$ (**24.34**);
- 4-electron donor: η^4-diene (e.g. **24.24**), η^4-C_4R_4 (cyclobutadienes);
- 5-electron donor: η^5-$C_5H_5^\bullet$ (as in **24.33**), μ_3-$Cl^\bullet$, μ_3-$Br^\bullet$, μ_3-$I^\bullet$, μ_3-$RP^\bullet$;
- 6-electron donor: η^6-C_6H_6 (and other η^6-arenes, e.g. η^6-C_6H_5Me);
- 1- or 3-electron donor: NO (**24.27** and **24.28**).

(24.34)

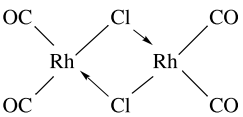
Counting electrons provided by bridging ligands, metal–metal bonds and net charges requires care. When bridging between two metal centres, an $X^\bullet$ (X = Cl, Br, I) or $R_2P^\bullet$ ligand uses the unpaired electron and one lone pair to give an interaction formally represented by structure **24.34**, i.e. one electron is donated to M, and two to M'. In a doubly bridged species such as $(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2$, the μ-Cl atoms are equivalent as are the Rh atoms, and the two Cl bridges together contribute three electrons to each Rh. A bridging $H^\bullet$ provides only one electron *in total*, shared between the metal atoms it bridges, e.g. in $[HFe_2(CO)_8]^-$, (**24.35**). Example **24.35** also illustrates that the formation of an M−M single bond provides each M atom with one extra electron.



Electron count:

Fe(0) = 8 electrons
3 terminal CO = 3 × 2 electrons
2 μ-CO = 2 × 1 electron per Fe
Fe–Fe bond = 1 electron per Fe
H = $^1/_2$ electron per Fe
1− charge = $^1/_2$ electron per Fe
Total = 18 electrons per Fe

(24.35)



Worked example 24.1 18-Electron rule

Confirm that the Cr centre in $[(\eta^6\text{-}C_6H_6)Cr(CO)_3]$ obeys the 18-electron rule, but Rh in $[(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2]$ does not.

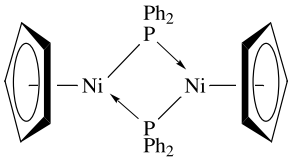
Cr(0) (group 6) contributes 6 electrons
η^6-C_6H_6 contributes 6 electrons
3 CO contribute 3 × 2 = 6 electrons

Total = 18 electrons

Rh(0) (group 9) contributes 9 electrons
μ-Cl contributes 3 electrons (1 to one Rh and 2 to the other Rh)
2 CO contribute 2 × 2 = 4 electrons

Total per Rh = 16 electrons

† Notation for bridging ligands: see Section 7.7.



Self-study exercises

1. Confirm that the Fe centres in $H_2Fe(CO)_4$ and $[(\eta^5\text{-}C_5H_5)Fe(CO)_2]^-$ obey the 18-electron rule.
2. Show that $Fe(CO)_4(\eta^2\text{-}C_2H_4)$, $HMn(CO)_3(PPh_3)_2$ and $[(\eta^6\text{-}C_6H_5Br)Mn(CO)_3]^+$ contain 18-electron metal centres.
3. Show that $[Rh(PMe_3)_4]^+$ contains a 16-electron metal centre. Comment on whether this violation of the 18-electron rule is expected.

Worked example 24.2 18-Electron rule: metal–metal bonding

Metal–metal bonding in multinuclear species is not always clear-cut. *Solely on the basis of the 18-electron rule*, suggest whether $(\eta^5\text{-Cp})Ni(\mu\text{-}PPh_2)_2Ni(\eta^5\text{-Cp})$ might be expected to contain a metal–metal bond.

The formula is instructive in terms of drawing a structure, except in respect of an M−M bond. Thus, we can draw an initial structure:

Now count the valence electrons around each metal centre: Ni(0) (group 10) contributes 10 electrons; η^5-Cp$^\bullet$ gives 5 electrons. Two μ-PPh_2 contribute 6 electrons, 3 per Ni. Total per Ni = 18 electrons.
Conclusion: each Ni atom obeys the 18-electron rule and no Ni−Ni bond is required.

Note that in all such examples, a prediction about the presence or not of the M−M bond *assumes* that the 18-electron rule is obeyed. Bridging ligands often play a very important role in supporting a dimetal framework.

Self-study exercises

1. Use the 18-electron rule to rationalize why manganese carbonyl forms a dimer $Mn_2(CO)_{10}$ containing an Mn–Mn bond, rather than a monomer $Mn(CO)_5$.
2. The presence of an Fe−Fe bond in the compound $(\eta^5\text{-Cp})(CO)Fe(\mu\text{-}CO)_2Fe(CO)(\eta^5\text{-Cp})$ has been a controversial topic. *Solely on the basis of the 18-electron rule*, show that an Fe−Fe bond is expected. What does your conclusion depend on? Are your assumptions infallible?

24.4 Covalent bond classification (CBC)

In the last section, we classified ligands in terms of the number of electrons they donate to a metal atom without the need to assign a prejudicial formal oxidation state to the metal. This 'neutral model' for electron-counting is also the basis for the *covalent bond classification (CBC)* approach.[†] In this bonding model, a metal atom interacts with formally neutral ligands which are classified in terms of the number of electrons donated. Figure 24.10 shows MO schemes for the formation of 2-centre 2-electron M–L interactions in which a monodentate ligand is able to donate two, one or no electrons. A 2-electron donor is classified as an L-ligand, a 1-electron donor as an X ligand, and a 0-electron donor as a Z ligand. L and Z ligands are Lewis bases (e.g. H_2O, CO, PR_3) and Lewis acids (e.g. BF_3), respectively. X ligands are radicals (e.g. H, Cl, Me).

In the ***covalent bond classification (CBC)*** approach, ligands are classified in a neutral state as L (2-electron donor), X (1-electron donor) or Z (0-electron donor), or a combination thereof.

Ligands such as η^4-dienes and η^6-arenes are classified as L_2 and L_3 donors following from a valence-bond description of each ligand (Fig. 24.11). Similarly, an η^3-allyl radical is classified as an LX ligand, and an η^5-cyclopentadienyl radical is an L_2X ligand (Fig. 24.11). Table 24.3 gives the CBC classification of some common ligands and ligand types in organometallic compounds. For ligands such as CO and η^2-alkenes, the CBC classification as a 2-electron L ligand only considers electron donation to the metal. If the metal-to-ligand back-donation is also taken into account, both L and Z classifications are required. For ligands such as NO and η^7-C_7H_7 for which a singly occupied donor orbital is degenerate with a vacant acceptor orbital, the accepting properties must be taken into account. As a result, the classifications of X_3 for NO bonded to a metal in a linear manner and of L_2X_3 for η^7-$C_7H_7^\bullet$ are less simple to derive.[†]

Once ligands have been classified, the molecule as a whole can be categorized. This exercise is useful for classifying compounds of a metal (or other central atom) without the need for assigning a formal oxidation state. With the ligand types classed as L, X or Z, the molecule or molecular ion is written in the form $[ML_lX_xZ_z]^{Q\pm}$ where $Q\pm$ is the overall charge. For example, $Cr(CO)_6$ is written as ML_6, $HMn(CO)_5$ as ML_5X, and $[(\eta^5\text{-Cp})Fe(CO)_2]^-$ as

[†] For further details of the CBC approach, see: M.L.H. Green (1995) *J. Organomet. Chem.*, vol. 500, p. 127; M.L.H. Green and G. Parkin (2014) *J. Chem. Educ.*, vol. 91, p. 807; G. Parkin (2006) in *Comprehensive Organometallic Chemistry III*, eds. R.H. Crabtree and D.M.P. Mingos, Elsevier, Oxford, vol. 1, p. 1.

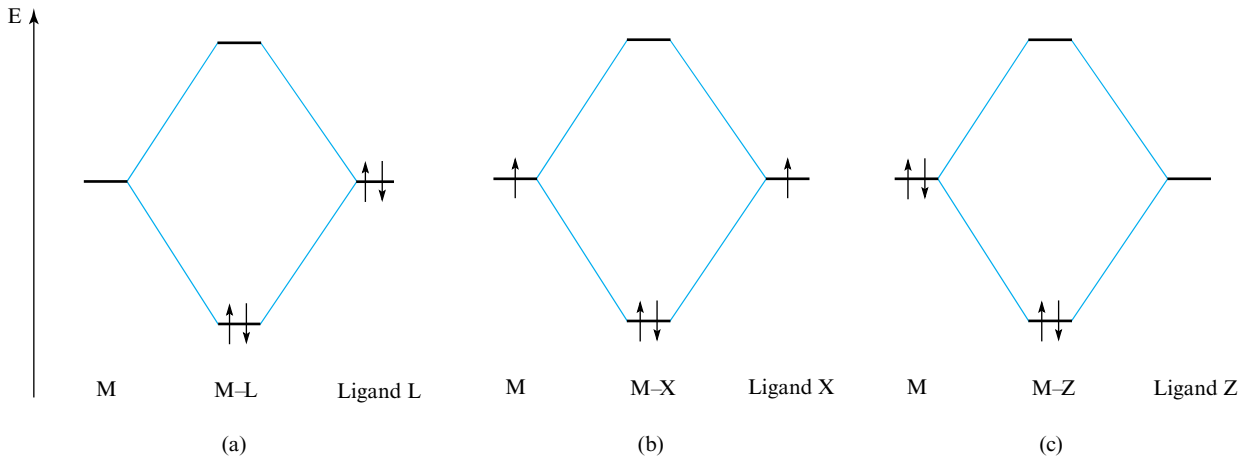


Fig. 24.10. The covalent bond classification (CBC) of (a) L (a 2-electron donor), (b) X (a 1-electron donor) and (c) Z (a 0-electron donor) ligands. Each ligand type is considered in its neutral form. The energy scale is arbitrary.

Table 24.3 Classifications of common ligands and ligand types within the CBC model.

Ligand	CBC description	Electron donor number
$H^{\bullet}$	X	1
$Cl^{\bullet}$ (terminally bonded)	X	1
$Br^{\bullet}$ (terminally bonded)	X	1
CO	L	2
PR_3	L	2
$R^{\bullet}$ (e.g. Me)	X	1
κ^1*C*-$C_5H_5^{\bullet}$	X	1
η^2-C_2H_4 (alkene)	L	2
η^3-$C_3H_5^{\bullet}$ (allyl radical)	LX	3
η^4-diene	L_2	4
η^5-$C_5H_5^{\bullet}$	L_2X	5
η^6-C_6H_6 (arene)	L_3	6
η^7-$C_7H_7^{\bullet}$	L_2X_3	7
NO (bent M–N–O)	X	1
NO (linear M–N–O)	X_3	3
CR (carbyne, see Section 24.13)	X_3	3
CR_2 (Fischer-type carbene, see Section 24.13)	L	2
CR_2 (Schrock-type carbene, see Section 24.13)	X_2	2
BR_3	Z	0

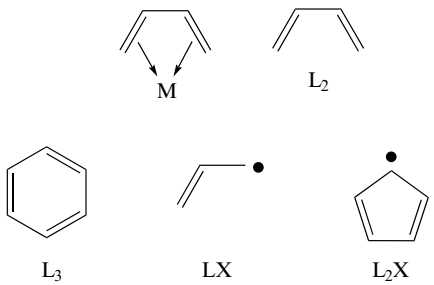

Fig. 24.11. Classifications of η^4-diene (showing coordination to a metal atom), η^6-arene, η^3-allyl and η^5-cyclopentadienyl ligands within the CBC model.

$[ML_4X]^-$. For a charged species, the charge is now localized on the ligands using the rules:

- for a cation, L^+ transforms to X (a 1-electron ligand); if no L ligand is present, X^+ transforms to Z;
- for an anion, X^- transforms to L (a 2-electron ligand); if no X ligand is present, L^- transforms to LX;
- if the classification derived after making these transformations contains both L and Z ligands, the classification is further reduced by LZ transforming to X_2.

The final result gives a classification in the form of a neutral species $ML_lX_xZ_z$.

Worked example 24.3 Applying the CBC approach

Derive a CBC class for $[(\eta^5\text{-Cp})Fe(CO)_2]^-$.

First, classify the ligands:

CO = L $\quad$ η^5-$Cp^{\bullet}$ = L_2X

Now combine these classifications:

$[(\eta^5\text{-Cp})Fe(CO)_2]^-$ becomes $[ML_4X]^-$

The negative charge is now localized on the X ligand, and then X^- transforms to L.

The final classification is ML_5.

Self-study exercises

1. Compare the CBC classes of $Fe(CO)_5$ and $[(\eta^5\text{-Cp})Fe(CO)_2]^-$.
[*Ans.* Both are ML_5]
2. Compare the CBC classes of $HMn(CO)_5$ and $[Mn(CO)_5]^-$.
[*Ans.* Both are ML_5X]
3. What is the CBC class of $[(\eta^5\text{-Cp})_2TiCl_2]$?
[*Ans.* ML_4X_4]
4. What is the CBC class of $[(\eta^5\text{-Cp})_2TiMe]^+$?
[*Ans.* ML_3X_4]

Once an $ML_lX_xZ_z$ classification is determined, the *electron number (EN)* may be found. The metal contributes its valence electrons (m), each L ligand contributes two electrons and each X ligand contributes one electron; Z ligands contribute no electrons. The value of *EN* for a given species is necessarily the same as that using the electron counting model described in Section 24.3. A second useful parameter is the *valence number (VN)* of the metal. Figure 24.10 showed that for an M–X bond, the M atom provides one electron, and for an M–Z bond, the M atom provides two electrons; the M atom provides no electrons for the formation of an M–L bond. These descriptions lead to the following equations for $ML_lX_xZ_z$:

$$EN = m + 2l + x$$

$$VN = x + 2z$$

Self-study exercises

1. The CBC class of $Cr(CO)_6$ is ML_6. Show that $Cr(CO)_6$ obeys the 18-electron rule, and show that the ML_6 model also gives $EN = 18$.
2. Use the CBC class of $[(\eta^5\text{-Cp})_2ZrEt_2]$ to show that $EN = 16$. Confirm this number using the electron counting model in Section 24.3.
3. Show that $VN = 4$ for $[(\eta^5\text{-Cp})_2TiCl_2]$, and that $VN = 1$ for $[HMn(CO)_5]$.
4. Give the CBC class of WMe_6, and show that $EN = 12$ and $VN = 6$.
[*Ans.* MX_6]

A valuable application of the CBC model is to assess preferred $ML_lX_xZ_z$ classes for particular metals, and to relate *EN* and *VN* numbers for a metal to the types of ligands based on their electronic and steric properties. Table 24.4 gives commonly occurring classes of organometallic complexes of the first row *d*-bock metals from groups 3–10. The values of *EN* in Table 24.4 provide an overview of how closely the 18-electron rule is obeyed. The early *d*-block metals, Sc and Ti, are satisfied with 14 or 16 electrons in the valence shell. The chart in Fig. 24.12 illustrates the relationship between different ligand classes and values of *EN* and *VN*. For example, π-acceptor ligands (e.g. CO) are associated with high *EN* which tend towards 18-electron compounds. Sterically demanding ligands favour low electron numbers ($EN = 10-14$) and low *VN*, while π- and σ-donors favour high *VN* and low *EN*.

24.5 Metal carbonyls: synthesis, physical properties and structure

Table 24.5 lists many of the stable, neutral, *d*-block metal carbonyl compounds containing six or fewer metal atoms.

Table 24.4 Common CBC classes of organometallic compounds in the first row of the *d*-block given as a percentage of the total number of compounds.[†] Where the total is <100%, other $ML_lX_xZ_z$ classes make small contributions to the total.

Group 3	Group 4	Group 5	Group 6	Group 7	Group 8	Group 9	Group 10
ScL_4X_3 36% ($EN = 14$)	TiL_4X_4 49% ($EN = 16$)	VL_6X 22% ($EN = 18$)	CrL_6 48% ($EN = 18$)	MnL_5X 79% ($EN = 18$)	FeL_4X_2 69% ($EN = 18$)	CoL_3X_3 54% ($EN = 18$)	NiL_2X_2 33% ($EN = 16$)
ScL_5X_3 33% ($EN = 16$)	TiL_5X_3 9% ($EN = 17$)	VL_4X_4 16% ($EN = 17$)	CrL_5X_2 24% ($EN = 18$)	MnL_4X_3 12% ($EN = 18$)	FeL_5 20% ($EN = 18$)	CoL_4X 34% ($EN = 18$)	NiL_3X_2 26% ($EN = 18$)
ScL_3X_3 10% ($EN = 12$)	TiL_2X_4 7% ($EN = 12$)	VL_4X_3 14% ($EN = 16$)	CrL_4X_4 7% ($EN = 18$)	MnL_3X_5 1% ($EN = 18$)	FeL_3X_4 7% ($EN = 18$)	CoL_2X_5 4% ($EN = 18$)	NiL_4 16% ($EN = 18$)

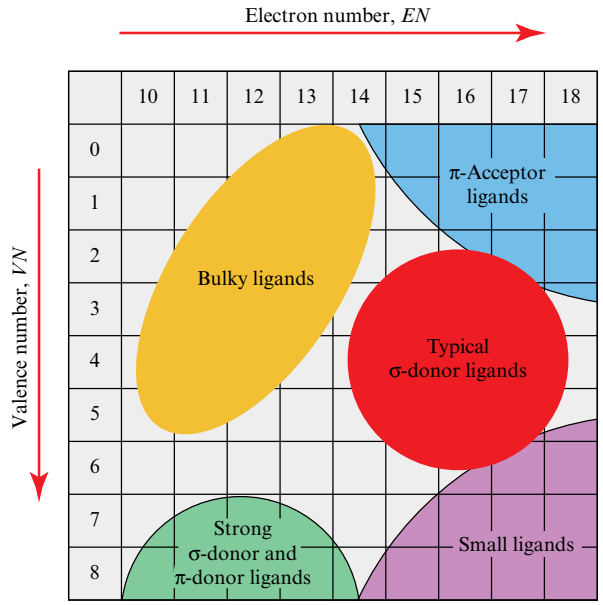

Fig. 24.12. Regions in a plot of electron number against valence number favoured by different types of ligands. [Redrawn with permission from Fig. 8 in M.L.H. Green (1995) *J. Organomet. Chem.*, vol. 500, p. 127 (Elsevier).]

A range of unstable carbonyls have been obtained by *matrix isolation*: the action of CO on metal atoms in a noble gas matrix at very low temperatures or the photolysis of stable metal carbonyls under similar conditions. Among species made this way are $Ti(CO)_6$, $Pd(CO)_4$, $Pt(CO)_4$, $Cu_2(CO)_6$, $Ag_2(CO)_6$, $Cr(CO)_4$, $Mn(CO)_5$, $Zn(CO)_3$, $Fe(CO)_4$, $Fe(CO)_3$ and $Ni(CO)_3$ (those of Cr, Mn, Fe and Ni being fragments formed by decomposition of stable carbonyls). In the rest of this section, we discuss compounds isolable at ordinary temperatures.

Synthesis and physical properties

The carbonyls $Ni(CO)_4$ and $Fe(CO)_5$ (both highly toxic) are the only ones normally obtained by action of CO on the finely divided metal. Formation of $Ni(CO)_4$ (eq. 21.4) occurs at 298 K and 1 bar pressure, but $Fe(CO)_5$ is made under 200 bar CO at 420–520 K. Most other simple metal carbonyls are prepared by *reductive carbonylation*, i.e. action of CO and a reducing agent (which may be excess CO) on a metal oxide, halide or other compound (e.g. reactions 24.4–24.12). Yields are often poor and we have not attempted to write stoichiometric reactions; for the preparation of $[Tc(H_2O)_3(CO)_3]^+$, see Box 22.6.

$$VCl_3 + Na + CO \xrightarrow[\text{in diglyme}]{420\text{ K, }150\text{ bar}} [Na(\text{diglyme})_2][V(CO)_6] \xrightarrow{HCl,\ Et_2O} V(CO)_6 \quad (24.4)$$

$$CrCl_3 + CO + Li[AlH_4] \xrightarrow[\text{in } Et_2O]{390\text{ K, }70\text{ bar}} Cr(CO)_6 + LiCl + AlCl_3 \quad (24.5)$$

$$MoCl_5 + CO + AlEt_3 \xrightarrow{373\text{ K, }200\text{ bar}} Mo(CO)_6 + AlCl_3 \quad (24.6)$$

$$WCl_6 + Fe(CO)_5 \xrightarrow{373\text{ K}} W(CO)_6 + FeCl_2 \quad (24.7)$$

$$OsO_4 + CO \xrightarrow{520\text{ K, }350\text{ bar}} Os(CO)_5 + CO_2 \quad (24.8)$$

$$Co(O_2CMe)_2{\cdot}4H_2O \xrightarrow[\text{in acetic anhydride}]{CO/H_2\ (4:1),\ 200\text{ bar, }430\text{ K}} Co_2(CO)_8 \quad (24.9)$$

$$RuCl_3{\cdot}xH_2O + CO \xrightarrow[\text{in MeOH}]{400\text{ K, }50\text{ bar}} Ru_3(CO)_{12} \quad (24.10)$$

$$RuCl_3{\cdot}xH_2O \xrightarrow[\text{in 2-ethoxyethanol}]{CO\ (1\text{ bar}),\ 353\text{ K, 1h; }408\text{ K, }45\text{ min}} \left\{[Ru(CO)_2Cl_2]_n \underset{}{\overset{CO}{\rightleftharpoons}} [Ru(CO)_3Cl_2]_2\right\} \xrightarrow[45\text{ min}]{KOH,\ 348\text{ K}} Ru_3(CO)_{12} \quad (24.11)$$

$$OsO_4 + CO \xrightarrow[\text{in MeOH}]{400\text{ K, }\leq 200\text{ bar}} Os_3(CO)_{12} \quad (24.12)$$

Diiron nonacarbonyl, $Fe_2(CO)_9$, is usually made by photolysis of $Fe(CO)_5$ (eq. 24.13), while $Fe_3(CO)_{12}$ is obtained by several methods, e.g. oxidation of $[HFe(CO)_4]^-$ using MnO_2.

$$2Fe(CO)_5 \xrightarrow{h\nu} Fe_2(CO)_9 + CO \quad (24.13)$$

Some metal carbonyls including $M(CO)_6$ (M = Cr, Mo, W), $Fe(CO)_5$, $Fe_2(CO)_9$, $Fe_3(CO)_{12}$, $Ru_3(CO)_{12}$, $Os_3(CO)_{12}$ and $Co_2(CO)_8$ are commercially available. All carbonyls are thermodynamically unstable with respect to oxidation in air, but the rates of oxidation vary: $Co_2(CO)_8$ reacts under ambient conditions, $Fe(CO)_5$ and $Ni(CO)_4$ are also easily oxidized (their vapours forming explosive mixtures with air), but $M(CO)_6$ (M = Cr, Mo, W) does not oxidize unless heated. Table 24.5 lists some physical properties of some of the more common metal carbonyls. Note the increased importance of M–M bonding as groups 8 and 9 are descended: e.g. whereas $Co_2(CO)_8$ is stable, $Rh_2(CO)_8$ is unstable with respect to $Rh_4(CO)_{12}$. The latter can also be formed by reaction 24.14, and above 400 K, it decomposes to $Rh_6(CO)_{16}$. Reactions 24.15 and 24.16 are routes to $Ir_4(CO)_{12}$ and $Ir_6(CO)_{16}$.

$$(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2 \xrightarrow[\text{in hexane, }NaHCO_3]{CO,\ 1\text{ bar, }298\text{ K}} Rh_4(CO)_{12} \quad (24.14)$$

Table 24.5 Neutral, low-nuclearity ($\leq M_6$) metal carbonyls of the *d*-block metals (dec. = decomposes).

Group number	5	6	7	8	9	10

				$Fe_2(CO)_9$ Golden crystals; mp 373 K (dec.)	**$Co_4(CO)_{12}$** Air-sensitive, black solid	
				$Fe_3(CO)_{12}$ Dark green solid; dec. 413 K	**$Co_6(CO)_{16}$** Black solid; slowly dec. in air	
Second row metals		**$Mo(CO)_6$** White solid; sublimes *in vacuo*	**$Tc_2(CO)_{10}$** White solid; slowly dec. in air; mp 433 K	**$Ru(CO)_5$** Colourless liquid; mp 251 K; dec. in air at 298 K to $Ru_3(CO)_{12} + CO$	**$Rh_4(CO)_{12}$** Red solid; >403 K dec. to $Rh_6(CO)_{16}$	
				$Ru_3(CO)_{12}$ Orange solid; mp 427 K; sublimes *in vacuo*	**$Rh_6(CO)_{16}$** Black solid; dec. >573 K	
Third row metals		**$W(CO)_6$** White solid; sublimes *in vacuo*	**$Re_2(CO)_{10}$** White solid; mp 450 K	**$Os(CO)_5$** Yellow liquid; mp 275 K	**$Ir_4(CO)_{12}$** Slightly air-sensitive yellow solid; mp 443 K	
				$Os_3(CO)_{12}$ Yellow solid; mp 497 K	**$Ir_6(CO)_{16}$** Red solid	

$$Na_3[IrCl_6] \xrightarrow[\text{2. base}]{\text{1. CO, 1 bar, in MeOH under reflux}} Ir_4(CO)_{12} \quad (24.15)$$

$$[Et_4N]_2[Ir_6(CO)_{15}] \xrightarrow{CF_3SO_3H \text{ under CO}} Ir_6(CO)_{16} \quad (24.16)$$

Metal carbonyl *clusters* containing four or more metal atoms are made by a variety of methods. Osmium forms a range of binary compounds and pyrolysis of $Os_3(CO)_{12}$ yields a mix of products (eq. 24.17) which can be separated by chromatography.

$$Os_3(CO)_{12} \xrightarrow{483\ K} Os_5(CO)_{16} + \underset{\text{major product}}{Os_6(CO)_{18}} + Os_7(CO)_{21} + Os_8(CO)_{23} \quad (24.17)$$

Metal carbonyl anions can be derived by reduction, e.g. reactions 24.18–24.23. Dimers such as $Mn_2(CO)_{10}$ and $Co_2(CO)_8$ undergo simple cleavage of the M−M bond, but in other cases, reduction is accompanied by an increase in metal nuclearity. In reactions 24.18 and 24.23, $Na[C_{10}H_8]$ (sodium naphthalide) is made from Na and naphthalene; both $Na[C_{10}H_8]$ and $K[C_{10}H_8]$ are powerful reducing agents.

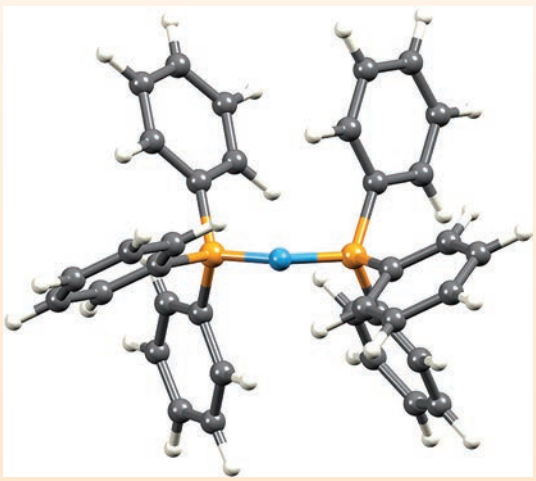
$$Fe(CO)_5 \xrightarrow{Na[C_{10}H_8]} Na_2[Fe(CO)_4] \quad (24.18)$$

$$Mn_2(CO)_{10} + 2Na \longrightarrow 2Na[Mn(CO)_5] \quad (24.19)$$

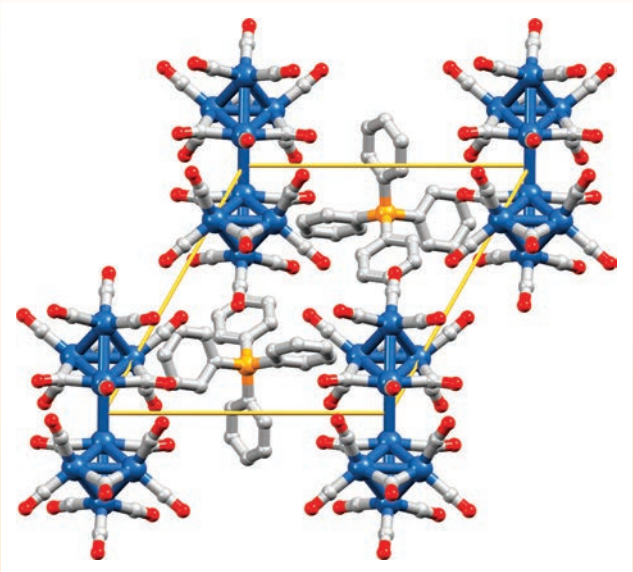
$$Co_2(CO)_8 + 2Na \longrightarrow 2Na[Co(CO)_4] \quad (24.20)$$

$$Ru_3(CO)_{12} \xrightarrow{Na,\ THF,\ \Delta} [Ru_6(CO)_{18}]^{2-} \quad (24.21)$$

$$Os_3(CO)_{12} \xrightarrow{Na,\ diglyme,\ \Delta} [Os_6(CO)_{18}]^{2-} \quad (24.22)$$



THEORY



Box 24.1 Large cations for large anions: 2

Metal cluster anions are usually stabilized in salts that contain large cations; common choices are $[Ph_4P]^+$, $[Ph_4As]^+$, $[^nBu_4N]^+$ and $[(Ph_3P)_2N]^+$ (see below). Compatibility between cation and anion sizes is important. The figure on the right shows part of the packing diagram for the salt $[Ph_4P]_2[Ir_8(CO)_{22}]$; the H atoms of the Ph rings are omitted for clarity. The diagram illustrates how well the large cations pack with the cluster anions, and this is essential for the stabilization and crystallization of such salts.

See also: Box 11.5 – Large cations for large anions: 1.

The structure of the $[(Ph_3P)_2N]^+$ cation (also written as $[PPN]^+$). The P–N–P angle varies between ~130 and 180°, but is typically close to 142°. Colour code: P, orange, N, blue; C, grey; H, white.

Colour coding: Ir, blue; C, grey; O, red; P, orange. The unit cell is shown in yellow. [Data from: F. Demartin *et al.* (1981) *J. Chem. Soc., Chem. Commun.*, p. 528.]

$$Ni(CO)_4 \xrightarrow{Na[C_{10}H_8]} [Ni_5(CO)_{12}]^{2-} + [Ni_6(CO)_{12}]^{2-} \qquad (24.23)$$

The salt $Na_2[Fe(CO)_4]$ (eq. 24.18) is *Collman's reagent*, and has numerous synthetic applications. It is very air-sensitive and is best prepared *in situ*. In reactions 24.21–24.23, Na^+ salts are the initial products, but the large cluster anions are isolated as salts of large cations such as $[(Ph_3P)_2N]^+$, $[Ph_4P]^+$ or $[Ph_4As]^+$ (see Box 24.1).

The use of superacid media has been central to developing synthetic routes to isolable salts of metal carbonyl cations. Two examples are $[Os(CO)_6]^{2+}$ and $[Ir(CO)_6]^{3+}$ (eqs. 22.78 and 22.105), both isolated as the $[Sb_2F_{11}]^-$ salts. Both syntheses involve reduction of high oxidation state metal fluorides (OsF_6 and IrF_6, respectively) and a similar method is used to prepare $[Pt(CO)_4]^{2+}$ (eq. 24.24). In contrast, $[Co(CO)_5]^+$ is made by oxidation of $Co_2(CO)_8$ (eq. 24.25); the oxidizing agent is probably $[H_2F]^+$.

The superacid HF/BF_3 is used to produce $[BF_4]^-$ salts of $[M(CO)_6]^{2+}$ (M = Fe, Ru, Os) (eqs. 24.26 and 24.27).

$$PtF_6 + 6CO + 4SbF_5 \xrightarrow{\substack{298-323\,K,\ 1\ bar\ CO \\ in\ liquid\ SbF_5}} [Pt(CO)_4][Sb_2F_{11}]_2 + 2COF_2 \qquad (24.24)$$

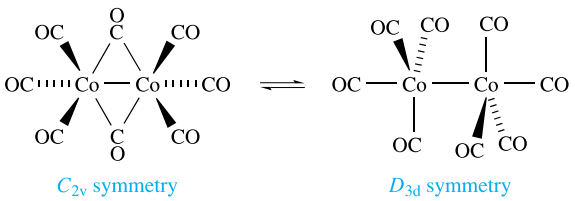
$$Co_2(CO)_8 + 2(CF_3)_3BCO + 2HF \xrightarrow{\substack{298\,K,\ 2\ bar\ CO \\ in\ liquid\ HF}} 2[Co(CO)_5][(CF_3)_3BF] + H_2 \qquad (24.25)$$

$$Fe(CO)_5 + XeF_2 + CO + 2BF_3 \xrightarrow{\substack{HF/BF_3,\ CO \\ 77\ to\ 298\ K}} [Fe(CO)_6][BF_4]_2 + Xe \qquad (24.26)$$

$$M_3(CO)_{12}\ (M = Ru, Os) \xrightarrow[195\ to\ 298\ K]{liquid\ HF,\ F_2} cis\text{-}[M(CO)_4F_2] \xrightarrow[298\ K]{HF/BF_3,\ CO} [M(CO)_6][BF_4]_2 \qquad (24.27)$$

Soc.*, vol. 99, p. 1104], (b) $Re_2(CO)_{10}$ showing the staggered configuration also adopted by $Mn_2(CO)_{10}$ and $Tc_2(CO)_{10}$ [M.R. Churchill *et al.* (1981) *Inorg. Chem.*, vol. 20, p. 1609], (c) $Fe_2(CO)_9$ [F.A. Cotton *et al.* (1974) *J. Chem. Soc., Dalton Trans.*, p. 800], (d) $Co_2(CO)_8$ [P.C. Leung *et al.* (1983) *Acta Crystallogr., Sect. B*, vol. 39, p. 535], (e) $Fe_3(CO)_{12}$ [D. Braga *et al.* (1994) *J. Chem. Soc., Dalton Trans.*, p. 2911] and (f) $Os_3(CO)_{12}$ which is isostructural with $Ru_3(CO)_{12}$ [M.R. Churchill *et al.* (1977) *Inorg. Chem.*, vol. 16, p. 878]. Colour code: Fe, green; Re, brown; Co, blue; Os, yellow; C, grey; O, red.

Structures



Mononuclear metal carbonyls possess the following structures (bond distances are for the solid state):†

- linear: $[Au(CO)_2]^+$ (Au–C = 197 pm);
- square planar: $[Rh(CO)_4]^+$ (Rh–C = 195 pm), $[Pd(CO)_4]^{2+}$ (Pd–C = 199 pm), $[Pt(CO)_4]^{2+}$ (Pd–C = 198 pm);
- tetrahedral: $Ni(CO)_4$ (Ni–C = 182 pm), $[Cu(CO)_4]^+$ (Cu–C = 196 pm), $[Co(CO)_4]^-$ (Co–C = 175 pm), $[Fe(CO)_4]^{2-}$ (Fig. 24.13a);
- trigonal bipyramidal: $Fe(CO)_5$ ($Fe–C_{axial}$ = 181 pm, $Fe–C_{equ}$ = 180 pm), $[Co(CO)_5]^+$ ($Co–C_{axial}$ = 183 pm, $Co–C_{equ}$ = 185 pm), $[Mn(CO)_5]^-$ in most salts ($Mn–C_{axial}$ = 182 pm, $Mn–C_{equ}$ = 180 pm);
- square-based pyramidal: $[Mn(CO)_5]^-$ in the $[Ph_4P]^+$ salt ($Mn–C_{apical}$ = 179 pm, $Mn–C_{basal}$ = 181 pm);
- octahedral: $V(CO)_6$ (V–C = 200 pm), $Cr(CO)_6$ (Cr–C = 192 pm), $Mo(CO)_6$ (Mo–C = 206 pm), $W(CO)_6$ (W–C = 207 pm), $[Fe(CO)_6]^{2+}$ (Fe–C = 191 pm), $[Ru(CO)_6]^{2+}$ (Ru–C = 202 pm), $[Os(CO)_6]^{2+}$ (Os–C = 203 pm), $[Ir(CO)_6]^{3+}$ (Ir–C = 203 pm).

With the exception of $V(CO)_6$, each obeys the 18-electron rule. The 17-electron count in $V(CO)_6$ suggests the possibility of dimerization to '$V_2(CO)_{12}$' containing a V–V bond, but this is sterically unfavourable. A mononuclear carbonyl of Mn would, like $V(CO)_6$, be a radical, but now, dimerization occurs and $Mn_2(CO)_{10}$ is the lowest nuclearity neutral binary carbonyl of Mn. A similar situation arises for cobalt: '$Co(CO)_4$' is a 17-electron species and the lowest nuclearity binary carbonyl is $Co_2(CO)_8$. The group 7 dimers $Mn_2(CO)_{10}$, $Tc_2(CO)_{10}$ and $Re_2(CO)_{10}$ are isostructural and have staggered arrangements of carbonyls (Fig. 24.13b); the M–M bond is unbridged and longer (Mn–Mn = 290 pm, Tc–Tc = 303 pm, Re–Re = 304 pm) than twice the metallic radius (see Tables 21.1 and 22.1). In $Fe_2(CO)_9$ (Fig. 24.13c), three CO ligands bridge between the Fe centres. Each Fe atom obeys the 18-electron rule if an Fe–Fe

† Electron diffraction data for gaseous $Fe(CO)_5$ are $Fe–C_{axial}$ = 181 pm and $Fe–C_{equ}$ = 184 pm, see: B.W. McClelland, A.G. Robiette, L. Hedberg and K. Hedberg (2001) *Inorg. Chem.*, vol. 40, p. 1358.

bond is present and this is consistent with the observed diamagnetism of the complex. Even so, many theoretical studies have been carried out to investigate the presence (or not) of Fe–Fe bonding in $Fe_2(CO)_9$. Figure 24.13d shows the *solid state* structure of $Co_2(CO)_8$. When solid $Co_2(CO)_8$ is dissolved in hexane, the IR spectrum changes. The spectrum of the solid contains bands assigned to terminal *and* bridging CO ligands, but in hexane, only absorptions due to terminal carbonyls are seen. This is explained by the equilibrium in scheme **24.36** and solid state ^{13}C NMR spectroscopic data show that terminal–bridge CO exchange occurs even in *solid* $Co_2(CO)_8$.

(24.36)

Self-study exercises

1. Confirm that each Tc centre in $Tc_2(CO)_{10}$ obeys the 18-electron rule.
2. Confirm that in *each* isomer of $Co_2(CO)_8$ shown in diagram **24.36**, each Co centre obeys the 18-electron rule.
3. Does the 18-electron rule allow you to assign the structure shown in Fig. 24.13c to $Fe_2(CO)_9$ in preference to a structure of the type $(CO)_4Fe(\mu\text{-}CO)Fe(CO)_4$?

Each group 8 metal forms a trinuclear binary carbonyl $M_3(CO)_{12}$ containing a triangular framework of metal atoms. However, the arrangement of CO ligands in $Fe_3(CO)_{12}$ (Fig. 24.13e) differs from that in $Ru_3(CO)_{12}$ and $Os_3(CO)_{12}$ (Fig. 24.13f). The latter contain equilateral M_3 triangles and four terminal CO per metal, whereas in the solid state, $Fe_3(CO)_{12}$ contains an isosceles Fe_3 triangle with one Fe–Fe edge (the shortest) bridged by two CO ligands. Each M atom in $Fe_3(CO)_{12}$, $Ru_3(CO)_{12}$ and $Os_3(CO)_{12}$ obeys the 18-electron rule. The solution ^{13}C NMR spectrum of $Fe_3(CO)_{12}$ exhibits one resonance even as low as 123 K showing that the molecule is fluxional. The process can be described in terms of exchange of terminal and bridging CO ligands, or by considering the tilting of the Fe_3-unit within a shell of CO ligands. X-ray data collected at several temperatures show that $Fe_3(CO)_{12}$ also undergoes a dynamic process in the solid state. This illustrates that the CO_{term}–CO_{bridge} (CO_{term} = terminal CO ligand) exchange is a low-energy process. This is one of many such examples.

The group 9 carbonyls $Co_4(CO)_{12}$ and $Rh_4(CO)_{12}$ (Fig. 24.14a) are isostructural, with three μ-CO ligands arranged around the edges of one face of the M_4 tetrahedron. In $Ir_4(CO)_{12}$, all ligands are terminal (Fig. 24.14b). Each group 9 metal forms a hexanuclear carbonyl, $M_6(CO)_{16}$, in which the metal atoms form an octahedral cluster. In $Co_6(CO)_{16}$, $Rh_6(CO)_{16}$ and the red isomer of $Ir_6(CO)_{16}$, each M atom has two CO_{term} and there are four μ_3-CO (Fig. 24.14c). A black isomer of $Ir_6(CO)_{16}$ has been isolated and in the solid state has 12 CO_{term} and four μ-CO (Fig. 24.14d). Other octahedral carbonyl clusters include $[Ru_6(CO)_{18}]^{2-}$ and $[Os_6(CO)_{18}]^{2-}$, but in contrast $Os_6(CO)_{18}$ has a bicapped tetrahedral structure (**24.37**). This is an example of a *condensed polyhedral* cluster.

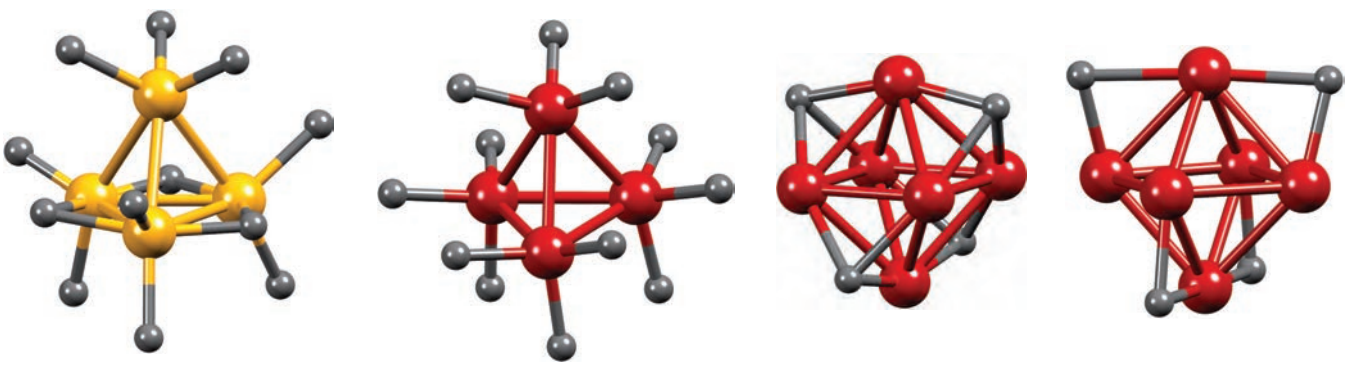


Fig. 24.14. The structures (X-ray diffraction) of (a) $Rh_4(CO)_{12}$ which is isostructural with $Co_4(CO)_{12}$ [C.H. Wei (1969) *Inorg. Chem.*, vol. 8, p. 2384], (b) $Ir_4(CO)_{12}$ [M.R. Churchill *et al.* (1978) *Inorg. Chem.*, vol. 17, p. 3528], (c) the red isomer of $Ir_6(CO)_{16}$ and (d) the black isomer of $Ir_6(CO)_{16}$ [L. Garlaschelli *et al.* (1984) *J. Am. Chem. Soc.*, vol. 106, p. 6664]. In (a) and (b), O atoms have been omitted for clarity. In (c) and (d), the terminal CO and the O atoms of the bridging CO ligands have been omitted; each Ir has two CO_{term}. Colour code: Rh, yellow; Ir, red; C, grey.

Soc., Dalton Trans.*, p. 521] and (f) $[Pt_9(CO)_{18}]^{2-}$ in the $[Ph_4P]^+$ salt [J.C. Calabrese *et al.* (1974) *J. Am. Chem. Soc.*, vol. 96, p. 2614]. Colour code: Os, yellow; Rh, blue; Ir, red; Pt, brown.

(24.37)

In a ***condensed polyhedral cluster***, two or more polyhedral cages are fused together through atom, edge or face sharing.

The syntheses of high-nuclearity metal carbonyl clusters are not readily generalized,[†] and we focus only on the structures of selected species. For seven or more metal atoms, metal carbonyl clusters tend to be composed of condensed (or less often, linked) tetrahedral or octahedral units. The group 10 metals form a series of clusters containing stacked triangles, e.g. $[Pt_9(CO)_{18}]^{2-}$ and $[Pt_{15}(CO)_{30}]^{2-}$. Figure 24.15 shows the metal cores of representative clusters. In $[Os_{20}(CO)_{40}]^{2-}$ (Fig. 24.15e), the Os atoms form a ccp arrangement. Some metal carbonyls possess 'raft' structures, i.e. the metal atoms form planar arrangements of edge-sharing triangles, e.g. $Os_5(CO)_{18}$ (Fig. 24.16).

[†] For further details, see for example: C.E. Housecroft (1996) *Metal–Metal Bonded Carbonyl Dimers and Clusters*, OUP, Oxford.

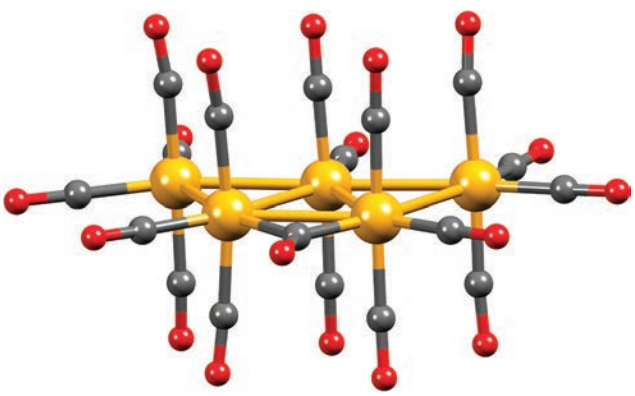

Fig. 24.16. The structure (X-ray diffraction) of $Os_5(CO)_{18}$, in which the Os atoms form a planar 'raft' [W. Wang *et al.* (1992) *J. Chem. Soc., Chem. Commun.*, p. 1737]. Colour code: Os, yellow; C, grey; O, red.

24.6 The isolobal principle and application of Wade's rules

In Section 13.11, we introduced *Wade's rules* to rationalize the structures of borane and related clusters. This method of counting electrons can be extended to simple organometallic clusters by making use of the *isolobal relationship* between cluster fragments.

Two cluster fragments are ***isolobal*** if they possess the same frontier orbital characteristics: same symmetry, same number of electrons available for cluster bonding, and *approximately* the same energy.

Figure 24.17 shows the frontier MOs (i.e. those close to and including the HOMO and LUMO) of BH and C_{3v} $M(CO)_3$ (M = Fe, Ru, Os) fragments. In Box 13.9, we considered how the frontier orbitals of six BH combined to give the cluster bonding MOs in $[B_6H_6]^{2-}$ (a process that can be extended to other clusters). Now we look at why it is that BH and some organometallic fragments can be regarded as being similar in terms of cluster bonding. Features of significance in Fig. 24.17 are that the BH and C_{3v} $M(CO)_3$ fragments have three frontier MOs with matching symmetries and containing the same number of electrons. The ordering of the MOs is not important. The BH and C_{3v} $M(CO)_3$ (M = Fe, Ru, Os) fragments are *isolobal* and their relationship allows BH units in borane clusters to be replaced (in theory and sometimes in practice, although syntheses are not as simple as this formal replacement suggests) by $Fe(CO)_3$, $Ru(CO)_3$ or $Os(CO)_3$ fragments. Thus, for example, we can go from $[B_6H_6]^{2-}$ to $[Ru_6(CO)_{18}]^{2-}$. Wade's rules categorize $[B_6H_6]^{2-}$ as a 7 electron pair *closo*-cluster, and similarly, $[Ru_6(CO)_{18}]^{2-}$ is a *closo*-species. Both are predicted to have (and have in practice) octahedral cages.

Moving to the left or right of group 8 removes or adds electrons to the frontier MOs shown in Fig. 24.17. Removing or adding a CO ligand removes or adds two electrons. (The frontier MOs also change, but this is unimportant if we are simply counting electrons.) Changing the ligands similarly alters the number of electrons available. Equation 24.28 shows how the number of electrons provided by a given fragment can be determined and Table 24.6 applies this to selected fragments. These numbers are used *within the Wade approach*, also known as *polyhedral skeletal electron pair theory* (PSEPT) or Wade–Mingos rules.

$$x = v + n - 12 \qquad (24.28)$$

where: x = number of cluster-bonding electrons provided by a fragment;

v = number of valence electrons from the metal atom;

n = number of valence electrons provided by the ligands

Worked example 24.4 Application of Wade–Mingos rules (PSEPT)

(a) Rationalize why $Rh_4(CO)_{12}$ has a tetrahedral core.
(b) What class of cluster is $Ir_4(CO)_{12}$?

[If you are unfamiliar with Wade's rules as applied to borane clusters, first review Section 13.11.]

(a) Break the formula of $Rh_4(CO)_{12}$ down into convenient units and determine the number of cluster-bonding electrons.

- Each $\{Rh(CO)_3\}$-unit provides 3 cluster-bonding electrons.
- Total number of electrons available in $Rh_4(CO)_{12} = (4 \times 3) = 12$ electrons = 6 pairs.
- Thus, $Rh_4(CO)_{12}$ has 6 pairs of electrons with which to bond 4 cluster units.
- There are $(n + 2)$ pairs of electrons for n vertices, and so $Rh_4(CO)_{12}$ is a *nido*-cage; the parent deltahedron is a trigonal bipyramid, and thus $Rh_4(CO)_{12}$ is expected to be tetrahedral.

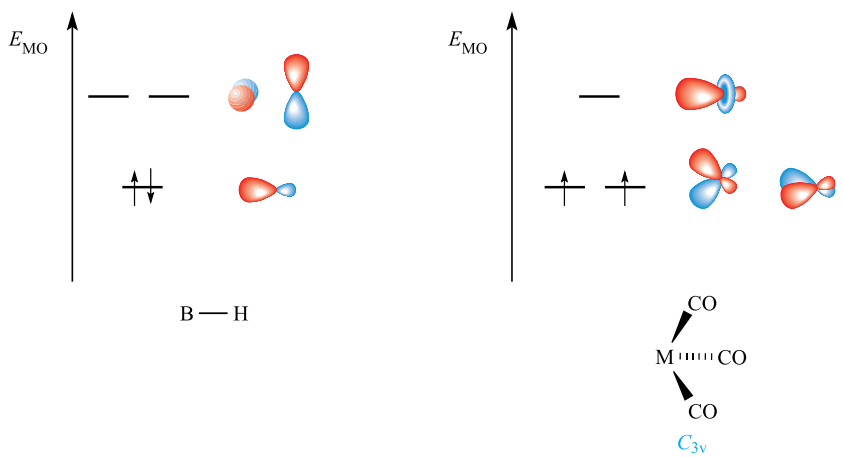

Fig. 24.17. The frontier MOs of a BH unit and a C_{3v} (i.e. 'conical') $M(CO)_3$ (M = Fe, Ru, Os) group. For the BH unit, the occupied MO is an *sp* hybrid; for $M(CO)_3$, the orbitals are represented by *pd* or *spd* hybrids. These orbitals combine with those of other cluster fragments to give cluster-bonding, non-bonding and antibonding MOs (see Box 13.9).

Table 24.6 The number of electrons (x in eq. 24.28) provided for cluster bonding by selected fragments; η^5-C_5H_5 = η^5-Cp.

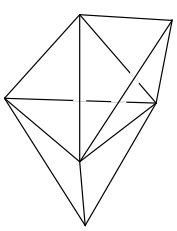
Cluster fragment	Group 6: Cr, Mo, W	Group 7: Mn, Tc, Re	Group 8: Fe, Ru, Os	Group 9: Co, Rh, Ir
$M(CO)_2$	−2	−1	0	1
$M(CO)_3$	0	1	2	3
$M(CO)_4$	2	3	4	5
$M(\eta^5\text{-}C_5H_5)$	−1	0	1	2
$M(\eta^6\text{-}C_6H_6)$	0	1	2	3
$M(CO)_2(PR_3)$	0	1	2	3

(b) Rh and Ir are both in group 9 and so $Ir_4(CO)_{12}$ is also a *nido*-cluster.

This example illustrates an important point about the use of such electron-counting schemes: *no information about the positions of the ligands can be obtained*. Although Wade–Mingos rules rationalize why $Rh_4(CO)_{12}$ and $Ir_4(CO)_{12}$ both have tetrahedral cores, they say nothing about the fact that the ligand arrangements are different (Figs. 24.14a and b).

Self-study exercises

1. Use the Wade–Mingos approach to rationalize why $Co_4(CO)_{12}$ has a tetrahedral core.
2. Using PSEPT, rationalize why $[Fe_4(CO)_{13}]^{2-}$ has a tetrahedral Fe_4 core.
3. The cluster $Co_2(CO)_6C_2H_2$ has a tetrahedral Co_2C_2 core. How many electrons does each CH unit contribute to cluster bonding? Show that there are six electron pairs available for cluster bonding.
4. $H_3Fe_3(CO)_9CH$ has a tetrahedral Fe_3C core. Show that this is consistent with the Wade–Mingos approach.



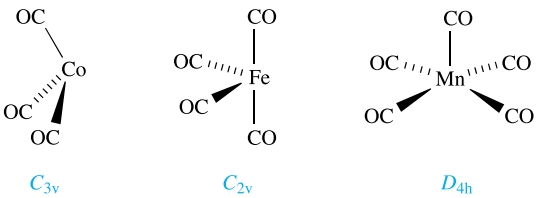
The diversity of cage structures among metal clusters is greater than that of boranes. Wade's rules (and later the Wade–Mingos rules) were developed for boranes and extension of the rules to rationalize the structures of high-nuclearity metal clusters is limited. Boranes tend to adopt rather open structures, and there are few examples of BH units in capping positions. However, application of the *capping principle* does allow satisfactory rationalization of some condensed cages such as $Os_6(CO)_{18}$ (**24.37**).

Within the remit of ***PSEPT***, the addition of one or more ***capping units*** to a deltahedral cage requires no additional bonding electrons. A capping unit is a cluster fragment placed over the *triangular* face of a central cage.

Worked example 24.5 Application of PSEPT: the capping principle

Rationalize why $Os_6(CO)_{18}$ adopts structure 24.37 rather than an octahedral cage.

- $Os_6(CO)_{18}$ can be broken down into 6 $Os(CO)_3$ fragments.
- Each $\{Os(CO)_3\}$-unit provides 2 cluster-bonding electrons.
- Total number of electrons available in $Os_6(CO)_{18}$ = (6 × 2) = 12 electrons = 6 pairs.
- Thus, $Os_6(CO)_{18}$ has 6 pairs of electrons with which to bond 6 cluster units.
- This corresponds to a monocapped structure, the parent deltahedron being one with 5 vertices, i.e. a trigonal bipyramid:



- The monocapped trigonal bipyramid is the same as a bicapped tetrahedron (**24.37**).
- A *closo*-octahedral cage requires 7 pairs of electrons, and $Os_6(CO)_{18}$ has insufficient electrons for this structure.

Self-study exercises

1. The Os_7 core of $Os_7(CO)_{21}$ is a capped octahedron. Show that this is consistent with the PSEPT capping principle.
2. Use the capping principle to account for the fact that $[Os_8(CO)_{22}]^{2-}$ has a bicapped octahedral structure.

Using the isolobal principle, one can relate clusters that contain fragments having analogous orbital properties. Some isolobal pairs of metal carbonyl and hydrocarbon fragments are:

- $Co(CO)_3$ (C_{3v}) and CH (provides three orbitals and three electrons);
- $Fe(CO)_4$ (C_{2v}) and CH_2 (provides two orbitals and two electrons);
- $Mn(CO)_5$ (D_{4h}) and CH_3 (provides one orbital and one electron).

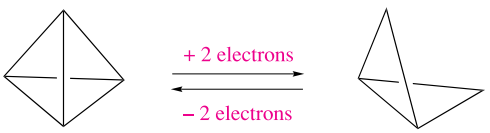
Thus, for example, $Co_4(CO)_{12}$, $Co_3(CO)_9CH$, $Co_2(CO)_6C_2H_2$ and C_4H_4 form an isolobal series. Isolobal relationships have a *theoretical* premise and tell us nothing about methods of cluster synthesis.

24.7 Total valence electron counts in *d*-block organometallic clusters

The structures of many polynuclear organometallic species are not conveniently described in terms of Wade–Mingos rules, and an alternative approach is to consider the *total valence electron count*, also called the *Mingos cluster valence electron count*.

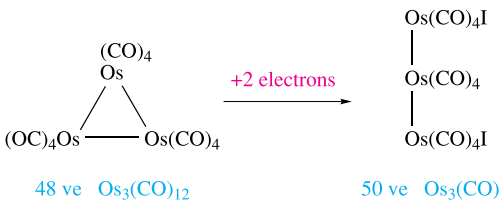
Single cage structures

Each low oxidation state *metal cluster* cage possesses a characteristic number of valence electrons (ve) as Table 24.7 shows. We shall not describe the MO basis for these numbers, but merely apply them to rationalize observed structures. Look back to Section 24.2 for the numbers of electrons donated by ligands. Any organometallic complex with a triangular M_3 framework requires 48 valence electrons, for example:



- $Ru_3(CO)_{12}$ has $(3 \times 8) + (12 \times 2) = 48$ ve;
- $H_2Ru_3(CO)_8(\mu\text{-}PPh_2)_2$ has $(2 \times 1) + (3 \times 8) + (8 \times 2) + (2 \times 3) = 48$ ve;
- $H_3Fe_3(CO)_9(\mu_3\text{-}CMe)$ has $(3 \times 1) + (3 \times 8) + (9 \times 2) + (1 \times 3) = 48$ ve.

Similarly, clusters with tetrahedral or octahedral cages require 60 or 86 valence electrons respectively, for example:

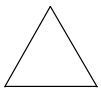


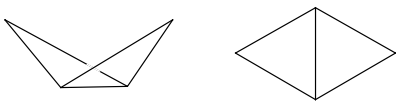
- $Ir_4(CO)_{12}$ has $(4 \times 9) + (12 \times 2) = 60$ ve;
- $(\eta^5\text{-}Cp)_4Fe_4(\mu_3\text{-}CO)_4$ has $(4 \times 5) + (4 \times 8) + (4 \times 2) = 60$ ve;
- $Rh_6(CO)_{16}$ has $(6 \times 9) + (16 \times 2) = 86$ ve;
- $Ru_6(CO)_{17}C$ has $(6 \times 8) + (17 \times 2) + 4 = 86$ ve.

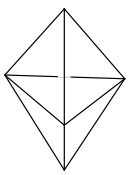
The last example is of a cage containing an *interstitial atom* (see structure **24.12**) which *contributes all of its valence electrons* to cluster bonding. An interstitial C atom contributes four electrons, a B atom three, an N or P atom five, and so on.

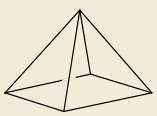
A difference of two between the valence electron counts in Table 24.7 corresponds to a 2-electron reduction (adding two electrons) or oxidation (removing two electrons). This formally corresponds to breaking or making an M–M edge in the cage. For example, going from the 60-electron tetrahedron to a 62-electron 'butterfly' involves breaking one edge of the M_4 cage, and vice versa:

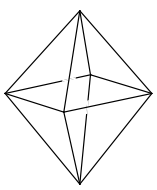
This can be applied more widely than for the structures listed in Table 24.7. Thus, the linear arrangement of the Os atoms in $Os_3(CO)_{12}I_2$ can be rationalized in terms of its 50 valence electron count, i.e. formally, the addition of two electrons to a 48-electron triangle:

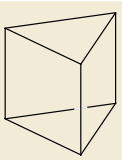












Worked example 24.6 An application of total valence electron counts

Suggest what change in cluster structure might accompany the reaction:

$$[Co_6(CO)_{15}N]^- \longrightarrow [Co_6(CO)_{13}N]^- + 2CO$$

Both clusters contain an interstitial N atom which contributes 5 electrons to cluster bonding. The negative charge contributes 1 electron.

Table 24.7 Characteristic total valence electron counts for selected low oxidation state metal clusters.

Cluster framework	Diagrammatic representation of the cage	Valence electron count
Triangle		48
Tetrahedron		60
Butterfly, or planar raft of four atoms		62
Square		64
Trigonal bipyramid		72
Square-based pyramid		74
Octahedron		86
Trigonal prism		90

Total valence electron count for

$$[Co_6(CO)_{15}N]^- = (6 \times 9) + (15 \times 2) + 5 + 1 = 90$$

Total valence electron count for

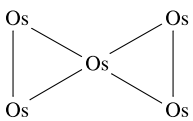
$$[Co_6(CO)_{13}N]^- = (6 \times 9) + (13 \times 2) + 5 + 1 = 86$$

i.e. the loss of two CO ligands corresponds to a loss of 4 electrons, and a change from a trigonal prism to octahedral Co_6-cage.

Self-study exercises

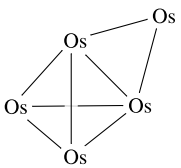
1. $[Ru_6(CO)_{17}B]^-$ and $[Os_6(CO)_{18}P]^-$ contain interstitial B and P atoms respectively. Account for the fact that while $[Ru_6(CO)_{17}B]^-$ has an octahedral M_6 core, $[Os_6(CO)_{18}P]^-$ adopts a trigonal prismatic core. [*Ans.* 86 ve; 90 ve]

2. Rationalize why $Os_3(CO)_{12}$ has a triangular Os_3 core but in $Os_3(CO)_{12}Br_2$, the Os atoms are in a linear arrangement. [*Ans.* 48 ve; 50 ve]



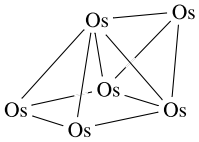
3. In $Os_4(CO)_{16}$, the Os atoms are arranged in a square, but in $Os_4(CO)_{14}$ they form a tetrahedral cluster. Rationalize this observation.

Condensed cages



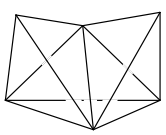
Structure **24.37** showed one type of *condensed cluster*. The sub-cluster units are connected either through shared M atoms, M–M edges or M_3 faces. The total valence electron count for a condensed structure is equal to the total number of electrons required by the sub-cluster units *minus* the electrons associated with the shared unit. The numbers to *subtract* are:

- 18 electrons for a shared M atom;
- 34 electrons for a shared M–M edge;
- 48 electrons for a shared M_3 face.

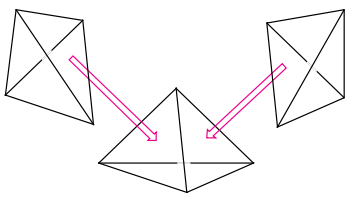


Examples of these families of condensed polyhedral clusters are $Os_5(CO)_{19}$ (atom-sharing, **24.38**), $H_2Os_5(CO)_{16}$ (edge-sharing, **24.39**) and $H_2Os_6(CO)_{18}$ (face-sharing, **24.40**).

(24.38)



(24.39)



(24.40)

Worked example 24.7 Electron counts in condensed cluster structures

$Os_6(CO)_{18}$ has structure 24.37, i.e. three face-sharing tetrahedra. Show that this structure is consistent with the number of valence electrons available.

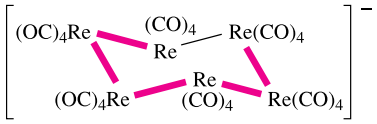
can be represented as three face-sharing tetrahedra:

Valence electron count for three tetrahedra $= 3 \times 60 = 180$
For each shared face, subtract 48 electrons.

Valence electron count for the bicapped tetrahedron $= 180 - (2 \times 48) = 84$

The number of valence electrons available in $Os_6(CO)_{18} = (6 \times 8) + (18 \times 2) = 84$

Thus, the observed structure is consistent with the number of valence electrons available.



Self-study exercises

1. While $[Os_6(CO)_{18}]^{2-}$ has an octahedral Os_6 core, that in $Os_6(CO)_{18}$ is a capped trigonal bipyramid. Use total valence electron counts to rationalize this difference.
2. The core in $Os_5(CO)_{19}$ is shown in structure **24.38**. Show that this shape is consistent with the total valence electron count of the cluster.
3. $[Os_6(CO)_{18}]^{2-}$ has an octahedral Os_6-core, but in $H_2Os_6(CO)_{18}$, the Os_6-unit is a capped square-based pyramid. Comment on this difference in terms of the total number of valence electrons available for cluster bonding.

Limitations of total valence counting schemes

For some clusters such as Rh_x species, the number of electrons available may not match the number apparently required by the structure adopted. Two examples in rhodium carbonyl chemistry are $[Rh_5(CO)_{15}]^-$ and $[Rh_9(CO)_{19}]^{3-}$. The former possesses 76 valence electrons and yet has a trigonal bipyramidal Rh_5-core, for which 72 electrons are usual. However, a look at the Rh–Rh bond lengths reveals that six edges are in the range 292–303 pm, while three are 273–274 pm, indicating that the extra electrons have caused bond lengthening. In $[Rh_9(CO)_{19}]^{3-}$, 122 electrons are available but the Rh_9-core consists of two face-sharing octahedra for which 124 electrons are required by the scheme outlined above.[†] An example of an unexpected cluster structure is found for $[H_5Re_6(CO)_{24}]^-$. Rather than adopt a closed-cluster structure, the Re_6-unit in $[H_5Re_6(CO)_{24}]^-$ possesses a cyclohexane-like ring with a chair conformation (**24.41**). Each Re centre obeys the 18-electron rule (each $Re(CO)_4$ unit has $7 + (4 \times 2)$ valence electrons, two Re–Re bonds per Re provide 2 electrons, and the five H atoms with the 1– charge provide 1 electron per Re), but the preference for an open- rather than closed-cluster structure cannot be predicted.

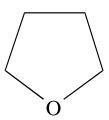
[†] For detailed discussion, see: D.M.P. Mingos and D.J. Wales (1990) *Introduction to Cluster Chemistry*, Prentice Hall, Englewood Cliffs, NJ.

(24.41)

These are but three examples of the limitations of electron-counting schemes.

Self-study exercise

X-ray crystallography confirms that $[Rh_6(P^iPr_3)_6H_{12}]^{2+}$ possesses an octahedral Rh_6-cage. Show that this cluster is 10 electrons short of the expected electron count.



24.8 Types of organometallic reactions

In this section, we introduce the main types of ligand transformations that take place at metal centres in organometallic compounds:

- ligand substitution;
- oxidative addition (including orthometallation);
- reductive elimination;
- alkyl and hydrogen migration;
- β-hydrogen elimination;
- α-hydrogen abstraction.

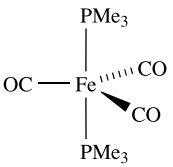
Substitution of CO ligands

The substitution of a CO ligand by another 2-electron donor (e.g. PR_3) may occur by photochemical or thermal activation, either by direct reaction of the metal carbonyl and incoming ligand, or by first replacing a CO by a more labile ligand such as THF or MeCN. An example of the latter is the formation of $Mo(CO)_5(PPh_3)$ (eq. 24.29) which is most effectively carried out by first making the THF (**24.42**) adduct *in situ*.

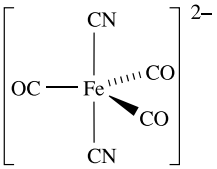
(24.42)

$$Mo(CO)_6 \xrightarrow[-CO]{\text{in THF, } h\nu} Mo(CO)_5(THF) \xrightarrow[-THF]{PPh_3} Mo(CO)_5(PPh_3) \qquad (24.29)$$

The substitution steps are *dissociative* (see Chapter 26). The outgoing ligand leaves, creating a 16-electron metal centre which is *coordinatively unsaturated*. The entry of a new 2-electron ligand restores the 18-electron count. Competition between ligands for coordination to the 16-electron centre may be countered by having the incoming ligand (L in eq. 24.30) present in excess.



$$M(CO)_n \xrightarrow{-CO} \{M(CO)_{n-1}\} \begin{matrix} \xrightarrow{L} M(CO)_{n-1}L \\ \xrightarrow{CO} M(CO)_n \end{matrix} \qquad (24.30)$$



In reaction 24.31, the incoming ligand provides four electrons and displaces two CO ligands. Multiple substitution by 2-electron donors is exemplified by reaction 24.32.

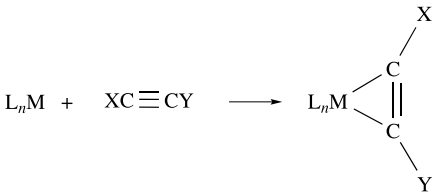
$$Fe(CO)_5 + \text{} \xrightarrow[\text{or } \Delta,\ 20\text{ bar}]{h\nu} Fe(CO)_3(\eta^4\text{-}CH_2CHCHCH_2) + 2CO \qquad (24.31)$$

$$Fe(CO)_5 + \text{excess } PMe_3 \xrightarrow{h\nu} Fe(CO)_3(PMe_3)_2 + 2CO \qquad (24.32)$$

(24.43)

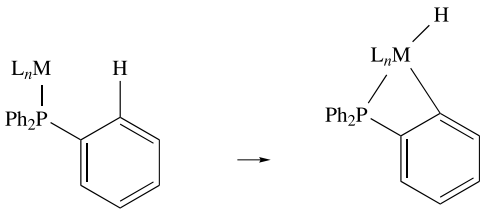
(24.44)

Mixed carbonyl/cyanido complexes of iron were described in Section 21.9. Their importance lies in their use as biomimetic models for [FeFe] and [NiFe]-hydrogenases (see Figs. 29.19 and 29.21). Photolysis of $Fe(CO)_5$ with $[Et_4N]CN$ leads to substitution reaction 24.33, and introduces cyanido ligands in axial positions (structure **24.44**).



$$Fe(CO)_5 + 2[Et_4N]CN \xrightarrow{\text{in MeCN, } h\nu} [Et_4N]_2[\textit{trans}\text{-}Fe(CO)_3(CN)_2] + 2CO \qquad (24.33)$$

Oxidative addition



Oxidative addition reactions are very important in organometallic synthesis. Oxidative addition involves:

- the addition of a molecule XY with cleavage of the X−Y single bond (eq. 24.34), addition of a multiply-bonded species with reduction in the bond order and formation of a metallacycle (eq. 24.35), addition of a C−H bond in an *orthometallation* step (eq. 24.36) or a similar addition;
- oxidation of the metal centre by two units;
- increase in metal coordination number by 2.

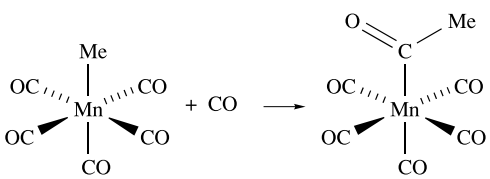
$$L_nM + X\text{–}Y \longrightarrow L_nM\begin{matrix} X \\ Y \end{matrix} \qquad (24.34)$$

(24.35)

(24.36)

Addition of O_2 to give an η^2-peroxido complex is related to reaction type 24.35. Each addition in eqs. 24.34–24.36 occurs *at a 16-electron metal centre*, taking it to an 18-electron centre in the product. Most commonly, the precursor has a d^8 or d^{10} configuration, e.g. Rh(I), Ir(I), Pd(0), Pd(II), Pt(0), Pt(II), and the metal must have an accessible higher oxidation state, e.g. Rh(III). If the starting compound contains an 18-electron metal centre, oxidative addition cannot occur without loss of a 2-electron ligand as in reaction 24.37.

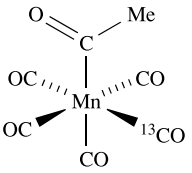
$$Os(CO)_5 + H_2 \xrightarrow{\Delta,\ 80\ bar} H_2Os(CO)_4 + CO \qquad (24.37)$$



Many examples of the addition of small molecules (e.g. H_2, HX, RX) are known. The reverse of oxidative addition is *reductive elimination*, e.g. reaction 24.38, in which an acyl substituent is converted to an aldehyde.

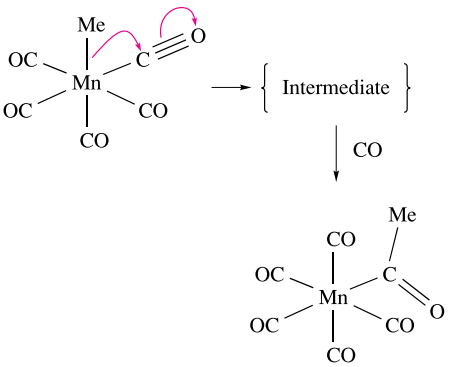
$$H_2Co\{C(O)R\}(CO)_3 \longrightarrow HCo(CO)_3 + RCHO \qquad (24.38)$$

Oxidative addition initially gives a *cis*-addition product, but ligand rearrangements can occur and the isolated product may contain the added groups mutually *cis* or *trans*.



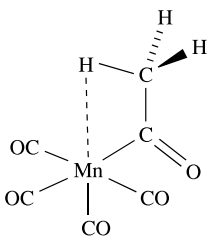
Alkyl and hydrogen migrations

Reaction 24.39 is an example of *alkyl migration*.



(24.39)

The reaction is also called *CO insertion* since the incoming CO molecule seems to have been inserted into the Mn–C_{Me} bond: this name is misleading. If reaction 24.39 is carried out using ^{13}CO, *none* of the incoming ^{13}CO ends up in the acyl group or in the position *trans* to the acyl group; the isolated product is **24.45**.



(24.45)

Reaction 24.39 involves the *intramolecular* transfer of an alkyl group to the C atom of a CO group which is *cis* to the original alkyl site. The incoming CO occupies the coordination site vacated by the alkyl group. Scheme 24.40 summarizes the process.

(24.40)

Scheme 24.40 implies that the intermediate is a coordinatively unsaturated species. In the presence of a solvent, S, such a species would probably be stabilized as $Mn(CO)_4(COMe)(S)$. In the absence of solvent, a 5-coordinate intermediate is likely to be stereochemically non-rigid (see Fig. 4.25 and discussion) and this is inconsistent with the observation of a selective *cis*-relationship between the incoming CO and acyl group. It has been concluded from the results of theoretical studies that the intermediate is stabilized by an *agostic* Mn–H–C interaction (structure **24.46**), the presence of which locks the stereochemistry of the system.[†]

(24.46)

[†] For a more detailed discussion, see: A. Derecskei-Kovacs and D.S. Marynick (2000) *J. Am. Chem. Soc.*, vol. 122, p. 2078. For a student-based computational study, see: C.D. Montgomery (2013) *J. Chem. Educ.*, vol. 90. p. 1396 – 'A mechanistic study of the migratory insertion reaction: A computational chemistry exercise'.

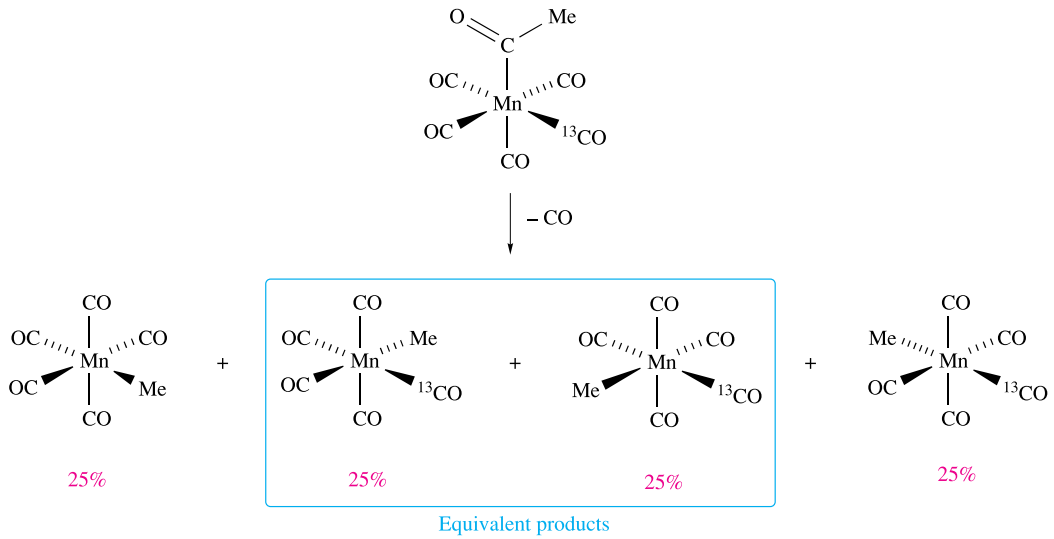


Fig. 24.18. The distribution of products from the decarbonylation of $Mn(CO)_4(^{13}CO)\{C(O)Me\}$ provides evidence for the migration of the Me group rather than movement of a CO molecule.

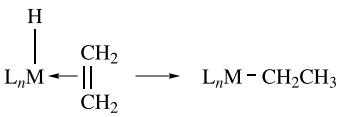
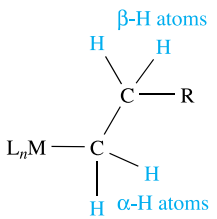


An ***agostic*** M–H–C interaction is a 3-centre 2-electron interaction between a metal centre, M, and a C–H bond in a ligand attached to M (e.g. structure **24.46**).

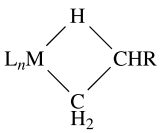
The migration of the methyl group is reversible and the *decarbonylation* reaction has been studied with the ^{13}C-labelled compound; the results are shown in Fig. 24.18. The distribution of the products is consistent with the migration of the Me group, and not with a mechanism that involves movement of the 'inserted' CO. The reaction products can be monitored using ^{13}C NMR spectroscopy.

The 'insertion of CO' into $M-C_{alkyl}$ bonds is well exemplified in organometallic chemistry, and one industrial example (eq. 24.41) is a step in the Monsanto process for the production of acetic acid (see Section 25.5).

$$[Rh(Me)(CO)_2I_3]^- + CO \longrightarrow [Rh(CMeO)(CO)_2I_3]^- \qquad (24.41)$$

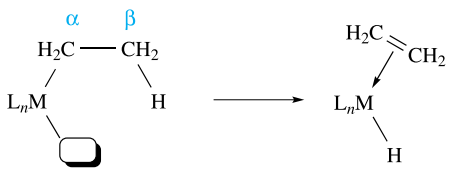


Alkyl migrations are not confined to the formation of acyl groups, and, for example, 'alkene insertion' involves the conversion of a coordinated alkene to a σ-bonded alkyl group. Equation 24.42 shows the migration of an *H atom*. Related alkyl migrations occur and result in *carbon chain growth* as exemplified in Fig. 25.15.



(24.42)

β-Hydrogen elimination



The reverse of reaction 24.42 is a *β-elimination* step. It involves the transfer of a β-H atom (structure **24.47**) from the alkyl group to the metal and the conversion of the σ-alkyl group to a π-bonded alkene, i.e. a C–H bond is activated. For β-elimination to occur, the metal centre must be unsaturated, with a vacant coordination site *cis* to the alkyl group (eq. 24.43). The first step is thought to involve a cyclic intermediate **24.48** with an agostic M–H–C interaction.

(24.47)

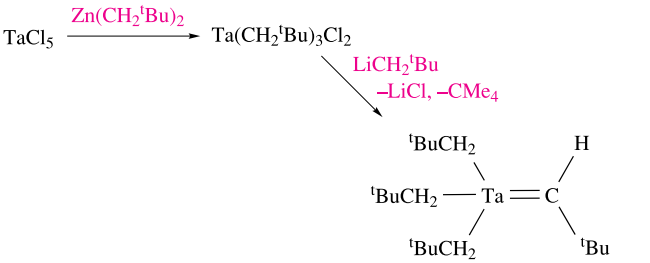
(24.48)

(24.43)

Vacant coordination site

$$L_nMCH_2CH_2R \longrightarrow L_nMH(\eta^2\text{-}RCH{=}CH_2) \longrightarrow L_nMH + RCH{=}CH_2 \qquad (24.44)$$

β-Elimination is responsible for the decomposition of some metal alkyl complexes (eq. 24.44), but the reaction may be hindered or prevented by:



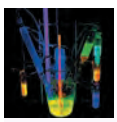
- steric hindrance;
- having a coordinatively *saturated* metal centre as in $(\eta^5\text{-}C_5H_5)Fe(CO)_2Et$;
- preparing an alkyl derivative which does not possess a β-hydrogen atom.

Examples of σ-bonded alkyl groups that cannot undergo β-elimination because they lack a β-H atom are Me, CH_2CMe_3, CH_2SiMe_3 and CH_2Ph. Thus, methyl derivatives cannot decompose by a β-elimination route and are usually more stable than their ethyl analogues. This does not mean that methyl derivatives are necessarily stable. The coordinatively unsaturated $TiMe_4$ decomposes at 233 K, but the stability can be increased by the formation of 6-coordinate adducts such as $Ti(bpy)Me_4$ and $Ti(Me_2PCH_2CH_2PMe_2)Me_4$.

α-Hydrogen abstraction

Early *d*-block metal complexes containing one or two α-hydrogen atoms (see **24.47**) may undergo *α-hydrogen abstraction* to yield *carbene* (*alkylidene*, **24.49**) or *carbyne* (*alkylidyne*, **24.50**) complexes. The solid state structure of the product of reaction 24.45 confirms differences in the Ta−C bond lengths: 225 pm for Ta−C_{alkyl} and 205 pm for Ta−$C_{carbene}$.

$L_nM{=}CR_2$ **(24.49)** $L_nM{\equiv}CR$ **(24.50)**



(24.45)

Abstraction of a second α-H atom gives a carbyne complex (e.g. reaction 24.46). Other routes to carbenes and carbynes are described in Section 24.13.

$$WCl_6 \xrightarrow[-CMe_4,\ -LiCl]{LiCH_2CMe_3} W(\equiv CCMe_3)(CH_2CMe_3)_3 \qquad (24.46)$$

Summary

A basic knowledge of the reaction types described in this section allows us to proceed to a discussion of the chemistry of selected organometallic complexes and (in Chapter 25) catalysis. Oxidative additions and alkyl migrations in particular are very important in the catalytic processes used in the manufacture of many organic chemicals. Selected important organometallic compounds used as catalysts are summarized in Box 24.2.

APPLICATIONS

Box 24.2 Homogeneous catalysts

Many of the reaction types discussed in Section 24.7 are represented in the catalytic processes described in Chapter 25. Unsaturated (16-electron) metal centres play an important role in catalytic cycles. Selected catalysts or catalyst precursors are summarized below.

Homogeneous catalyst	Catalytic application
$RhCl(PPh_3)_3$	Alkene hydrogenation
cis-$[Rh(CO)_2I_2]^-$	Monsanto acetic acid synthesis; Tennessee–Eastman acetic anhydride process
cis-$[Ir(CO)_2I_2]^-$	Cativa acetic acid process
$HCo(CO)_4$	Hydroformylation; alkene isomerization
$HRh(CO)_4$	Hydroformylation (only for certain branched alkenes)[†]
$HRh(CO)(PPh_3)_3$	Hydroformylation
$[Ru(CO)_2I_3]^-$	Homologation of carboxylic acids
$[HFe(CO)_4]^-$	Water–gas shift reaction
$(\eta^5\text{-}C_5H_5)_2TiMe_2$	Alkene polymerization
$(\eta^5\text{-}C_5H_5)_2ZrH_2$	Hydrogenation of alkenes and alkynes
$Pd(PPh_3)_4$	Many laboratory applications including the Heck reaction

[†] $HRh(CO)_4$ is more active than $HCo(CO)_4$ in hydroformylation, but shows a lower regioselectivity (see eq. 25.5 and discussion).

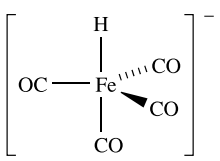
24.9 Metal carbonyls: selected reactions

The degradation of $Ni(CO)_4$ or $Fe(CO)_5$ to the respective metal and CO is a means of manufacturing high-purity nickel and iron. The thermal decomposition of $Ni(CO)_4$ is used in the Mond process to refine nickel (see eq. 21.4). Iron powder for use in magnetic cores in electronic components is produced by thermally decomposing $Fe(CO)_5$. The Fe particles act as nucleation centres for the production of particles up to 8 μm in diameter.

Reactions 24.18–24.23 illustrated conversions of neutral carbonyl compounds to carbonylate anions. Reduction by Na is typically carried out using Na/Hg amalgam. With Na in liquid NH_3, highly reactive anions can be formed (eqs. 24.47–24.50).

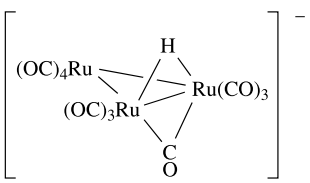
$$Cr(CO)_4(Me_2NCH_2CH_2NMe_2\text{-}N,N') \xrightarrow{\text{Na, liquid NH}_3} Na_4[Cr(CO)_4] \quad (24.47)$$

$$M_3(CO)_{12} \xrightarrow[\text{low temp.}]{\text{Na, liquid NH}_3} Na_2[M(CO)_4] \qquad M = Ru, Os \quad (24.48)$$



$$Ir_4(CO)_{12} \xrightarrow{\text{Na, THF, CO (1 bar)}} Na[Ir(CO)_4] \quad (24.49)$$

$$Na[Ir(CO)_4] \xrightarrow[\text{2. liquid NH}_3\text{, 195 K, warm to 240 K}]{\text{1. Na, HMPA, 293 K}} Na_3[Ir(CO)_3] \qquad \text{HMPA} = (Me_2N)_3PO \quad (24.50)$$



The IR spectra (see Section 24.2) of highly charged anions exhibit absorptions for the terminal CO ligands in regions usually characteristic of bridging carbonyls, e.g. 1680 and 1471 cm^{-1} for $[Mo(CO)_4]^{4-}$, and 1665 cm^{-1} for $[Ir(CO)_3]^{3-}$.

The action of alkali on $Fe(CO)_5$ (eq. 24.51) gives $[HFe(CO)_4]^-$ (**24.51**). Nucleophilic attack by $[OH]^-$ on a CO ligand is followed by Fe–H bond formation and elimination of CO_2. The $[HFe(CO)_4]^-$ ion has a variety of synthetic uses.

$$Fe(CO)_5 + 3NaOH \xrightarrow{H_2O} Na[HFe(CO)_4] + Na_2CO_3 + H_2O \quad (24.51)$$

(24.51)

(24.52)

Hydrido ligands can be introduced by various routes including protonation (eqs. 24.2 and 24.52), reaction with H_2 (eqs. 24.53 and 24.54) and action of $[BH_4]^-$ (eqs. 24.55 and 24.56).

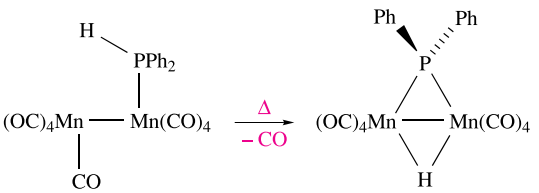
$$Na[Mn(CO)_5] \xrightarrow{H_3PO_4\text{, in THF}} HMn(CO)_5 \quad (24.52)$$

$$Mn_2(CO)_{10} + H_2 \xrightarrow{\text{200 bar, 470 K}} 2HMn(CO)_5 \quad (24.53)$$

$$Ru_3(CO)_{12} + H_2 \xrightarrow{\text{in boiling octane}} (\mu\text{-}H)_4Ru_4(CO)_{12} \quad (24.54)$$

$$Cr(CO)_6 \xrightarrow{Na[BH_4]} [(OC)_5Cr(\mu\text{-}H)Cr(CO)_5]^- \quad (24.55)$$

$$Ru_3(CO)_{12} \xrightarrow{Na[BH_4]\text{ in THF}} [HRu_3(CO)_{11}]^- \quad (24.56)$$



Reactions 24.57–24.59 illustrate preparations of selected metal carbonyl halides (see Section 24.9) from binary carbonyls.

$$Fe(CO)_5 + I_2 \longrightarrow Fe(CO)_4I_2 + CO \quad (24.57)$$

$$Mn_2(CO)_{10} + X_2 \longrightarrow 2Mn(CO)_5X \qquad X = Cl, Br, I \quad (24.58)$$

$$M(CO)_6 + [Et_4N]X \longrightarrow [Et_4N][M(CO)_5X] + CO \qquad M = Cr, Mo, W;\ X = Cl, Br, I \quad (24.59)$$

Large numbers of derivatives are formed by displacement of CO by other ligands (see eqs. 24.29–24.33 and discussion). Whereas substitution by *tertiary* phosphane ligands usually gives terminal ligands, the introduction of a *secondary* or *primary* phosphane into a carbonyl complex creates the possibility of oxidative addition of a P–H bond. Where a second metal centre is present, the formation of a bridging R_2P ligand is possible (reaction 24.60).

(24.60)

We saw earlier that CO displacement can be carried out photolytically or thermally, and that activation of the starting compound (as in reaction 24.29) may be necessary. In multinuclear compounds, activation of one site can control the degree of substitution, e.g. $Os_3(CO)_{11}(NCMe)$ is used as an *in situ* intermediate during the formation of monosubstituted derivatives (eq. 24.61).

Table 24.8 Selected properties of $HMn(CO)_5$, $H_2Fe(CO)_4$ and $HCo(CO)_4$.

Property	$HMn(CO)_5$	$H_2Fe(CO)_4$	$HCo(CO)_4$
Physical appearance at 298 K	Colourless liquid	Yellow liquid	Yellow liquid
Stability	Stable up to 320 K	Dec. $\geq$253 K	Dec. >247 K (mp)
pK_a values	15.1	$pK_a(1) = 4.4$ $pK_a(2) = 14.0$	<0.4
^1H NMR δ/ ppm	−10.7	−11.2	−7.9

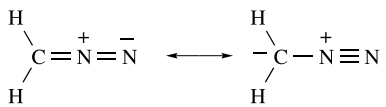
$$Os_3(CO)_{12} \xrightarrow{MeCN,\ Me_3NO} Os_3(CO)_{11}(NCMe) \xrightarrow{L\ (e.g.\ PR_3)} Os_3(CO)_{11}L \qquad (24.61)$$

In the first step of the reaction, Me_3NO oxidizes CO to CO_2, liberation of which leaves a vacant coordination site that is occupied temporarily by the labile MeCN ligand. This method can be applied to higher nuclearity clusters to achieve control over otherwise complex reactions.

Displacement of CO by a nitrosyl ligand alters the electron count and, for an 18-electron centre to be retained, one-for-one ligand substitution cannot occur. Reaction 24.62 shows the conversion of octahedral $Cr(CO)_6$ to tetrahedral $Cr(NO)_4$, in which NO is a 3-electron donor.

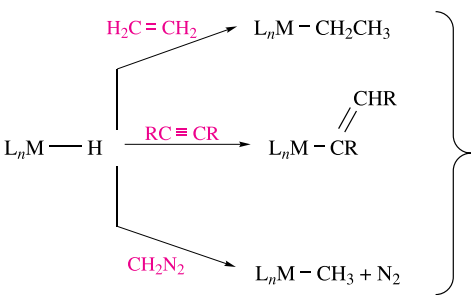
$$Cr(CO)_6 + \text{excess NO} \longrightarrow Cr(NO)_4 + 6CO \qquad (24.62)$$

Reactions of metal carbonyls with unsaturated organic ligands are discussed in later sections.



Self-study exercises

1. The reaction of $Mn_2(CO)_{10}$ with Na/Hg can be monitored by IR spectroscopy in the region 2100–1800 cm^{-1}. The starting material and product show absorptions at 2046, 2015 and 1984 cm^{-1}, and at 1896 and 1865 cm^{-1}, respectively. Suggest a likely product of the reaction. Check that the Mn centre in the product obeys the 18-electron rule. Account for the changes in the IR spectra.
[*Ans.* $Na[Mn(CO)_5]$, see Section 24.2]



2. Photolysis of a benzene solution of *trans*-$W(N_2)_2(dppe)_2$ (dppe = $Ph_2PCH_2CH_2PPh_2$) with Ph_2PH gives *trans*-$WH(PPh_2)(dppe)_2$ in which the $W–P_{PPh_2}$ bond distance of 228 pm is consistent with a double bond. (a) How is a coordinated N_2 ligand related to metal-bound CO? (b) Explain what types of reaction have occurred during the conversion of *trans*-$W(N_2)_2(dppe)_2$ to *trans*-$WH(PPh_2)(dppe)_2$.
[*Ans.* (a) See Section 24.2; (b) see: L.D. Field *et al.* (1998) *J. Organomet. Chem.*, vol. 571, p. 195]

24.10 Metal carbonyl hydrides and halides

Methods of preparing selected hydrido complexes were given in eqs. 24.2 and 24.52–24.56. Selected properties of the mononuclear complexes $HMn(CO)_5$, $H_2Fe(CO)_4$ and $HCo(CO)_4$ are given in Table 24.8. $HCo(CO)_4$ is an industrial catalyst (see Section 25.5). Metal hydrides play an important role in organometallic chemistry, and scheme 24.63 illustrates some ligand transformations involving M–H bonds. Each reaction of L_nMH with an alkene or alkyne is an H atom migration. This type of reaction can be extended to CH_2N_2 (**24.53**), H atom migration to which results in the loss of N_2 and formation of a metal-bound methyl group.

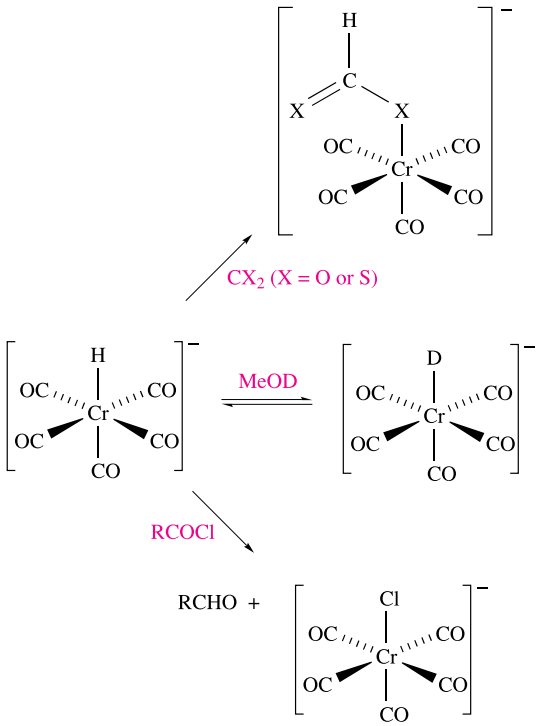
(24.53)

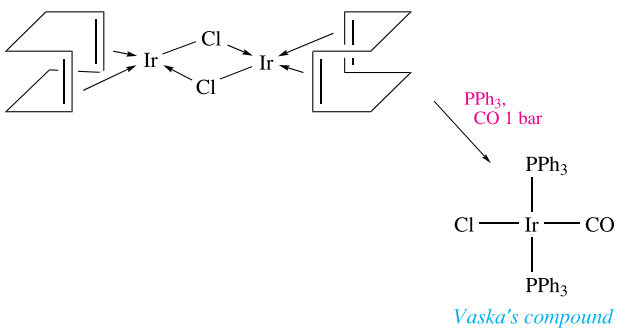
(24.63)

Mononuclear hydrido carbonyl anions include $[HFe(CO)_4]^-$ and $[HCr(CO)_5]^-$, both of which can be made by the action of hydroxide on the parent metal carbonyl (eqs. 24.51 and 24.64). Selected reactions of $[HCr(CO)_5]^-$ are shown in Fig. 24.19.†

$$Cr(CO)_6 + 2KOH \xrightarrow[298\ K,\ 10\ min]{CH_2Cl_2/EtOH} K[HCr(CO)_5] + KHCO_3 \qquad (24.64)$$

† For an overview of reactions and role of $[HCr(CO)_5]^-$ in homogeneous catalysis, see: J.-J. Brunet (2000) *Eur. J. Inorg. Chem.*, p. 1377.





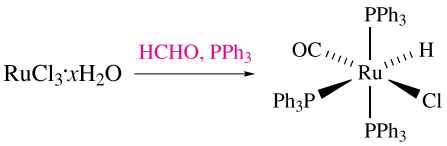


Fig. 24.19. Selected reactions of $[HCr(CO)_5]^-$.

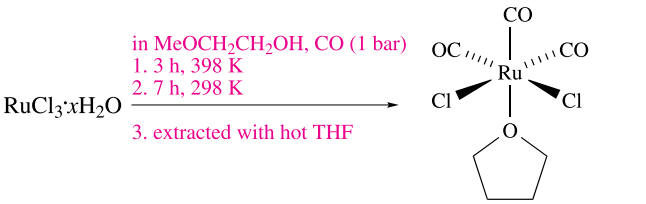
Methods of forming carbonyl halides include starting from binary metal carbonyls (eqs. 24.57–24.59) or metal halides (eqs. 24.65–24.67).



$$RhCl_3{\cdot}xH_2O \xrightarrow{CO,\ 373\ K} (CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2 \qquad (24.65)$$

(24.66)

(24.67)

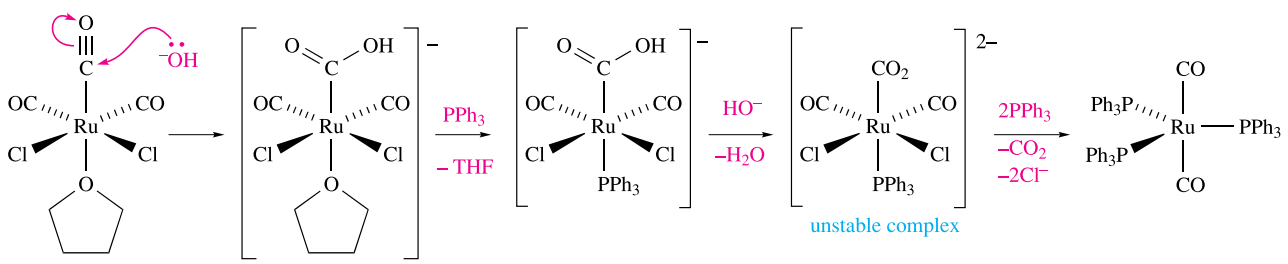
(24.68)

The product of reaction 24.68 is a useful precursor to $Ru(PPh_3)_3(CO)_2$ (eq. 24.69). This 18-electron complex readily loses one PPh_3 ligand to give an unsaturated Ru centre to which H_2, $R_2C{=}CR_2$, $RC{\equiv}CR$ and related molecules easily add.

(24.69)

The proposed mechanism of reaction 24.69 involves initial attack by HO^- at one CO ligand, followed by ligand substitution by PPh_3, deprotonation of the CO_2H ligand, and then dissociation of CO_2 and $2Cl^-$. The addition of two PPh_3 ligands regenerates an 18-electron centre (Fig. 24.20).

The 16-electron halide complexes *cis*-$[Rh(CO)_2I_2]^-$, *cis*-$[Ir(CO)_2I_2]^-$ and *trans*-$[Ir(CO)Cl(PPh_3)_2]$ (Vaska's compound) undergo many oxidative addition reactions and have important catalytic applications (see Chapter 25). Vaska's compound readily takes up O_2 to give the peroxido complex **24.54**. The product of reaction 24.67 is a catalyst precursor for alkene hydrogenation.



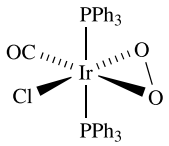


Fig. 24.20. Proposed mechanism for the conversion of *fac*-$Ru(CO)_3Cl_2(THF)$ to $Ru(CO)_2(PPh_3)_3$.

(24.54)

24.11 Alkyl, aryl, alkene and alkyne complexes

σ-Bonded alkyl and aryl ligands

Simple σ-bonded organic derivatives of low oxidation state *d*-block metals are generally more reactive than analogous main group metal species. The origin is kinetic rather than thermodynamic: the availability of vacant 3*d* atomic orbitals in titanium alkyl complexes means that they (except $TiMe_4$) readily undergo β-elimination to give alkene complexes (see Section 24.8).

Alkyl and aryl derivatives can be made by reactions such as 24.70–24.78, the last being an example of an oxidative addition to a 16-electron complex. Choice of alkylating agent can affect the course of the reaction. For example, whereas LiMe is suitable in reaction 24.70, its use instead of $ZnMe_2$ in reaction 24.72 would reduce MoF_6.

$$TiCl_4 + 4LiMe \xrightarrow{\text{in } Et_2O,\ 193\ K} TiMe_4 + 4LiCl \qquad (24.70)$$

$$WCl_6 + 3Al_2Me_6 \longrightarrow WMe_6 + 3Al_2Me_4Cl_2 \qquad (24.71)$$

$$MoF_6 + 3ZnMe_2 \xrightarrow{Et_2O,\ 143\ K} MoMe_6 + 3ZnF_2 \qquad (24.72)$$

$$MoMe_6 \xrightarrow[\text{in } Et_2O,\ 258\ K]{\text{excess LiMe}} [Li(Et_2O)]^+[MoMe_7]^- \qquad (24.73)$$

$$ScCl_3(THF)_3 + 3PhLi \xrightarrow{Et_2O/THF,\ 273\ K} ScPh_3(THF)_2 + THF + 3LiCl \qquad (24.74)$$

$$Na_2[Fe(CO)_4] + EtBr \longrightarrow Na[Fe(CO)_4Et] + NaBr \qquad (24.75)$$

$$Na[Mn(CO)_5] + PhCH_2Cl \longrightarrow Mn(CO)_5(CH_2Ph) + NaCl \qquad (24.76)$$

$$Li[Mn(CO)_5] + PhC(O)Cl \xrightarrow{-LiCl} Mn(CO)_5\{C(O)Ph\} \xrightarrow{\Delta} Mn(CO)_5Ph + CO \qquad (24.77)$$

$$cis\text{-}[Rh(CO)_2I_2]^- + MeI \longrightarrow mer\text{-}[Rh(CO)_2I_3Me]^- \qquad (24.78)$$

Hexamethyltungsten (eq. 24.71) was the first example of a discrete trigonal prismatic complex (Box 20.3). It is highly reactive in air and is potentially explosive.

Alkene ligands

Alkene complexes are often made by displacement of CO or halide ion by an alkene. The formation of *Zeise's salt*,[†] $K[PtCl_3(\eta^2\text{-}C_2H_4)]$ (reaction 24.79), is catalysed by $SnCl_2$ with $[PtCl_3(SnCl_3)]^{2-}$ being the intermediate. The $[PtCl_3(\eta^2\text{-}C_2H_4)]^-$ ion (Fig. 24.21a) contains a square planar (or pseudo-square planar) Pt(II) centre and in the solid state, the ethene ligand lies perpendicular to the coordination 'square plane', thereby minimizing steric interactions.

$$K_2[PtCl_4] + H_2C{=}CH_2 \xrightarrow{SnCl_2} K[PtCl_3(\eta^2\text{-}C_2H_4)] + KCl \qquad (24.79)$$

Addition of an alkene to 16-electron metal complexes is exemplified by reaction 24.80. Ethene readily dissociates from $Ir(CO)Cl(\eta^2\text{-}C_2H_4)(PPh_3)_2$, but the related complex $Ir(CO)Cl(\eta^2\text{-}C_2(CN)_4)(PPh_3)_2$ is very stable.

$$trans\text{-}Ir(CO)Cl(PPh_3)_2 + R_2C{=}CR_2 \longrightarrow Ir(CO)Cl(\eta^2\text{-}C_2R_4)(PPh_3)_2 \qquad (24.80)$$

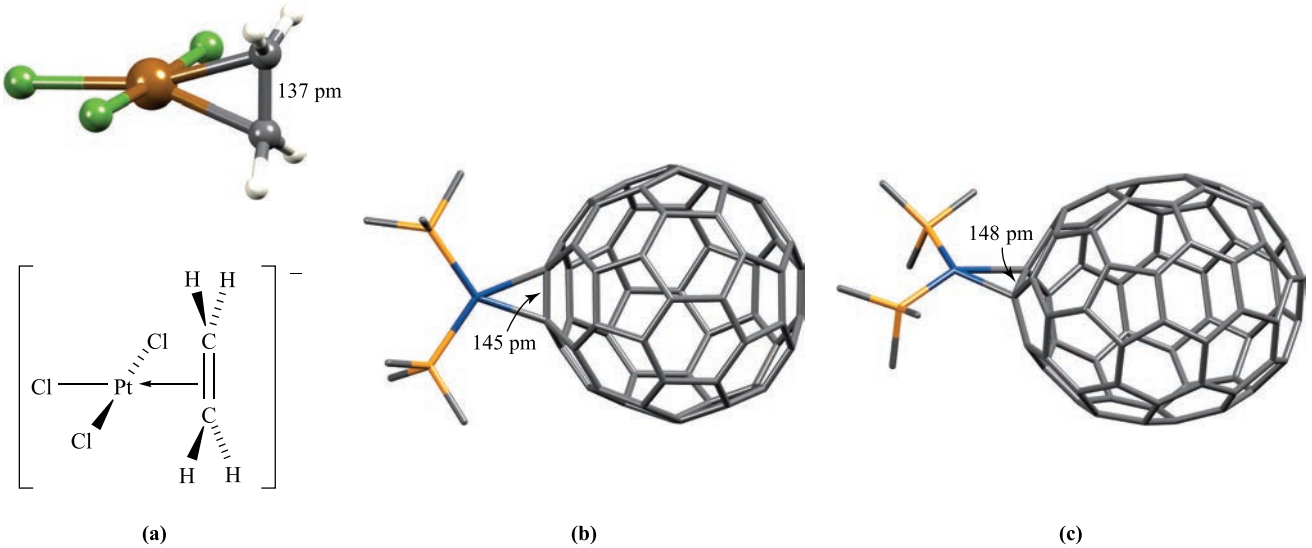
Additions to the family of alkene complexes are fullerene derivatives such as $Mo(\eta^2\text{-}C_{60})(CO)_5$, $W(\eta^2\text{-}C_{60})(CO)_5$ (eq. 24.81), $Rh(CO)(\eta^2\text{-}C_{60})(H)(PPh_3)_2$, $Pd(\eta^2\text{-}C_{60})(PPh_3)_2$ (Fig. 24.21b), $(\eta^5\text{-}Cp)_2Ti(\eta^2\text{-}C_{60})$ and $Pd(\eta^2\text{-}C_{70})(PPh_3)_2$ (Fig. 24.21c). The C_{60} cage (see Section 14.4) functions as a polyene with localized C=C bonds, and in $C_{60}\{Pt(PEt_3)_2\}_6$, six C=C bonds (remote from one another) in the C_{60} cage have undergone addition. Reaction 24.82 illustrates C_{60}-for-ethene substitution (the 16-electron centre is retained), and reaction 24.83 shows addition to Vaska's compound (a 16- to 18-electron conversion). Equation 24.84 shows the formation of a fullerene complex of titanium, by fullerene displacement of a coordinated alkyne.

$$M(CO)_6 + C_{60} \xrightarrow{h\nu \text{ or sunlight}} M(\eta^2\text{-}C_{60})(CO)_5 + CO \qquad (24.81)$$
$$M = Mo, W$$

$$Pt(\eta^2\text{-}C_2H_4)(PPh_3)_2 + C_{60} \xrightarrow{-C_2H_4} Pt(\eta^2\text{-}C_{60})(PPh_3)_2 \qquad (24.82)$$

$$trans\text{-}Ir(CO)Cl(PPh_3)_2 + C_{60} \longrightarrow Ir(CO)Cl(\eta^2\text{-}C_{60})(PPh_3)_2 \qquad (24.83)$$

[†] For an account of the achievements of William C. Zeise including the discovery of Zeise's salt, see: D. Seyferth (2001) *Organometallics*, vol. 20, p. 2.



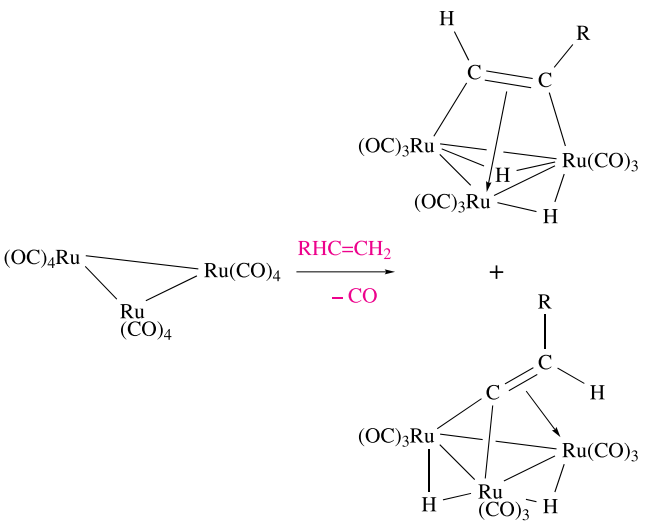


Fig. 24.21. (a) The structure of the anion in Zeise's salt, $K[PtCl_3(\eta^2\text{-}C_2H_4)]$. The Pt(II) centre can be regarded as being square planar as indicated in the schematic representation [neutron diffraction: R.A. Love *et al.* (1975) *Inorg. Chem.*, vol. 14, p. 2653]. (b) The structure of $Pd(\eta^2\text{-}C_{60})(PPh_3)_2$ [X-ray diffraction: V.V. Bashilov *et al.* (1993) *Organometallics*, vol. 12, p. 991]. (c) The structure of $Pd(\eta^2\text{-}C_{70})(PPh_3)_2$ [X-ray diffraction: M.M. Olmstead *et al.* (1999) *J. Organomet. Chem.*, vol. 578, p. 85]. In (b) and (c), a stick-representation is used for clarity, and only the *ipso*-C atoms of the Ph rings are shown. Colour code: Pt, brown; Pd, blue; C, grey; Cl, green; P, orange; H, white.

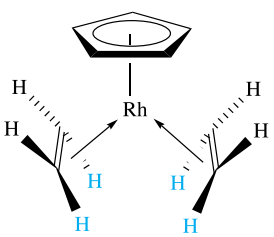


$$(\eta^5\text{-Cp})_2Ti(\eta^2\text{-}Me_3SiC{\equiv}CSiMe_3) + C_{60} \longrightarrow (\eta^5\text{-Cp})_2Ti(\eta^2\text{-}C_{60}) + Me_3SiC{\equiv}CSiMe_3 \quad (24.84)$$

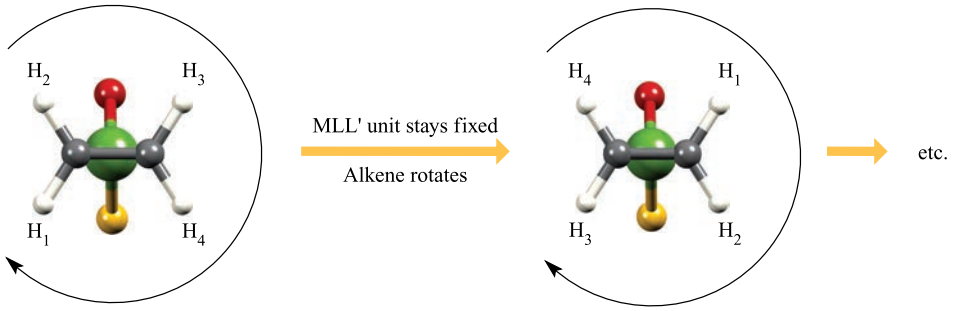
Reactions of alkenes with metal carbonyl clusters may give simple substitution products such as $Os_3(CO)_{11}(\eta^2\text{-}C_2H_4)$ or may involve oxidative addition of one or more C–H bonds. Reaction 24.85 illustrates the reaction of $Ru_3(CO)_{12}$ with $RHC{=}CH_2$ (R = alkyl) to give isomers of $H_2Ru_3(CO)_9(RCCH)$ in which the organic ligand acts as a 4-electron donor (one π- and two σ-interactions).

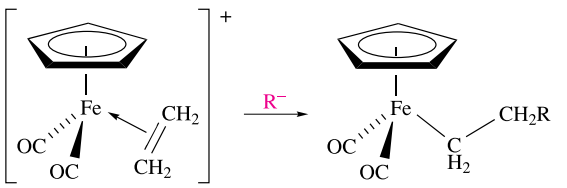
(24.85)

In solution, alkene complexes are often fluxional, with rotation occurring as shown in Fig. 24.22. The model compound in the figure contains a mirror plane passing through M, L and L'. The limiting *low*-temperature ^1H spectrum shows one resonance for H_1 and H_4, and another due to H_2 and H_3, i.e. a static picture of the molecule. On raising the temperature, the molecule gains sufficient energy for the alkene to rotate and the limiting *high*-temperature spectrum contains one resonance since H_1, H_2, H_3 and H_4 become equivalent on the NMR timescale. In $(\eta^5\text{-Cp})Rh(\eta^2\text{-}C_2H_4)_2$, two alkene proton signals are observed at 233 K (the different H environments are blue and black respectively in **24.55**). At 373 K, the proton environments become equivalent on the NMR spectroscopic timescale as each alkene ligand rotates about the metal–ligand coordinate bond.

(24.55)

Coordinated alkenes may be displaced by other ligands (eq. 24.82). Unlike free alkenes, which undergo electrophilic additions, *coordinated* alkenes are susceptible to





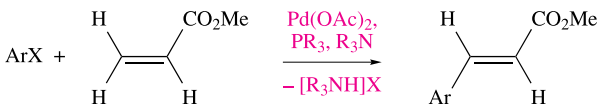


Fig. 24.22. Schematic representation of the rotation of an η^2-C_2H_4 ligand in a complex MLL'(η^2-C_2H_4). The complex is viewed along a line connecting the centre of the C–C bond and the M atom; the M atom is shown in green, and ligands L and L' in red and yellow. Because L and L' are *different*, rotation of the alkene interchanges the environments of H_1 and H_4 with H_3 and H_2.

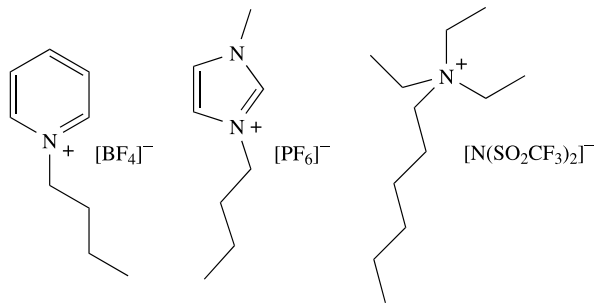
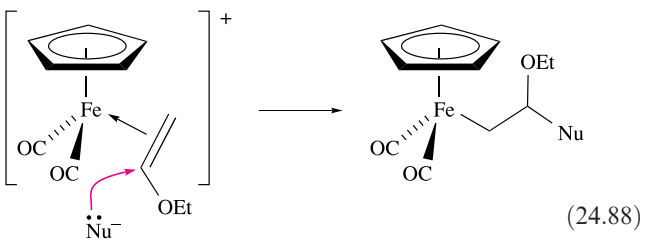
nucleophilic attack and many reactions of catalytic importance involve this pathway (see Chapter 25). Reaction 24.86 shows that addition of a nucleophile, R^-, leads to a σ-bonded complex. The mechanism may involve direct attack at one alkene C atom, or attack at the $M^{\delta+}$ centre followed by alkyl migration (see Section 24.8).



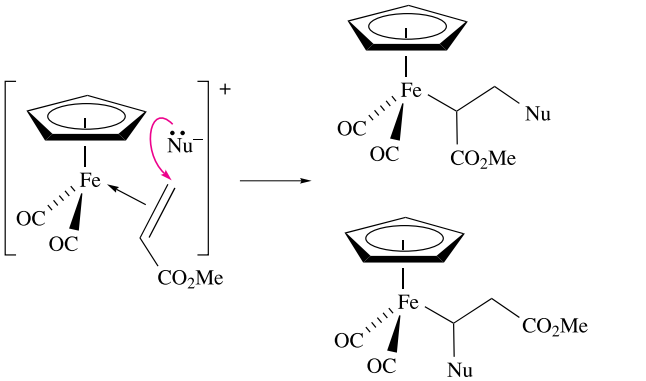
(24.86)

Applications in organic synthesis make particular use of $[(\eta^5\text{-Cp})Fe(CO)_2(\eta^2\text{-alkene})]^+$ complexes and those involving alkenes coordinated to Pd(II) centres. The latter is the basis for the Wacker process (see Fig. 25.2) and for the Heck reaction (eq. 24.87). The Heck reaction is a palladium-catalysed C–C bond forming reaction between an aryl or vinyl halide and an activated alkene in the presence of base. In 2010, Richard Heck shared the Nobel Prize in Chemistry with Ei-ichi Negishi and Akira Suzuki 'for palladium-catalysed cross couplings in organic synthesis'.



(24.87)

When $Pd(OAc)_2$ is used as the catalyst in Heck reactions with an ionic liquid (see Section 9.12) as solvent, the ionic liquid stabilizes clusters of Pd atoms producing particles of diameter 1.0–1.6 nm. (The dimensions are measured using transmission electron microscopy, see Box 13.8.) The induction periods of these Heck reactions correlate with the time taken for the Pd nanoparticles to form, consistent with the Pd clusters being the active catalysts. Compared with $Pd(OAc)_2$-catalysed reactions carried out in organic media, product separation and catalyst recycling in ionic liquids are more efficient. Nowadays, catalyst recycling is of prime importance (see Section 25.6), and the use of ionic liquids rather than conventional organic solvents is often advantageous. Ionic liquids used in Heck reactions[†] include the following:

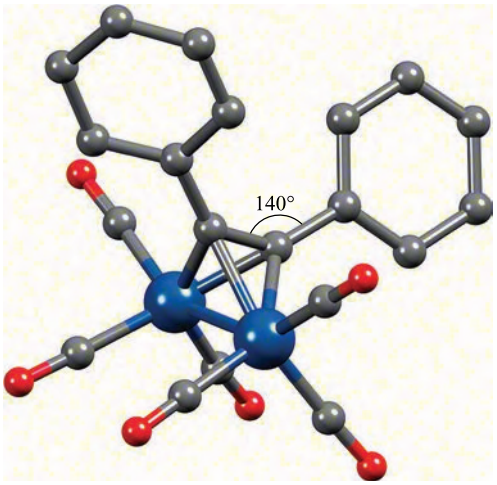


Often, nucleophilic addition to coordinated alkenes is regioselective, with the nucleophile attacking at the C atom carrying the *least* electron-withdrawing group. In reactions 24.88 and 24.89, a strongly electron-releasing group is exemplified by EtO, and an electron-withdrawing group by CO_2Me (Nu = nucleophile).

(24.88)

[†] For a review, see: P. Mastrorilli *et al.* (2015) *Top. Organomet. Chem.*, vol. 51, p. 237 – 'Ionic liquids in palladium-catalyzed cross-coupling reactions'.

(24.89)



Coordinated alkenes are susceptible to nucleophilic attack. This reaction has important applications in synthetic organic chemistry and catalysis.

Self-study exercises

1. Explain how the O_2CMe group directs nucleophilic addition as shown in reaction 24.89.
2. Why does the product of eq. 24.86 not undergo β-hydride elimination? [*Ans.* See text under eq. 24.44]

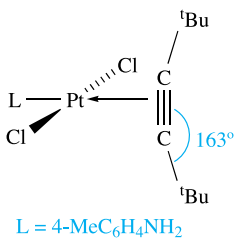
Alkyne ligands

Many mono- and polynuclear organometallic complexes involving alkyne ligands are known. An alkyne RC≡CR has *two* fully occupied π-MOs and may act as a 2- or 4-electron donor. The bonding in a monometallic alkyne complex can be described in a similar manner to that in an alkene complex (see Section 24.2), but allowing for the participation of the two orthogonal π-MOs. A typical C≡C bond length in a free alkyne is 120 pm and, in complexes, this lengthens to ≈124–137 pm depending on the mode of bonding. In **24.56**, the C−C bond length (124 pm) is consistent with a weakened triple bond; the alkyne lies perpendicular to the $PtCl_2L$-plane and occupies one site in the square planar coordination sphere of the Pt(II) centre. A similar example is $[PtCl_3(\eta^2\text{-}C_2Ph_2)]^-$ (eq. 24.90). In **24.57**, the alkyne acts as a 4-electron donor, forming a metallacycle. The C−C bond length (132 pm) is consistent with a double bond. A decrease in the alkyne C−C−C_R bond angle accompanies the change in bonding mode on going from **24.56** to **24.57**. The addition of an alkyne to $Co_2(CO)_8$ (eq. 24.91) results in the formation of a Co_2C_2 cluster (Fig. 24.23) in which the alkyne C−C bond is lengthened to 136 pm.

C—C in Co_2C_2-unit = 136 pm

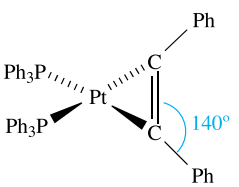
Fig. 24.23. The structure (X-ray diffraction) of $Co_2(CO)_6(C_2Ph_2)$ [D. Gregson *et al.* (1983) *Acta Crystallogr., Sect. C*, vol. 39, p. 1024]. Hydrogen atoms are omitted for clarity; colour code: Co, blue; C, grey; O, red.

$$K_2[PtCl_4] \xrightarrow{\text{18-crown-6 (see Figure 11.8)}} {}^1/_2[K(18\text{-crown-6})]_2[Pt_2Cl_6]$$



$$\downarrow \text{PhC}\equiv\text{CPh}$$

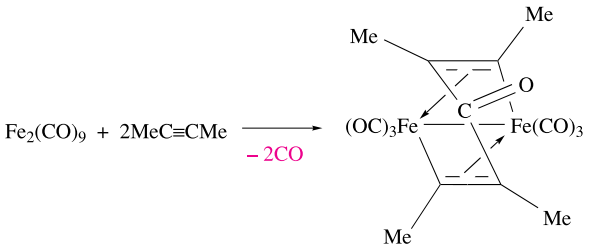
$$[K(18\text{-crown-6})]^+[PtCl_3(\eta^2\text{-}C_2Ph_2)]^-$$



(24.90)

$$Co_2(CO)_8 + PhC{\equiv}CPh \longrightarrow Co_2(CO)_6(C_2Ph_2) + 2CO$$

(24.91)



(24.56)

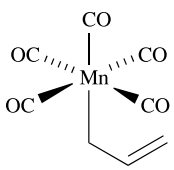
(24.57)

The reactions between alkynes and multinuclear metal carbonyls give various product types, with alkyne coupling and alkyne–CO coupling often being observed, e.g. reaction 24.92, in which the organic ligand in the product is a 6-electron donor (two σ- and two π-interactions). Predicting the outcome of such reactions is difficult.

(24.92)

In solution, π-bonded alkynes of the type in structure **24.56** undergo rotations analogous to those of alkenes.

Self-study exercises



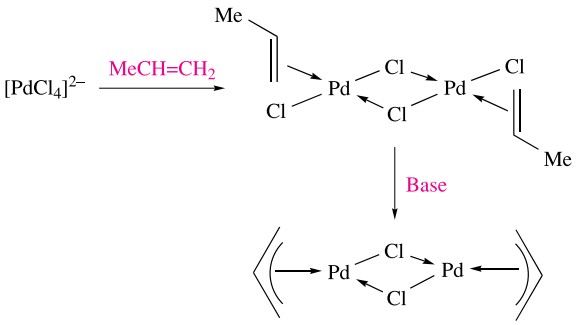
1. The solution ^{1}H NMR spectrum of [K(18-crown-6)][$PtCl_3(\eta^2$-MeC≡CMe)] exhibits a singlet at δ 3.60 ppm and a pseudo-triplet at δ 2.11 ppm (J 32.8 Hz). Assign the signals and explain the origin of the 'pseudo-triplet'. Sketch the pseudo-triplet and show where the coupling constant of 32.8 Hz is measured.
2. [K(18-crown-6)][$PtCl_3(\eta^2$-MeC≡CMe)] reacts with ethene to give [K(18-crown-6)][**X**]. The ^{1}H and ^{13}C NMR spectra of the product are as follows: ^{1}H NMR: δ/ppm 3.63 (singlet), 4.46 (pseudo-triplet, J 64.7 Hz); ^{13}C NMR δ/ppm 68.0 (pseudo-triplet, J 191.8 Hz), 70.0 (singlet). Suggest the identity of $[\mathbf{X}]^-$, and assign the spectra.

[*Ans. to both questions*: See D. Steinborn *et al.* (1995) *Inorg. Chim. Acta*, vol. 234, p. 47; see Box 19.1]

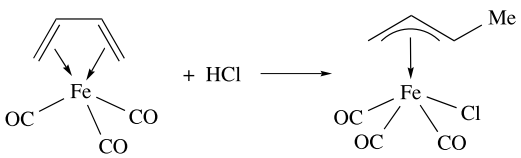
24.12 Allyl and buta-1,3-diene complexes

Allyl and related ligands

π-Allyl and related complexes can be prepared by reactions such as 24.93–24.97. The last two reactions illustrate formation of allyl ligands by deprotonation of coordinated propene, and protonation of coordinated buta-1,3-diene respectively. Reactions 24.94 and 24.95 are examples of pathways that go via σ-bonded intermediates (e.g. **24.58**) which eliminate CO.



(24.58)



$$NiCl_2 + 2C_3H_5MgBr \xrightarrow{\text{in } Et_2O,\ 263\ K} Ni(\eta^3\text{-}C_3H_5)_2 + 2MgBrCl \qquad (24.93)$$

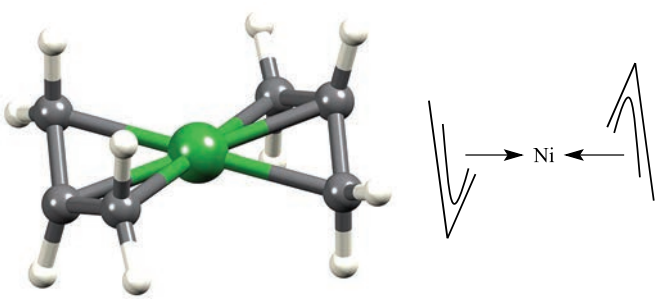
$$Na[Mn(CO)_5] + H_2C{=}CHCH_2Cl \longrightarrow Mn(\eta^3\text{-}C_3H_5)(CO)_4 + CO + NaCl \qquad (24.94)$$

$$Na[(\eta^5\text{-}Cp)Mo(CO)_3] + H_2C{=}CHCH_2Cl \xrightarrow{h\nu,\ \text{in THF}} (\eta^5\text{-}Cp)Mo(\eta^3\text{-}C_3H_5)(CO)_2 + NaCl + CO \qquad (24.95)$$

(24.96)

(24.97)

In Fig. 24.8, we showed the three π-MOs that the π-allyl ligand uses in bonding to a metal centre. In $Mo(\eta^3\text{-}C_3H_5)(\eta^4\text{-}C_4H_6)(\eta^5\text{-}C_5H_5)$ (Fig. 24.6b), the central and two outer Mo–C bond lengths in the $Mo(\eta^3\text{-}C_3)$ unit are different (221 and 230 pm respectively). This is a typical observation for π-allyl ligands, e.g. 198 and 203 pm respectively for the central and outer Ni–C bonds in $Ni(\eta^3\text{-}C_3H_5)_2$ (Fig. 24.24). In the latter, the two allyl ligands are staggered. In Fig. 24.6b and 24.24, note the orientations of the H atoms with respect to the metal centres. The two H atoms in each terminal CH_2 group of a coordinated $\eta^3\text{-}C_3H_5$ ligand are non-equivalent. In solution, however,



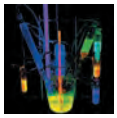


Fig. 24.24. The structure (neutron diffraction at 100 K) of $Ni(\eta^3\text{-}C_3H_5)_2$ and a schematic representation of the complex [R. Goddard *et al.* (1985) *Organometallics*, vol. 4, p. 285]. Colour code: Ni, green; C, grey; H, white.

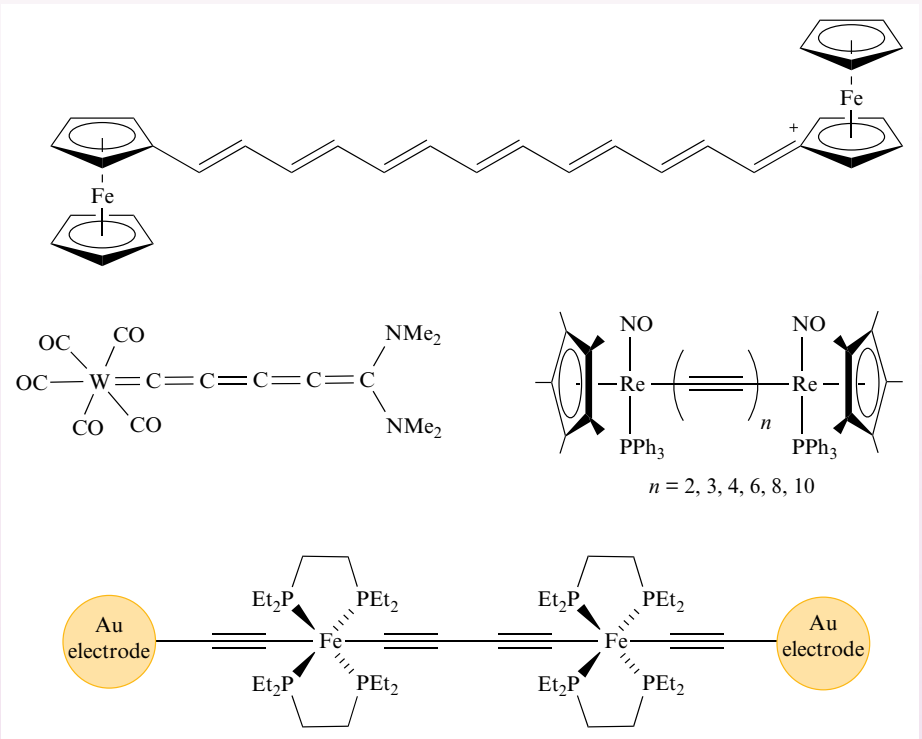

APPLICATIONS

Box 24.3 Molecular wires

The ability of chemists to design molecules for electronic applications is becoming a reality and 'molecular wires' are a topical area of research. A molecular wire is a molecule capable of transporting charge carriers from one end of the wire to the other. Molecules with extended conjugated systems are prime candidates for molecular wires since the conjugation provides the necessary electronic communication between atomic centres. The molecule must also possess a small band gap. (For details on charge carriers and band gaps, see Section 6.9.)

Although commercial applications are still future goals, much progress has been made in the design of potential molecular wires. Molecules so far studied have included organic molecules with conjugated alkyne functionalities, porphyrins connected by alkyne units, chains of connected thiophenes, and organometallic complexes. Examples of the latter are shown below:

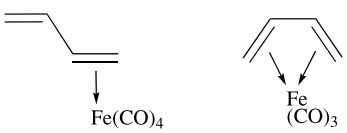
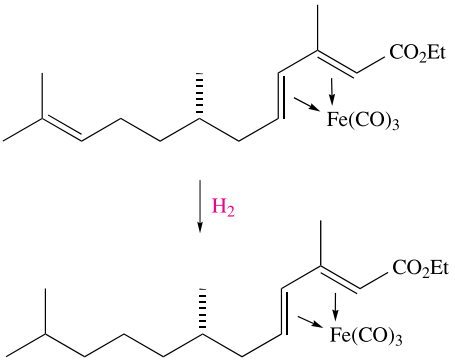
they are often equivalent on the NMR spectroscopic timescale, and this can be rationalized in terms of the η^3-κC^1-η^3 (i.e. π–σ–π) rearrangement shown in scheme 24.98. An η^3-κC^1 rearrangement also features in some reactions of allyl ligands.



(24.98)

Bis(allyl)nickel (Fig. 24.24) is one of the best-known allyl complexes, but it is pyrophoric, and decomposes above 293 K. Bulky substituents can be used to stabilize analogues of Ni(η^3-C_3H_5)$_2$. For example, Ni{η^3-1,3-(Me$_3$Si)$_2$C$_3$H$_3$}$_2$ is kinetically stable in air for up to several days, and decomposes only when heated above 373 K.

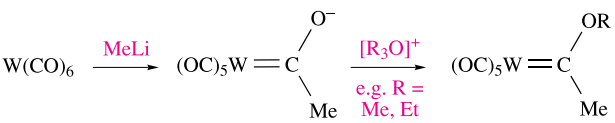


Buta-1,3-diene and related ligands

Photolysis of $Fe(CO)_5$ with buta-1,3-diene gives complex **24.59**, an orange liquid which loses CO at room temperature to give **24.60**, an air-stable yellow solid. The coordinated diene is difficult to hydrogenate, and does not undergo Diels–Alder reactions which are characteristic of conjugated dienes. Structural data for **24.60** confirm that the Fe atom is equidistant from each C atom of the ligand. Bonding schemes for the metal–ligand interaction were discussed in Section 24.2.

(24.59) **(24.60)**

Iron tricarbonyl complexes of 1,3-dienes (e.g. cyclohexa-1,3-diene) play an important role in organic synthesis. The complexes are stable under a variety of reaction conditions, and iron carbonyls are inexpensive. The $Fe(CO)_3$ group acts as a protecting group for the diene functionality (e.g. against additions to the C=C bonds), allowing reactions to be carried out on other parts of the organic molecule as illustrated by reaction 24.99.

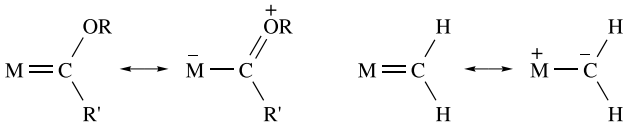


(24.99)

The presence of the $Fe(CO)_3$ group also permits reactions with *nucleophiles* to be carried out at the diene functionality with control of the stereochemistry, the nucleophile being able to attack only on the side of the coordinated diene *remote* from the metal centre. The organic ligand can be removed in the final step of the reaction.†

24.13 Carbene and carbyne complexes

In Section 24.8, we introduced carbene and carbyne complexes when we discussed α-hydrogen abstraction. Equations 24.45 and 24.46 exemplified methods of preparation. Carbenes can also be made by nucleophilic attack on a carbonyl C atom followed by alkylation (eq. 24.100).

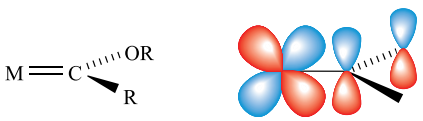


(24.100)

Compounds of the type formed in reactions such as 24.100 are called *Fischer-type carbenes*. They possess a low oxidation state metal, a heteroatom (O in this example) and an *electrophilic* carbene centre (i.e. subject to attack by nucleophiles, e.g. reaction 24.101). Resonance pair **24.61** gives a bonding description for a Fischer-type carbene complex.

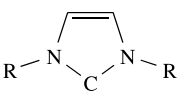
(24.101)

† For detailed discussion of the use of metal carbonyl 1,3-diene complexes in organic synthesis, see: L.R. Cox and S.V. Ley (1998) *Chem. Soc. Rev.*, vol. 27, p. 301 – 'Tricarbonyl complexes: An approach to acyclic stereocontrol'; W.A. Donaldson and S. Chaudhury (2009) *Eur. J. Org. Chem.*, p. 3831 – 'Recent applications of acyclic (diene)iron complexes and (dienyl)iron cations in organic synthesis'.



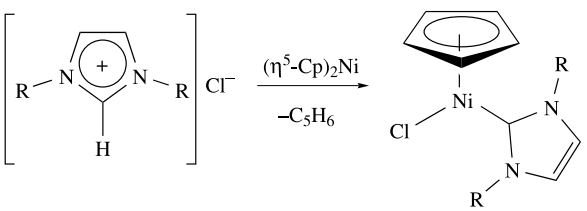
(24.61) **(24.62)**

In contrast, *Schrock-type carbenes* are made by reactions such as 24.45, contain an early *d*-block metal in a high oxidation state, and show nucleophilic character (i.e. susceptible to attack by electrophiles, e.g. reaction 24.102). Resonance pair **24.62** describes a Schrock-type carbene complex.

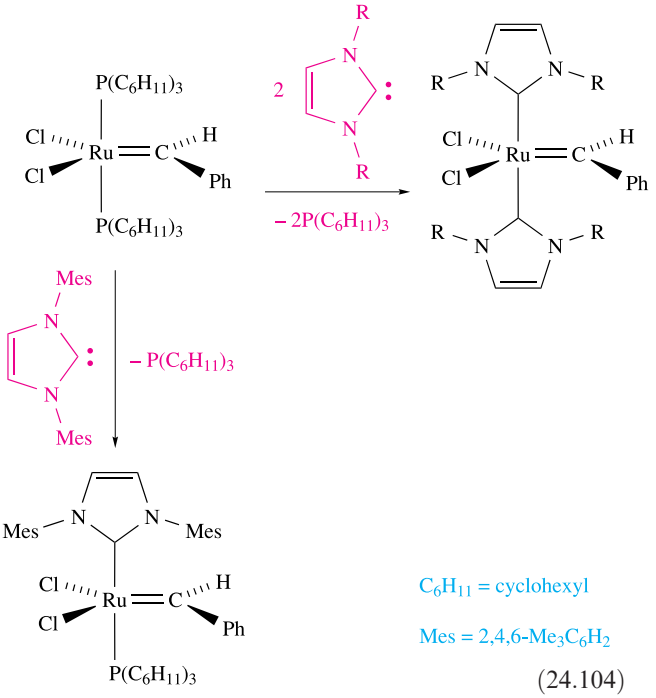


$$(\eta^5\text{-Cp})_2\text{MeTa}{=}\text{CH}_2 + \text{AlMe}_3 \longrightarrow (\eta^5\text{-Cp})_2\text{Me}\overset{+}{\text{Ta}}{-}\text{CH}_2{-}\overset{-}{\text{Al}}\text{Me}_3 \qquad (24.102)$$

The M−$C_{carbene}$ bonds in both Fischer- and Schrock-type complexes are *longer* than typical M−$C_{CO(term)}$ bonds, but *shorter* than typical M−C single bonds, e.g. in$(OC)_5$Cr=C(OMe)Ph, Cr−$C_{carbene}$ = 204 pm and Cr−C_{CO} = 188 pm. This implies some degree of (*d*–*p*) π-character as indicated by resonance structures **24.61** and **24.62**. The π-system can be extended to the heteroatom in the Fischer-type system as shown in diagram **24.63**.

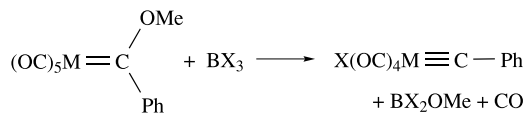


(24.63)



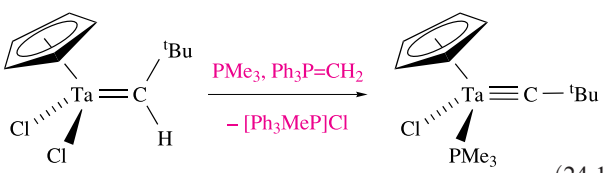
N-Heterocyclic carbenes (**24.64**) have become important ligands in organometallic chemistry, notable examples being Grubbs' second and third generation catalysts. Synthetic routes to *N*-heterocyclic carbene complexes (which are stable to air) typically involve salt metathesis or elimination reactions. Reaction 24.103 shows the use of a 1,3-dialkylimidazolium salt as a precursor, and scheme 24.104 illustrates conversions relevant to Grubbs' catalysts (see next page).

(24.64)



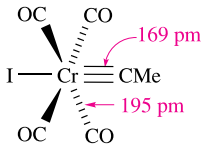
(24.103)

(24.104)



N-Heterocyclic carbenes are good σ-donors. The M–$C_{carbene}$ bond distances (typically >210 pm) are longer than those in Fischer- or Schrock-type carbene complexes. This implies that the metal-to-carbene back-bonding that is characteristic of Fischer- and Schrock-type carbenes is not as important in *N*-heterocyclic carbene complexes.

One route to a carbyne (alkylidyne) complex is reaction 24.46. Equation 24.105 illustrates the initial method of Fischer. The abstraction of an α-H atom from a Schrock-type carbene yields the corresponding carbyne complex (eq. 24.106).



(24.105)

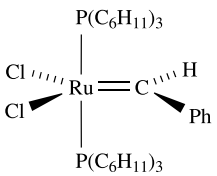
M = Cr, Mo, W X = Cl, Br, I

(24.106)

An M−$C_{carbyne}$ bond is typically shorter than an M−$C_{CO(term)}$ bond, e.g. structure **24.65**. The multiple bonding can be considered in terms of an *sp* hybridized $C_{carbyne}$ atom, with one M−C σ-interaction (using an sp_z hybrid) and two π-interactions (using the $C_{carbyne}$ $2p_x$ and $2p_y$ atomic orbitals overlapping with the metal d_{xz} and d_{yz} atomic orbitals).

(24.65)

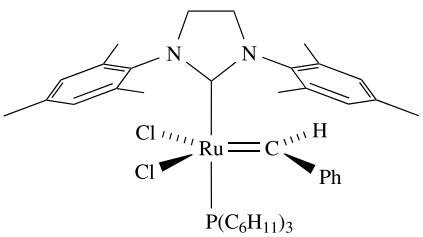
Alkylidyne (carbyne) complexes containing μ_3-CR groups interacting with a triangle of metal atoms include $Co_3(CO)_9(\mu_3\text{-CMe})$ and $H_3Ru_3(CO)_9(\mu_3\text{-CMe})$, and we considered the bonding in such compounds in terms of the isolobal principle in Section 24.6. Reactions 24.107 and 24.108 illustrate methods of introducing μ_3-CR groups into clusters. The precursor in reaction 24.108 is unsaturated and contains an Os=Os bond which undergoes additions. The intermediate in this reaction contains a bridging carbene group which undergoes oxidative addition of a C−H bond on heating.



$$Co_2(CO)_8 \xrightarrow{MeCCl_3} Co_3(CO)_9CMe \qquad (24.107)$$

$$H_2Os_3(CO)_{10} \xrightarrow[-N_2]{CH_2N_2} H_2Os_3(CO)_{10}(\mu\text{-}CH_2)$$

$$\xrightarrow[-CO]{\Delta} H_3Os_3(CO)_9(\mu_3\text{-}CH) \qquad (24.108)$$



In mononuclear carbyne complexes, the M≡C bond undergoes addition reactions, e.g. addition of HCl and alkynes.

Structures **24.66** (Grubbs' catalyst), **24.67** (Grubbs' second generation catalyst), **24.68** (Grubbs' third generation catalyst), **24.69** (Hoveyda–Grubbs' second generation catalyst) and **24.70** (Schrock-type complex) show important carbene compounds that are used as catalysts in *alkene* (*olefin*) *metathesis*, i.e. metal-catalysed reactions in which C=C bonds are redistributed.[†] Examples include ring-opening metathesis polymerization (ROMP) and ring-closing metathesis (RCM). The importance of alkene metathesis (see Section 25.3) was acknowledged by the award of the 2005 Nobel Prize in Chemistry to Robert H. Grubbs, Richard R. Schrock and Yves Chauvin 'for the development of the metathesis method in organic synthesis'.

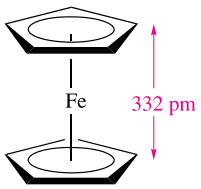
24.14 Complexes containing η^5-cyclopentadienyl ligands

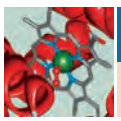


The cyclopentadienyl ligand was discussed in Chapter 23 and in Sections 24.1 and 24.2. Now we look at examples of some of its more important *d*-block metal complexes.

In a ***sandwich complex***, the metal centre lies between two π-bonded hydrocarbon (or derivative) ligands. Complexes of the type $(\eta^5\text{-Cp})_2M$ are called ***metallocenes***.

[†] This definition is taken from: T.M. Trnka and R.H. Grubbs (2001) *Acc. Chem. Res.*, vol. 34, p. 18 – 'The development of L_2X_2Ru=CHR olefin metathesis catalysts: an organometallic success story'.

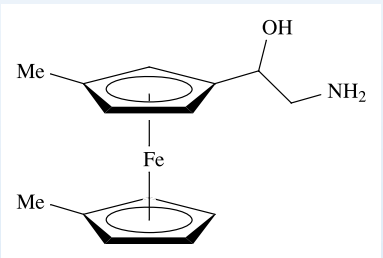
Ferrocene and other metallocenes



The best-known cyclopentadienyl complex is the *sandwich compound* ferrocene, $(\eta^5\text{-Cp})_2\text{Fe}$. It is a diamagnetic, orange solid (mp 446 K) which obeys the 18-electron rule (structure **24.33**). Within the CBC model (Section 24.4), ferrocene is in the common FeL_4X_2 class (Table 24.4). In the gas phase, the two cyclopentadienyl rings are *eclipsed* (**24.71**) but the solid exists in several phases in which the rings are co-parallel but in different orientations.

(24.71)

Solving the structure has been hampered by disorder problems. The barrier to rotation of the two rings is low and at 298 K, there is motion even in the solid state. In derivatives of ferrocene with substituents on the Cp rings, the barrier to rotation is higher, and in $(\eta^5\text{-}C_5Me_5)_2Fe$, the two C_5 rings are staggered in both the gas and solid states. The bonding in $(\eta^5\text{-Cp})_2\text{Fe}$ can be described in terms of the interactions between the π-MOs of the ligands (see Box 23.2) and the metal 3*d* atomic orbitals (see end-of-chapter problem 24.29). Ferrocene is oxidized (e.g. by I_2 or $FeCl_3$) to the paramagnetic, blue ferrocenium ion, $[(\eta^5\text{-Cp})_2\text{Fe}]^+$. Equation 24.109 gives E° relative to the standard hydrogen electrode, but the Fc^+/Fc couple is commonly used as a convenient internal, secondary reference electrode (i.e. E° is defined as 0 V for reference purposes, see Box 8.2).



$$\underset{\text{Fc}^+}{[(\eta^5\text{-Cp})_2\text{Fe}]^+} + e^- \rightleftharpoons \underset{\text{Fc}}{(\eta^5\text{-Cp})_2\text{Fe}} \qquad E^\circ = +0.40\,\text{V} \qquad (24.109)$$

BIOLOGY AND MEDICINE

Box 24.4 Biosensors for glucose oxidase

The iron-centred redox properties of a ferrocene derivative similar to that shown below are the basis of the ExacTech™ and Precision QID™ blood glucose meters manufactured by Medisense Inc. The pen-like construction of the ExacTech™ meter is shown in the photograph and its function is to measure glucose levels in people with diabetes. The iron centre facilitates electron transfer between glucose and glucose oxidase, and a glucose level reading is obtained in about 30 seconds. The lifetime of one pen-meter is about 4000 readings, and one advantage of the design is its ease of use, making it particularly suitable for use by children with diabetes.

Blood glucose being tested using an ExacTech™. A drop of blood is placed in a chemically coated strip which activates the digital display of the sensor.

Metallocenes of the first row metals are known for V(II), Cr(II), Mn(II), Fe(II), Co(II), Ni(II) and Zn(II). Reaction 24.110 is a general synthesis for all except $(\eta^5\text{-Cp})_2\text{V}$ (where the starting chloride is VCl_3) and $(\eta^5\text{-Cp})_2\text{Zn}$ (prepared by reaction 24.111). Reaction 24.112 gives an alternative synthesis for ferrocene and nickelocene. Titanocene, $(\eta^5\text{-Cp})_2\text{Ti}$, is a 14-electron, paramagnetic species. It is highly reactive and has not been isolated, although it can be made *in situ* by treating $(\eta^5\text{-Cp})_2TiCl_2$ with Mg. Sterically demanding substituents are needed to stabilize the system, e.g. $(\eta^5\text{-}C_5H_4SiMe_3)_2\text{Ti}$ (scheme 24.113).

$$MCl_2 + 2Na[Cp] \longrightarrow (\eta^5\text{-Cp})_2M + 2NaCl \qquad (24.110)$$

$$Zn\{N(SiMe_3)_2\}_2 + 2C_6H_5 \xrightarrow{Et_2O,\ 298\ K} (\eta^5\text{-Cp})_2Zn + 2(Me_3Si)_2NH \qquad (24.111)$$

$$MCl_2 + 2C_5H_6 + 2Et_2NH \longrightarrow (\eta^5\text{-Cp})_2M + 2[Et_2NH_2]Cl \quad (M = Fe, Ni) \qquad (24.112)$$

$$2Li[C_5H_4SiMe_3] + TiCl_3 \xrightarrow[-2LiCl]{} (\eta^5\text{-}C_5H_4SiMe_3)_2TiCl \xrightarrow[-NaCl]{Na/Hg} (\eta^5\text{-}C_5H_4SiMe_3)_2Ti \qquad (24.113)$$

The complexes $(\eta^5\text{-Cp})_2\text{V}$ (air-sensitive, violet solid), $(\eta^5\text{-Cp})_2\text{Cr}$ (air-sensitive, red solid), $(\eta^5\text{-Cp})_2\text{Mn}$ (brown solid, pyrophoric when finely divided), $(\eta^5\text{-Cp})_2\text{Co}$ (very air-sensitive, black solid) and $(\eta^5\text{-Cp})_2\text{Ni}$ (green solid) are paramagnetic; $(\eta^5\text{-Cp})_2\text{Cr}$ and $(\eta^5\text{-Cp})_2\text{Ni}$ have two unpaired electrons. The 19-electron complex $(\eta^5\text{-Cp})_2\text{Co}$ is readily oxidized to the 18-electron $[(\eta^5\text{-Cp})_2\text{Co}]^+$, yellow salts of which are air-stable. Nickelocene is a 20-electron complex and in its reactions (Fig. 24.25) often relieves this situation, forming 18-electron complexes. The 19-electron cation $[(\eta^5\text{-Cp})_2\text{Ni}]^+$ forms when $[(\eta^5\text{-Cp})_2\text{Ni}]$ reacts with $[H(OEt_2)_2][B(3,5\text{-}(CF_3)_2C_6H_3)_4]$ (*Brookhart's acid*). In both crystalline $[(\eta^5\text{-Cp})_2\text{Ni}]$ and $[(\eta^5\text{-Cp})_2\text{Ni}]^+[B(3,5\text{-}(CF_3)_2C_6H_3)_4]^-$, the cyclopentadienyl rings are mutually eclipsed. Manganocene, unlike the other metallocenes, is dimorphic. The room-temperature form is polymeric and structurally similar to $(\eta^5\text{-Cp})_2\text{Pb}$ (Fig. 23.20c), while the high-temperature form is structurally related to ferrocene. Zincocene (air-sensitive, colourless solid) is diamagnetic and, in the solid state, is structurally similar to $(\eta^5\text{-}C_5H_5)_2\text{Pb}$ (Fig. 23.20c). The compound $(\eta^5\text{-}C_5Me_5)_2Zn_2$ was (in 2004) the first example of a *dimetallocene*. It formally contains a $\{Zn_2\}^{2+}$ core, and is made by reaction 24.114. The ratio of products depends on reaction conditions, but when carried out in Et_2O at 263 K, the reaction gives $(\eta^5\text{-}C_5Me_5)_2Zn_2$ (Fig. 24.26) as the dominant product. The

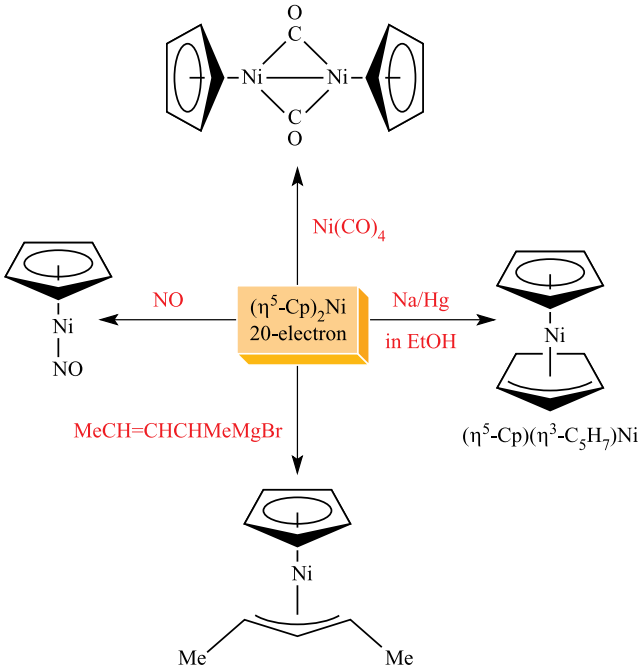

Fig. 24.25. Selected reactions of nickelocene, $(\eta^5\text{-Cp})_2\text{Ni}$.

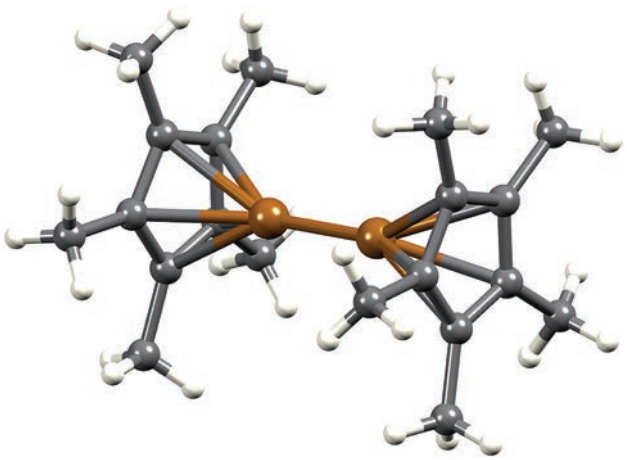

Fig. 24.26. The solid state structure (X-ray diffraction at 173 K) of $(\eta^5\text{-}C_5Me_5)_2Zn_2$ [I. Resa *et al.* (2004) *Science*, vol. 305, p. 1136]. The Zn–Zn distance is 230.5 pm. Colour code: Zn, brown; C, grey; H, white.

Zn–Zn bond length of 230.5 pm is consistent with a metal–metal bonding interaction (see also reaction 21.117).

$$(\eta^5\text{-}C_5Me_5)_2Zn + Et_2Zn \longrightarrow (\eta^5\text{-}C_5Me_5)_2Zn_2 + (\eta^5\text{-}C_5Me_5)ZnEt \qquad (24.114)$$

In Section 24.11, we described examples of fullerenes acting as η^2-alkenes (Fig. 24.21). Fullerenes can also mimic the η^5-bonding mode of a Cp ring and examples include $Re(CO)_3(\eta^5\text{-}C_{60}Me_5)$ (Fig. 24.27), $Fe(CO)_2Br(\eta^5\text{-}C_{60}Me_5)$ and $(\eta^5\text{-Cp})Ru(C_{60}Ph_5)$. Such compounds may be prepared

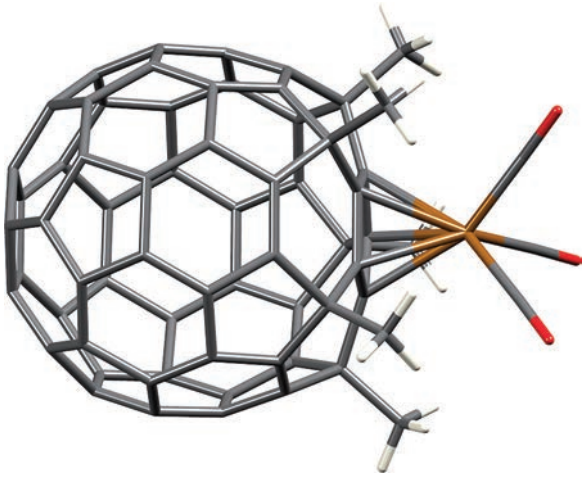

Fig. 24.27. The structure of $Re(CO)_3(\eta^5\text{-}C_{60}Me_5)$ determined by X-ray diffraction [Y. Matsuo *et al.* (2008) *Organometallics*, vol. 27, p. 3403]. A stick-representation is used for clarity. Colour code: Re, brown; C, grey; O, red; H, white.

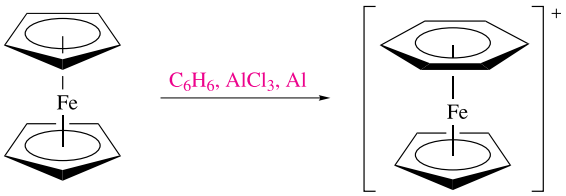
by first converting C_{60} to a $[C_{60}R_5]^-$ anion and then reacting with a metal halide or alkoxide.† The five R groups in the $\{C_{60}R_5\}$ unit surround the $\eta^5\text{-}C_5$ ring as shown in Fig. 24.27.



The chemistry of ferrocene dominates that of the other metallocenes. It is commercially available and large numbers of derivatives are known. The rings in $(\eta^5\text{-Cp})_2Fe$ possess aromatic character, and selected reactions are shown in Fig. 24.28. Protonation occurs at the Fe(II) centre and this is indicated by the appearance of a signal at δ −2.1 ppm in the ^1H NMR spectrum of $[(\eta^5\text{-Cp})_2FeH]^+$. The regioselective double deprotonation of each cyclopentadienyl ring in ferrocene occurs when $(\eta^5\text{-Cp})_2Fe$ is treated with an appropriate 'superbase'. Such a base is produced by combining certain lithium or heavier group 1 metal amides with magnesium amides in the presence of a Lewis base cosolvent. This combination of reactants provides both a deprotonating agent and a so-called *inverse crown ether* to stabilize the deprotonated species. The term *inverse crown ether* arises from the fact that each Lewis base donor of a conventional crown ether is replaced by a Lewis acid (in this case, Na^+ and Mg^{2+}).‡ In reaction 24.115, the $^iPr_2N^-$ anions formally remove H^+ from $(\eta^5\text{-Cp})_2Fe$, while the *s*-block metal ions and N atoms form the inverse crown host which stabilizes the $[(\eta^5C_5H_3)_2Fe]^{4-}$ ion (Fig. 24.29).

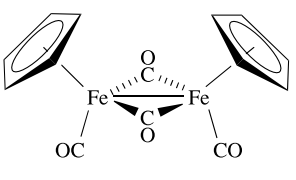
† For details, see: M. Sawamura, H. Iikura and E. Nakamura (1996) *J. Am. Chem. Soc.*, vol. 118, p. 12850; Y. Matsuo, Y. Kuninobu, A. Muramatsu, M. Sawamura and E. Nakamura (2008) *Organometallics*, vol. 27, p. 3403.

‡ For reviews of inverse crown chemistry, see: R.E. Mulvey (2001) *Chem. Commun.*, p. 1049; R.E. Mulvey (2013) *Dalton Trans.*, vol. 42, p. 6676.

$$(\eta^5\text{-}C_5H_5)_2Fe + 8{}^iPr_2NH + 4BuNa + 8Bu_2Mg \longrightarrow \{(\eta^5\text{-}C_5H_3)_2Fe\}Na_4Mg_4(N{}^iPr_2)_8 + 12BuH \qquad (24.115)$$

The exchange of an η^5-Cp ring for an η^6-arene ligand (eq. 24.116) is accompanied by a change in overall charge so that the Fe atom remains an 18-electron centre.

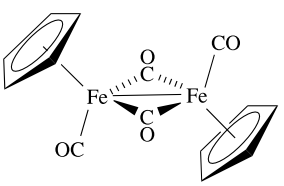
(24.116)



Self-study exercise

The reaction of $(\eta^5\text{-Cp})(\eta^5\text{-}C_5H_4I)Fe$ with ^nBuLi followed by treatment with half an equivalent of $ZnBr_2$ gave compound **A**. This was immediately reacted with hexaiodobenzene to yield **B**, the mass spectrum of which showed a parent ion at m/z = 1182. The solution ^1H NMR spectrum of **B** exhibited three signals: δ/ppm 4.35 (m, 12H), 4.32 (m, 12H), 3.99 (s, 30 H). In the $^{13}C\{^1H\}$ NMR spectrum of **B**, five signals were observed. Deduce the structure of **B**, and rationalize the observed NMR spectroscopic data. Suggest a structure for compound **A**.

[*Ans.* See Y.Yu *et al.* (2006) *Chem. Commun.*, p. 2572]



$(\eta^5\text{-Cp})_2Fe_2(CO)_4$ and derivatives

Reactions between metal carbonyls and cyclopentadiene usually yield mixed ligand complexes, e.g. $Fe(CO)_5$ reacts with C_5H_6 to give $(\eta^5\text{-Cp})_2Fe_2(CO)_4$. Two isomers of $(\eta^5\text{-Cp})_2Fe_2(CO)_4$ exist, *cis* (**24.72**) and *trans* (**24.73**), and both have been confirmed in the solid state. The Fe–Fe bond length (253 pm) is consistent with a single bond giving each Fe centre 18 electrons.

cis-isomer

(24.72)

trans-isomer

(24.73)

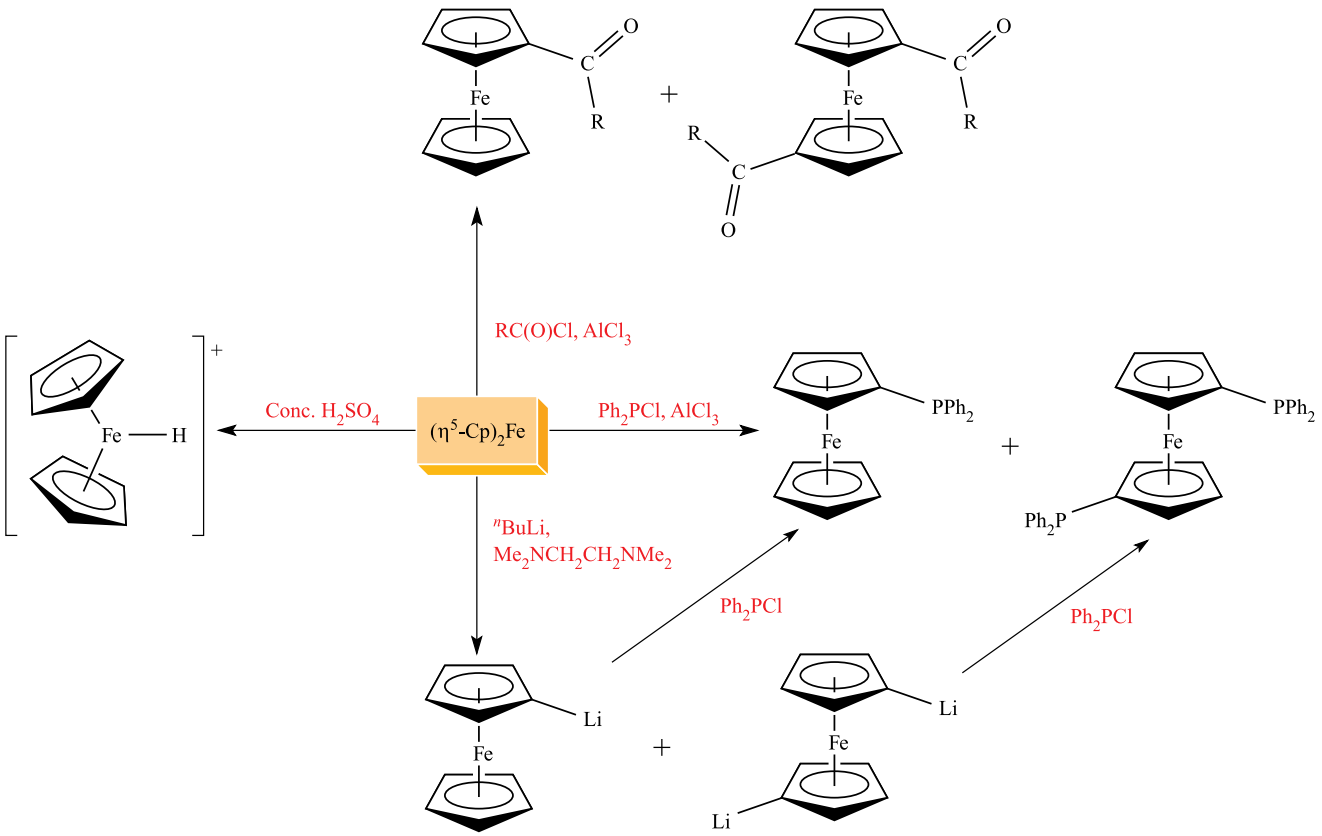


Fig. 24.28. Selected reactions of ferrocene, $(\eta^5\text{-Cp})_2\text{Fe}$.

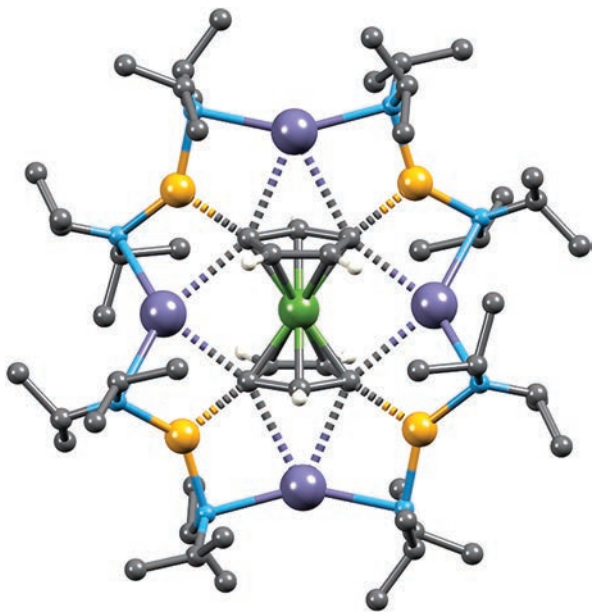

Fig. 24.29. The structure of $\{(\eta^5\text{-}C_5H_3)_2Fe\}Na_4Mg_4(N^iPr_2)_8$ (X-ray diffraction at 160 K) in which the $[(\eta^5\text{-}C_5H_3)_2Fe]^{4-}$ anion is stabilized within the $[Na_4Mg_4(N^iPr_2)_8]^{4+}$ host [P.C. Andrikopoulos *et al.* (2004) *J. Am. Chem. Soc.*, vol. 126, p. 11612]. Colour code: Fe, green; C, grey; H, white; N, blue; Na, purple; Mg, yellow.

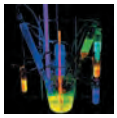
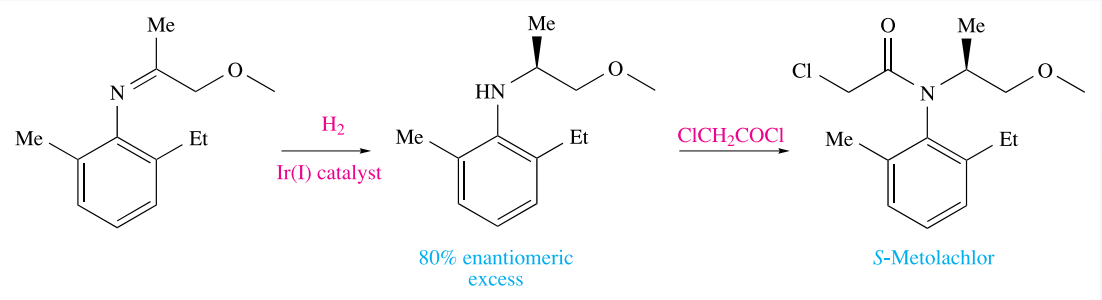


In solution at 298 K, both the *cis*- and *trans*-forms are present and the terminal and bridging ligands exchange by an intramolecular process. Above 308 K, *cis* ⟶ *trans* isomerism occurs, probably through an unbridged intermediate. The *cis*-isomer can be obtained by crystallization at low temperatures.

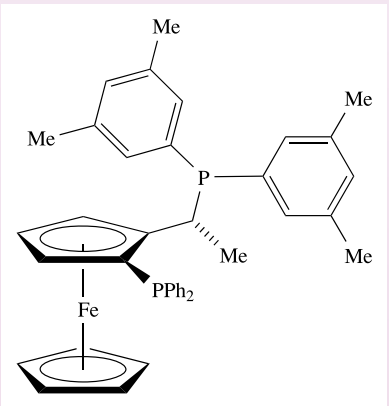
The dimer $(\eta^5\text{-Cp})_2Fe_2(CO)_4$ is commercially available and is a valuable starting material in organometallic chemistry. Reactions with Na or halogens cleave the Fe–Fe bond (eqs. 24.117 and 24.118) giving useful organometallic reagents, reactions of which are exemplified in eqs. 24.119–24.122.

$$(\eta^5\text{-Cp})_2Fe_2(CO)_4 + 2Na \longrightarrow 2Na[(\eta^5\text{-Cp})Fe(CO)_2] \qquad (24.117)$$

$$(\eta^5\text{-Cp})_2Fe_2(CO)_4 + X_2 \longrightarrow 2(\eta^5\text{-Cp})Fe(CO)_2X$$



$$X = Cl, Br, I \qquad (24.118)$$



APPLICATIONS

Box 24.5 Enantioselectivity in the preparation of the herbicide *S*-Metolachlor

Each year, Novartis manufactures ≈10 000 tonnes of the herbicide *S*-Metolachlor, the synthesis of which is shown in the scheme below. It is used to control the growth of grass and broadleaved weeds among agricultural crops. The (*R*)-enantiomer of Metolachlor is inactive as a herbicide, and so if the chemical is applied as a racemate, half of the applied chemical is ineffective. The key to enantioselectivity is the first step of *asymmetric hydrogenation*.

The hydrogenation step is catalysed by an iridium(I) complex containing the chiral ferrocenyl bisphosphane ligand shown below. The ligand coordinates to the Ir(I) centre through the two *P*-donor atoms, and the complete catalyst system comprises Ir(I), the ferrocenyl ligand, I^- and H_2SO_4. The 80% enantiomeric excess (ee) is not as high as would be required for, say, chiral drug synthesis, but is adequate for the production of a herbicide. Chiral catalysts play a vital role in directing asymmetric syntheses, and the % ee is highly sensitive to the choice of chiral ligand; 'ee' is explained in Section 25.5. The manufacture of *S*-Metolachlor provides an example of an industrial application of one particular chiral ferrocenyl bisphosphane ligand.

Herbicide application to a field of bloom-stage cotton plants in Mississippi, US.

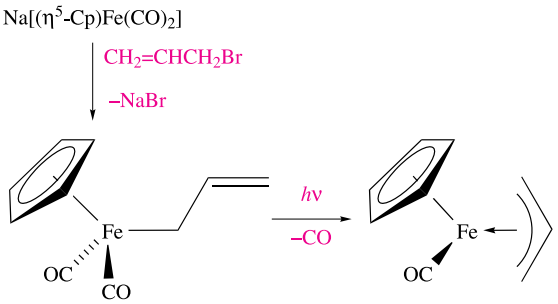
APPLICATIONS

Box 24.6 Zirconocene derivatives as catalysts

The development of Ziegler–Natta-type catalysts (see Section 25.8) has, since the 1980s, included the use of zirconocene derivatives. In the presence of methylaluminoxane $[MeAl(\mu\text{-}O)]_n$ as a co-catalyst, compounds **A**, **B** and **C** (shown below) are active catalysts for propene polymerization. Compounds **A** and **B** are chiral because of the relative orientations of the two halves of the organic ligand. A racemic mixture of **A** facilitates the formation of *isotactic* polypropene, while use of catalyst **C** results in *syndiotactic* polypropene (see Section 25.8 for definitions of syndiotactic, isotactic and atactic). If $(\eta^5\text{-Cp})_2ZrCl_2$ is used, *atactic* polypropene is produced. Such catalysts are commercially available. The active species in the catalyst system is a cation of the general type $[Cp_2ZrR]^+$, and such cations are used directly as polymerization catalysts. Formed by protonolysis, oxidative Zr−R cleavage, or abstraction of R^- from Cp_2ZrR_2 (e.g. R = Me), $[Cp_2ZrR]^+$ reagents are active catalysts *without* the need for addition of the methylaluminoxane co-catalyst.

A **B** **C**



Zirconocene derivatives are used to catalyse a range of organic hydrogenation and C−C bond-forming reactions. In the presence of methylaluminoxane, chiral complex **A** catalyses asymmetric hydrogenations (see Section 25.5), with the active species being a cationic zirconium hydrido complex.

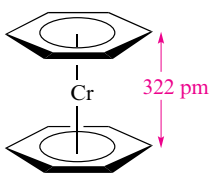
Self-study exercises

1. Give two synthetic routes to ferrocene.
[*Ans.* See eqs. 24.110 and 24.112]

2. Explain what is meant in the main text by the *regioselective* deprotonation of ferrocene to give $[(\eta^5\text{-}C_5H_3)_2Fe]^{4-}$.

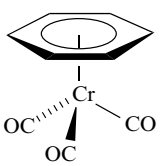
3. At 295 K, the IR spectrum of a solution of $(\eta^5\text{-}C_5H_4{}^{i}Pr)_2Ti$ shows absorptions arising from C–H vibrational modes. When the sample is cooled to 195 K under an atmosphere of N_2, new absorptions at 1986 and 2090 cm^{-1} appear. These bands disappear when the sample is warmed to 295 K. Rationalize these observations.
[*Ans.* See T.E. Hanna *et al.* (2004) *J. Am. Chem. Soc.*, vol. 126, p. 14688]

24.15 Complexes containing η^6- and η^7-ligands



η^6-Arene ligands

Arenes such as benzene and toluene can act as 6π-electron donors as illustrated in eqs. 24.116 and 24.122. A wide range of arene complexes exist, and sandwich complexes can be made by co-condensation of metal and arene vapours (eq. 24.123) or by reaction 24.124.



$$Cr(g) + 2C_6H_6(g) \xrightarrow[\text{warm to 298 K}]{\text{co-condense on to surface at 77 K;}} (\eta^6\text{-}C_6H_6)_2Cr \qquad (24.123)$$

$$\left.\begin{aligned} &3CrCl_3 + 2Al + AlCl_3 + 6C_6H_6 \\ &\quad \rightarrow 3[(\eta^6\text{-}C_6H_6)_2Cr]^+[AlCl_4]^- \\ &2[(\eta^6\text{-}C_6H_6)_2Cr]^+ + 4[OH]^- + [S_2O_4]^{2-} \\ &\quad \rightarrow 2(\eta^6\text{-}C_6H_6)_2Cr + 2H_2O + 2[SO_3]^{2-} \end{aligned}\right\} \qquad (24.124)$$

The group 6 metals form air-sensitive 18-electron complexes $(\eta^6\text{-}C_6H_6)_2M$ (M = Cr, Mo, W). In the solid state, the two benzene rings in $(\eta^6\text{-}C_6H_6)_2Cr$ are eclipsed (**24.74**). The C−C bonds are equal in length (142 pm) and slightly longer than in free benzene (140 pm). The bonding can be described in terms of the interaction between the π-MOs of the ligands (Fig. 24.30) and the metal 3*d* atomic orbitals, with the occupied ligand π-MOs acting as donors and the vacant MOs functioning as acceptors.

(24.74)

(24.75)

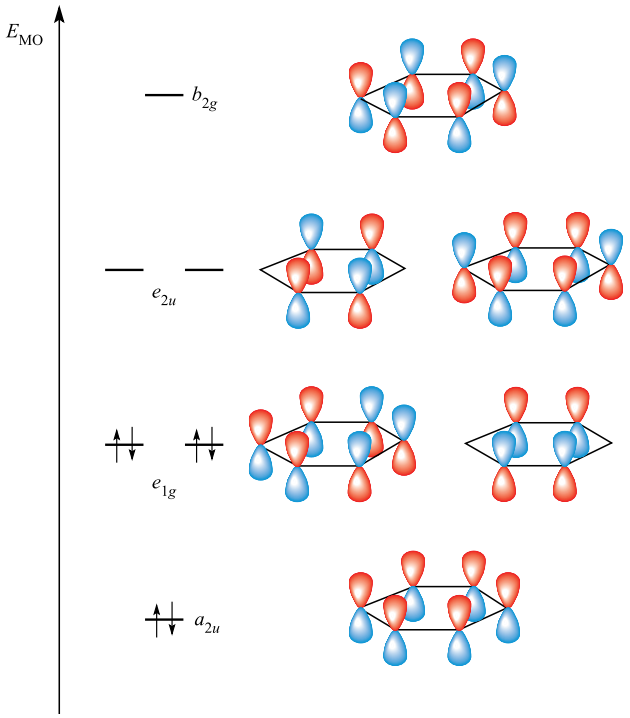


Fig. 24.30. The π-molecular orbitals of C_6H_6; the energy scale is arbitrary. The symmetry labels apply to D_{6h} C_6H_6; these labels are not applicable to the ligand in a complex of other symmetry.

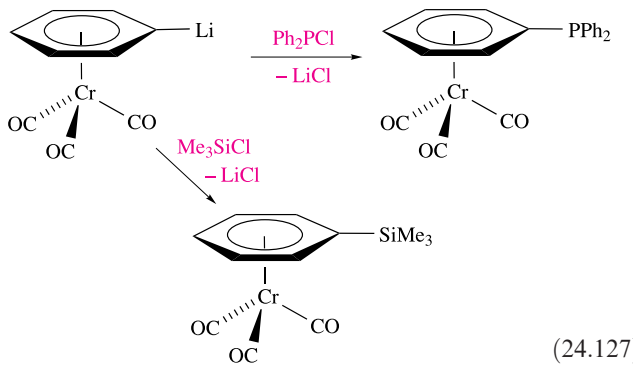
Surprisingly, the brown Cr complex is easily oxidized by I_2 to the 17-electron, air-stable yellow $[(\eta^6\text{-}C_6H_6)_2Cr]^+$. The ease of oxidation precludes $(\eta^6\text{-}C_6H_6)_2Cr$ from undergoing electrophilic substitution reactions. Electrophiles oxidize $(\eta^6\text{-}C_6H_6)_2Cr$ to $[(\eta^6\text{-}C_6H_6)_2Cr]^+$ which does not react further. The lithiated derivative $(\eta^6\text{-}C_6H_5Li)_2Cr$ can be made by reaction of $(\eta^6\text{-}C_6H_6)_2Cr$ with $^{n}BuLi$ (compare with the lithiation of ferrocene, Fig. 24.28) and is a precursor to other derivatives.



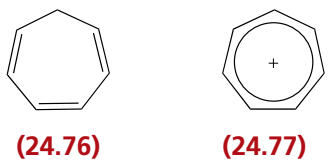
The reaction of $Cr(CO)_6$ or $Cr(CO)_3(NCMe)_3$ with benzene gives the *half-sandwich complex* $(\eta^6\text{-}C_6H_6)Cr(CO)_3$ (**24.75**), and related complexes can be made similarly. The $Cr(CO)_3$ unit in $(\eta^6\text{-arene})Cr(CO)_3$ complexes withdraws electrons from the arene ligand making it *less* susceptible to electrophilic attack than the free arene, but *more* susceptible to attack by nucleophiles (reaction 24.125).

$$(\eta^6\text{-}C_6H_5Cl)Cr(CO)_3 + NaOMe \rightarrow (\eta^6\text{-}C_6H_5OMe)Cr(CO)_3 + NaCl \qquad (24.125)$$

As in $(\eta^6\text{-}C_6H_6)_2Cr$, the benzene ligand in $(\eta^6\text{-}C_6H_6)Cr(CO)_3$ can be lithiated (eq. 24.126) and then derivatized (scheme 24.127). The reactivity of half-sandwich complexes is not confined to sites within the π-bonded ligand: eq. 24.128 illustrates substitution of a CO ligand for PPh_3.

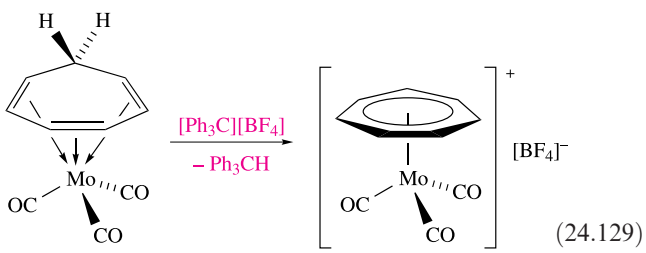
$(\eta^6\text{-}C_6H_6)Cr(CO)_3$

$$\xrightarrow[-{}^{n}BuH]{{}^{n}BuLi,\ TMEDA} (\eta^6\text{-}C_6H_5Li)Cr(CO)_3 \qquad (24.126)$$



(24.127)

$(\eta^6\text{-}C_6H_6)Cr(CO)_3 + PPh_3$

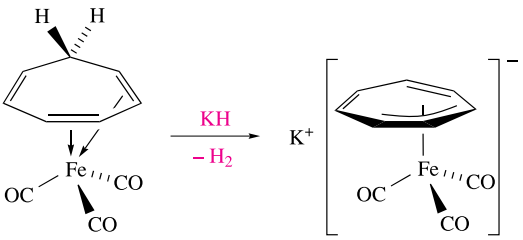


$$\xrightarrow{h\nu} (\eta^6\text{-}C_6H_6)Cr(CO)_2(PPh_3) + CO \qquad (24.128)$$

Cycloheptatriene and derived ligands

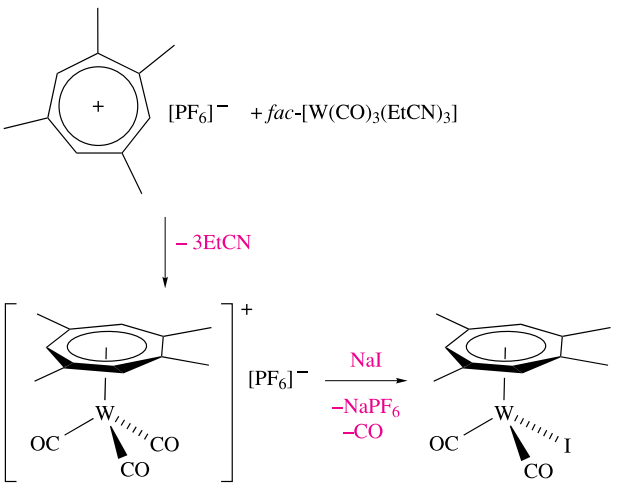
Cycloheptatriene (**24.76**) can act as a 6π-electron donor, and in its reaction with $Mo(CO)_6$, it forms $(\eta^6\text{-}C_7H_8)Mo(CO)_3$. The solid state structure of this complex (Fig. 24.31a) confirms that the ligand coordinates as a triene, the ring being folded with the CH_2 group bent away from the metal centre. Reaction 24.129 shows the abstraction of H^- from coordinated $\eta^6\text{-}C_7H_8$ to give the planar $[\eta^7\text{-}C_7H_7]^+$ ion, **24.77** (the cycloheptatrienylium cation),[†] which has an aromatic π-system and retains the ability of cycloheptatriene to act as a 6π-electron donor.

(24.76) **(24.77)**



(24.129)

[†] The non-systematic name for the cycloheptatrienylium cation is the *tropylium cation*.



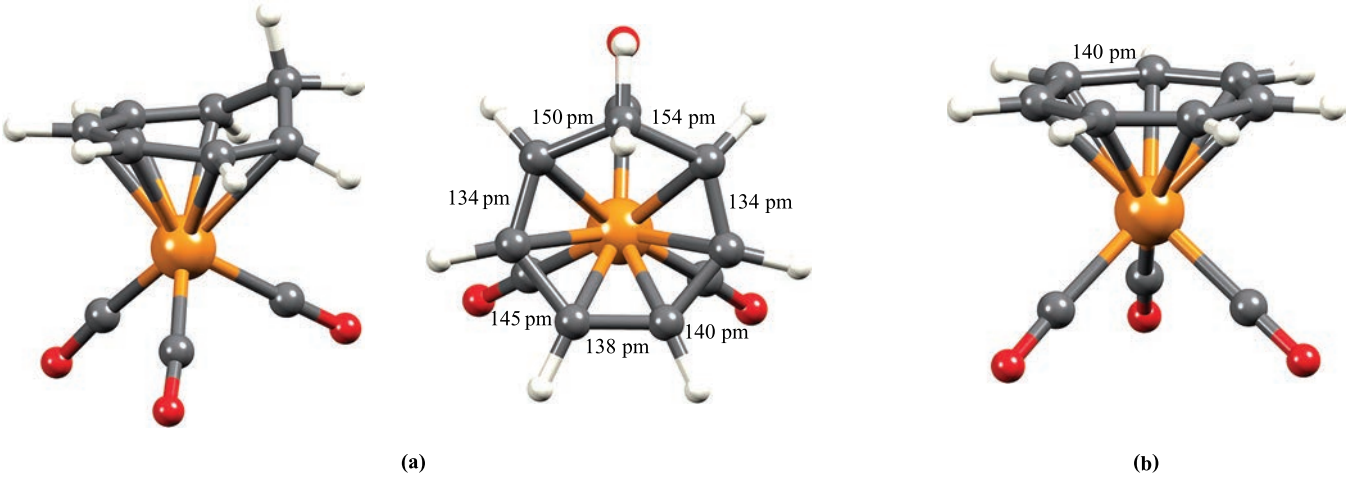
The planarity of the $[C_7H_7]^+$ ligand has been confirmed in the structure of $[(\eta^7\text{-}C_7H_7)Mo(CO)_3]^+$ (Fig. 24.31b). All the C–C bond lengths are close to 140 ppm in contrast to the variation observed in $(\eta^6\text{-}C_7H_8)Mo(CO)_3$ (Fig. 24.31a).

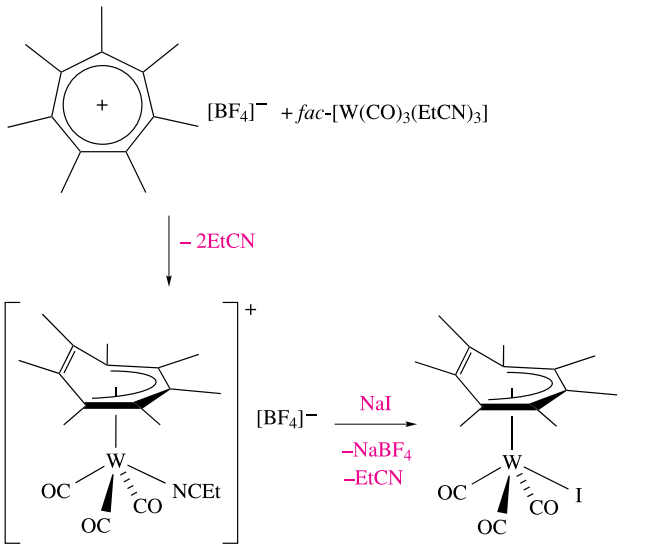
In the complex $(\eta^4\text{-}C_7H_8)Fe(CO)_3$, cycloheptatriene acts as a diene, giving the Fe(0) centre its required 18 electrons. Equation 24.130 shows that deprotonation generates a coordinated $[C_7H_7]^-$ ligand which bonds in an η^3 manner, allowing the metal to retain 18 electrons. At room temperature, the $[C_7H_7]^-$ ligand is fluxional, and on the NMR timescale, the $Fe(CO)_3$ unit effectively 'visits' every carbon atom.

(24.130)

In $[C_7Me_7][BF_4]$, the cation is *non-planar* as a result of steric hindrance between the methyl groups. The introduction of methyl substituents affects the way in which $[C_7R_7]^+$ (R = H or Me) coordinates to a metal centre. Schemes 24.131 and 24.132 show two related reactions that lead to different types of products. The C_7-ring adopts an η^7-mode in the absence of steric crowding, and an η^5-mode when the methyl groups are sterically congested. The differing numbers of EtCN or CO ligands in the products in the two schemes are consistent with the W centre satisfying the 18-electron rule.

(24.131)





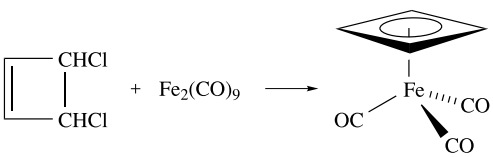


Fig. 24.31. The structures (X-ray diffraction) of (a) $[(\eta^6\text{-}C_7H_8)Mo(CO)_3]$ [J.D. Dunitz *et al.* (1960) *Helv. Chim. Acta*, vol. 43, p. 2188] and (b) $[(\eta^7\text{-}C_7H_7)Mo(CO)_3]^+$ in the $[BF_4]^-$ salt [G.R. Clark *et al.* (1973) *J. Organomet. Chem.*, vol. 50, p. 185]. Colour code: Mo, orange; C, grey; O, red; H, white.

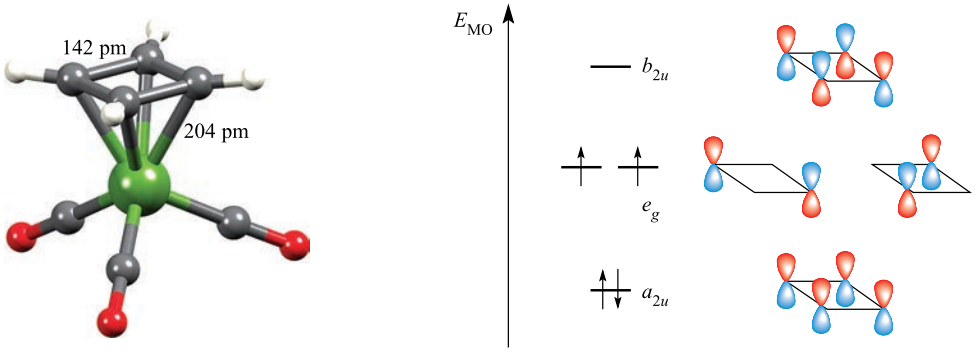
(24.132)

24.16 Complexes containing the η^4-cyclobutadiene ligand

Cyclobutadiene, C_4H_4, is anti-aromatic (i.e. it does not have $4n + 2$ π-electrons) and readily polymerizes. However, it can be stabilized by coordination to a low oxidation state metal centre. Yellow crystalline $(\eta^4\text{-}C_4H_4)Fe(CO)_3$ is made by reaction 24.133 and its solid state structure (Fig. 24.32a) shows that (in contrast to the free ligand in which the double bonds are localized) the C–C bonds in coordinated C_4H_4 are of equal length.

(24.133)



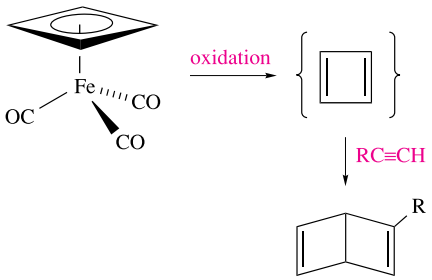


Fig. 24.32. (a) The structure (X-ray diffraction) of $(\eta^4\text{-}C_4H_4)Fe(CO)_3$ [P.D. Harvey *et al.* (1988) *Inorg. Chem.*, vol. 27, p. 57]. (b) The π-molecular orbitals of C_4H_4 in which the ligand geometry is as in its complexes, i.e. a *square* C_4 framework; the symmetry labels apply to D_{4h} C_4H_4; these labels are not applicable to the ligand in a complex of other symmetry. Colour code: Fe, green; C, grey; O, red; H, white.

A C_4H_4 ligand with the geometry found in its complexes, i.e. a *square* C_4 framework, has the π-MOs shown in Fig. 24.32b and is *paramagnetic*. However, $(\eta^4\text{-}C_4H_4)Fe(CO)_3$ is *diamagnetic* and this provides evidence for pairing of electrons between ligand and metal: a C_{3v} $Fe(CO)_3$ fragment also has two unpaired electrons (Fig. 24.17).

Cyclobutadiene complexes can also be formed by the cycloaddition of alkynes as in reaction 24.134.

$$2PdCl_2(NCPh)_2 + 4PhC{\equiv}CPh \longrightarrow (\eta^4\text{-}C_4Ph_4)ClPd(\mu\text{-}Cl)_2PdCl(\eta^4\text{-}C_4Ph_4) \qquad (24.134)$$

In its reactions, *coordinated* cyclobutadiene exhibits aromatic character, undergoing electrophilic substitution, e.g. Friedel–Crafts acylation. A synthetic application of $(\eta^4\text{-}C_4H_4)Fe(CO)_3$ in organic chemistry is as a stable source of cyclobutadiene. Oxidation of the complex releases the ligand, making it available for reaction with, for example, alkynes as in scheme 24.135.

(24.135)

KEY TERMS

The following terms were introduced in this chapter. Do you know what they mean?

- organometallic compound
- hapticity of a ligand
- Dewar–Chatt–Duncanson model
- synergic effect
- Tolman cone angle
- 18-electron rule
- covalent bond classification (CBC)
- condensed polyhedral cluster
- isolobal principle
- polyhedral skeletal electron pair theory (PSEPT)
- capping principle (within Wade–Mingos rules)
- total valence electron counts (for metal frameworks)
- reductive carbonylation
- ligand substitution
- oxidative addition
- orthometallation
- reductive elimination
- alkyl and hydrogen migration
- CO insertion
- β-hydrogen elimination
- agostic M–H–C interaction
- α-hydrogen abstraction
- carbene (alkylidene)
- carbyne (alkylidyne)
- sandwich complex
- metallocene
- half-sandwich complex

PROBLEMS

24.1 (a) Explain the meaning of the following notations: μ-CO; μ_4-PR; η^5-C_5Me_5; η^4-C_6H_6; μ_3-H. (b) Why can the cyclopentadienyl and CO ligands be regarded as being versatile in their bonding modes? (c) Is PPh_3 a 'versatile ligand'?

24.2 What is a synergic effect, and how does it relate to metal–carbonyl bonding?

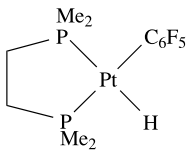
24.3 Comment on the following:

(a) Infrared spectra of $[V(CO)_6]^-$ and $Cr(CO)_6$ show absorptions at 1859 and 1981 cm^{-1} respectively assigned to ν_{CO}, and 460 and 441 cm^{-1} assigned to ν_{MC}.

(b) The Tolman cone angles of PPh_3 and $P(4\text{-}MeC_6H_4)_3$ are both 145°, but that of $P(2\text{-}MeC_6H_4)_3$ is 194°.

(c) Before reaction with PPh_3, $Ru_3(CO)_{12}$ may be treated with Me_3NO in MeCN.

(d) In the complex $[Os(en)_2(\eta^2\text{-}C_2H_4)(\eta^2\text{-}C_2H_2)]^{2+}$ the $Os-C_{ethyne}-H_{ethyne}$ bond angle is 127°.



24.4 (a) Draw a structure corresponding to the formula $[(CO)_2Ru(\mu\text{-}H)(\mu\text{-}CO)(\mu\text{-}Me_2PCH_2PMe_2)_2Ru(CO)_2]^+$. (b) The ^1H NMR spectrum of the complex in part (a) contains a quintet centred at δ −10.2 ppm. Assign the signal and explain the origin of the observed multiplicity.

24.5 The solution ^1H NMR spectrum of the tetrahedral cluster $[(\eta^5\text{-}C_5Me_4SiMe_3)_4Y_4(\mu\text{-}H)_4(\mu_3\text{-}H)_4(THF)_2]$ exhibits the following signals at room temperature: δ/ppm 0.53 (s, 36H), 1.41 (m, 8H), 2.25 (s, 24H), 2.36 (s, 24H), 3.59 (m, 8H), 4.29 (quintet, $J_{^{89}Y^1H}$ 15.3 Hz, 8H). Assign the signals in the spectrum,

and rationalize the appearance of the signal at δ 4.29 ppm. [Data: ^{89}Y, 100% abundant, $I = \frac{1}{2}$.]

24.6 The structure of $(\mu_3\text{-H})_4Co_4(\eta^5\text{-}C_5M_4Et)_4$ was determined by single crystal X-ray diffraction in 1975, and by neutron diffraction in 2004. In both structure determinations, the bridging H atoms were located. To what extent can *precise* locations for these H atoms be given using single crystal X-ray and neutron diffraction techniques? Give reasons for your answer.

24.7 Consider the following compound:

Predict the appearance of the signal assigned to the metal hydride in the ^{1}H NMR spectrum of this compound given the following coupling constants: $J_{^1H^{31}P(cis)}$ 17 Hz, $J_{^1H^{31}P(trans)}$ 200 Hz, $J_{^1H^{195}Pt}$ 1080 Hz. Ignore long-range ^{1}H–^{19}F coupling. [Data: ^{31}P, 100% abundant, $I = \frac{1}{2}$; ^{195}Pt, 33.8% abundant, $I = \frac{1}{2}$.]

24.8 Rationalize the following observations.
(a) On forming $[IrBr(CO)(\eta^2\text{-}C_2(CN)_4)(PPh_3)_2]$, the C–C bond in $C_2(CN)_4$ lengthens from 135 to 151 pm.
(b) During the photolysis of $Mo(CO)_5(THF)$ with PPh_3, a signal in the ^{31}P NMR spectrum at δ −6 ppm disappears and is replaced by one at δ +37 ppm.
(c) On going from $Fe(CO)_5$ to $Fe(CO)_3(PPh_3)_2$, absorptions in the IR spectrum at 2025 and 2000 cm^{-1} are replaced by a band at 1885 cm^{-1}.

24.9 Draw a bonding scheme (similar to that in Fig. 24.7b) for the interaction of an η^3-allyl ligand with a low oxidation state metal centre.

24.10 Show that the metal centres in the following complexes obey the 18-electron rule:
(a) $(\eta^5\text{-Cp})Rh(\eta^2\text{-}C_2H_4)(PMe_3)$
(b) $(\eta^3\text{-}C_3H_5)_2Rh(\mu\text{-Cl})_2Rh(\eta^3\text{-}C_3H_5)_2$
(c) $Cr(CO)_4(PPh_3)_2$
(d) $Fe(CO)_3(\eta^4\text{-}CH_2CHCHCH_2)$
(e) $Fe_2(CO)_9$
(f) $[HFe(CO)_4]^-$
(g) $[(\eta^5\text{-Cp})CoMe(PMe_3)_2]^+$
(h) $RhCl(H)_2(\eta^2\text{-}C_2H_4)(PPh_3)_2$

24.11 Within covalent bond classification (CBC), what is the difference between L, X and Z ligands? Use a simple MO approach to illustrate your answer.

24.12 Derive a CBC classification for:
(a) $W(CO)_6$
(b) $(\eta^5\text{-Cp})_2WH_2$
(c) WMe_6
(d) $(\eta^5\text{-Cp})_2Fe$
(e) $(\eta^6\text{-}C_6H_6)_2Cr$
(f) $(\eta^6\text{-}C_6H_6)Cr(CO)_3$

24.13 The CBC model shows that within the chemistry of Mn, ≈79% of compounds fall into the MnL_5X class. Show that each of the following fits this description and that each has a value of EN = 18.
(a) $Mn(CO)_5Br$
(b) $[Mn(CO)_5]^-$
(c) $MeMn(CO)_5$
(d) $[Mn(CO)_6]^+$
(e) $[(\eta^6\text{-}C_6H_5Br)Mn(CO)_3]^+$
(f) $Mn(CO)_5C(O)Me$

24.14 Reaction of $Fe(CO)_5$ with $Na_2[Fe(CO)_4]$ in THF gives a salt $Na_2[\mathbf{A}]$ and CO. The Raman spectrum of $[Et_4N]_2[\mathbf{A}]$ shows an absorption at 160 cm^{-1} assigned to an unbridged Fe–Fe bond. Suggest an identity and structure for $[\mathbf{A}]^{2-}$.

24.15 Suggest possible structures for the cation in $[Fe_2(NO)_6][PF_6]_2$ and state how you would attempt to distinguish between them experimentally.

24.16 Comment on the following observations:
(a) In the IR spectrum of free $MeCH{=}CH_2$, $\bar{\nu}_{C=C}$ comes at 1652 cm^{-1}, but in the complex $K[PtCl_3(\eta^2\text{-}MeCH{=}CH_2)]$, the corresponding absorption is at 1504 cm^{-1}.
(b) At 303 K, the ^{1}H NMR spectrum of $(\eta^5\text{-Cp})(\eta^1\text{-Cp})Fe(CO)_2$ shows two singlets.

24.17 Use Wade's rules (PSEPT) to suggest structures for $Os_7(CO)_{21}$ and $[Os_8(CO)_{22}]^{2-}$.

24.18 For each of the following clusters, confirm that the total valence electron count is consistent with the metal cage framework adopted: (a) $[Ru_6(CO)_{18}]^{2-}$, octahedron; (b) $H_4Ru_4(CO)_{12}$, tetrahedron; (c) $Os_5(CO)_{16}$, trigonal bipyramid; (d) $Os_4(CO)_{16}$, square; (e) $Co_3(CO)_9(\mu_3\text{-CCl})$, triangle; (f) $H_2Os_3(CO)_9(\mu_3\text{-PPh})$, triangle; (g) $HRu_6(CO)_{17}B$, octahedron; (h) $Co_3(\eta^5\text{-Cp})_3(CO)_3$, triangle; (i) $Co_3(CO)_9Ni(\eta^5\text{-Cp})$, tetrahedron.

24.19 (a) $Os_5(CO)_{18}$ has a metal framework consisting of three edge-sharing triangles (a *raft* structure). Show that the valence electron count for this raft is consistent with the number available. (b) Figure 24.33 (p. 968) shows the metal core of $[Ir_8(CO)_{22}]^{2-}$. What would be an appropriate electron-counting scheme for this cluster?

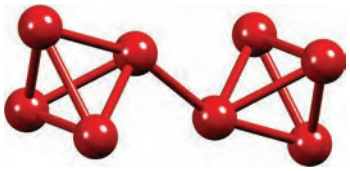


Fig. 24.33. Figure for problem 24.19b.

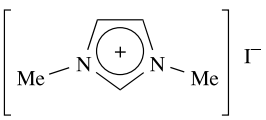
24.20 Suggest products in the following reactions, and give likely structures for the products: (a) $Fe(CO)_5$ irradiated with C_2H_4; (b) $Re_2(CO)_{10}$ with Na/Hg; (c) $Na[Mn(CO)_5]$ with ONCl; (d) $Na[Mn(CO)_5]$ with H_3PO_4; (e) $Ni(CO)_4$ with PPh_3.

24.21 In Section 24.8, we stated that the distribution of the products in Fig. 24.18 is consistent with the migration of the Me group, and not with a mechanism that involves movement of the 'inserted' CO. Confirm that this is true by determining the distribution of products for the CO insertion mechanism and comparing it with that for the Me migration mechanism.

24.22 Illustrate, with examples, what is meant by (a) oxidative addition, (b) reductive elimination, (c) α-hydrogen abstraction, (d) β-hydrogen elimination, (e) alkyl migration and (f) orthometallation.

24.23 The reaction of $Cr(CO)_6$ with $Ph_2P(CH_2)_4PPh_2$ leads to the formation of two products, **A** and **B**. The ^{31}P NMR spectrum of **A** shows two signals ($\delta + 46.0$ and –16.9 ppm, relative integrals 1 : 1), while that of **B** exhibits one signal ($\delta + 46.2$ ppm). The IR spectra of **A** and **B** are almost identical in the region 2200–1900 cm^{-1}, with bands at 2063, 1983 and 1937 cm^{-1}. Suggest identities for **A** and **B** and explain why three absorptions are observed in the IR spectrum of each compound.



24.24 In the Heck reaction (eq. 24.87), the active catalyst is $Pd(PPh_3)_2$. Write equations to show (a) oxidative addition of PhBr to $Pd(PPh_3)_2$ to give **A**, (b) addition of $CH_2{=}CHCO_2Me$ to **A** followed by migration of the Ph group to give the σ-bonded alkyl derivative **B**, and (c) β-hydride elimination to generate the Pd(II) complex **C** and free alkene **D**.

24.25 Discuss the following statements:
(a) Complexes $Fe(CO)_3L$ where L is a 1,3-diene have applications in organic synthesis.
(b) The fullerenes C_{60} and C_{70} form a range of organometallic complexes.
(c) $Mn_2(CO)_{10}$ and C_2H_6 are related by the isolobal principle.

24.26 Explain why scheme 24.98 is invoked to explain the equivalence of the H atoms in each terminal CH_2 group of an η^3-allyl ligand, rather than a process involving rotation about the metal–ligand coordination axis.

24.27 Explain the difference between a Fischer-type carbene and a Schrock-type carbene.

24.28 The reaction of 1,3-dimethylimidazolium iodide (shown on the next page) with one equivalent of KO^tBu in THF, followed by addition of one equivalent of $Ru_3(CO)_{12}$ leads to product **A**. The IR spectrum of **A** has several strong absorptions between 2093 and 1975 cm^{-1}, and the solution ^1H NMR spectrum of **A** exhibits singlets at δ 7.02 and 3.80 ppm (relative integrals 1 : 3). (a) What role does KO^tBu play in the reaction? (b) What is the likely identity of **A**? (c) Draw a possible structure of **A** and comment on possible isomers.

24.29 With reference to Box 23.2, develop a qualitative bonding scheme for $(\eta^5\text{-Cp})_2Fe$.

24.30 Suggest products in the following reactions: (a) excess $FeCl_3$ with $(\eta^5\text{-Cp})_2Fe$; (b) $(\eta^5\text{-Cp})_2Fe$ with PhC(O)Cl in the presence of $AlCl_3$; (c) $(\eta^5\text{-Cp})_2Fe$ with toluene in the presence of Al and $AlCl_3$; (d) $(\eta^5\text{-Cp})Fe(CO)_2Cl$ with $Na[Co(CO)_4]$.

24.31 In the reaction of ferrocene with MeC(O)Cl and $AlCl_3$, how could one distinguish between the products $Fe(\eta^5\text{-}C_5H_4C(O)Me)_2$ and $(\eta^5\text{-Cp})Fe(\eta^5\text{-}C_5H_4C(O)Me)$ by methods other than elemental analysis and X-ray crystallography?

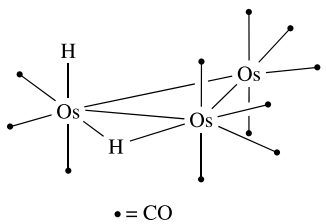
24.32 The reaction of $[(C_6Me_6)RuCl_2]_2$ (**A**) with C_6Me_6 in the presence of $AgBF_4$ gives $[(C_6Me_6)_2Ru][BF_4]_2$ containing cation **B**. Treatment of this compound with Na in liquid NH_3 yields a neutral Ru(0) complex, **C**. Suggest structures for **A**, **B** and **C**.

24.33 (a) Suggest structures for the complexes $LFe(CO)_3$ where L = 2,5-norbornadiene (**24.23**) or cycloheptatriene. (b) How is the bonding mode of the cycloheptatriene ligand affected on going from $LFe(CO)_3$ to $LMo(CO)_3$? (c) For L = cycloheptatriene, what product would you expect from the reaction of $LMo(CO)_3$ and $[Ph_3C][BF_4]$?

24.34 Describe the bonding in $(\eta^4\text{-}C_4H_4)Fe(CO)_3$, accounting for the diamagnetism of the complex.

OVERVIEW PROBLEMS

24.35 Comment on each of the following statements.



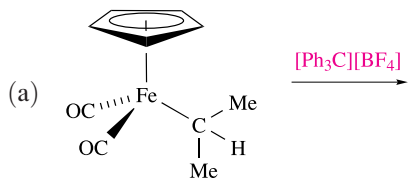
(a) $Re_2(CO)_{10}$ adopts a staggered conformation in the solid state, whereas $[Re_2Cl_8]^{2-}$ adopts an eclipsed conformation.

(b) In anions of type $[M(CO)_4]^{n-}$, $n = 1$ for M = Co, but $n = 2$ for M = Fe.

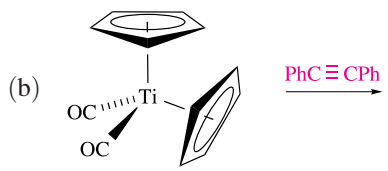
(c) The reaction of benzoyl chloride with $[(Ph_3P)_2N][HCr(CO)_5]$ which has first been treated with MeOD, produces PhCDO.

24.36 (a) Confirm that $H_2Os_3(CO)_{11}$ has sufficient valence electrons to adopt a triangular metal framework. Do the modes of bonding of the CO and H ligands affect the total valence electron count? Comment on the fact that $H_2Os_3(CO)_{10}$ also has a triangular Os_3-core.

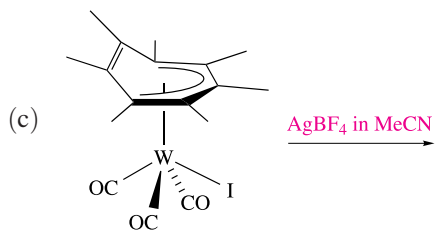
(b) The ^1H NMR spectrum of $H_2Os_3(CO)_{11}$ in deuterated toluene at 183 K shows two major signals (relative integrals 1 : 1) at δ −10.46 and −20.25 ppm; both are doublets with $J = 2.3$ Hz. The signals are assigned to the terminal and bridging H atoms, respectively, in the structure shown below:



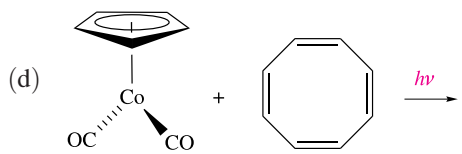
The ^1H NMR spectrum also exhibits two pairs of low-intensity signals: δ −12.53 and −18.40 ppm (both doublets, $J = 17.1$ Hz) and δ −8.64 and −19.42 ppm (no coupling resolved). These signals are assigned to two other isomers of $H_2Os_3(CO)_{11}$. From other NMR spectroscopic experiments, it is possible to show that the two H atoms in each isomer are attached to the same Os centre. Suggest structures for the minor isomers that are consistent with the NMR spectroscopic data.



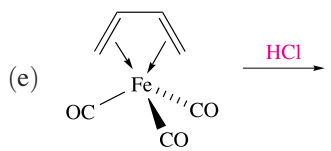
24.37 (a) The cluster $H_3Os_6(CO)_{16}B$ contains an interstitial B atom and has an Os_6 cage derived from a pentagonal bipyramid with one equatorial vertex missing. Comment on this structure in terms of both Wade's rules and a total valence electron count for the cluster.



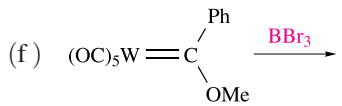
(b) Give a description of the bonding in $[Ir(CO)_6]^{3+}$ and compare it with that in the isoelectronic compound $W(CO)_6$. How would you expect the IR spectra of these species to differ in the carbonyl stretching region?



24.38 Reduction of $Ir_4(CO)_{12}$ with Na in THF yields the salt $Na[Ir(CO)_x]$ (**A**) which has a strong absorption in its IR spectrum (THF solution) at 1892 cm^{-1}. Reduction of **A** with Na in liquid NH_3, followed by addition of Ph_3SnCl and Et_4NBr, gives $[Et_4N][\mathbf{B}]$ as the iridium-containing product; CO is lost during the reaction. Elemental analysis of $[Et_4N][\mathbf{B}]$ shows that it contains 51.1% C, 4.55% H and 1.27% N. The IR spectrum of $[Et_4N][\mathbf{B}]$ shows one strong absorption in the carbonyl region at 1924 cm^{-1}, and the solution ^1H NMR spectrum exhibits multiplets between δ 7.1 and 7.3 ppm (30H), a quartet at δ 3.1 ppm (8H) and a triplet at δ 1.2 ppm (12H). Suggest structures for **A** and $[\mathbf{B}]^-$. Comment on possible isomerism in $[\mathbf{B}]^-$ and the preference for a particular isomer.



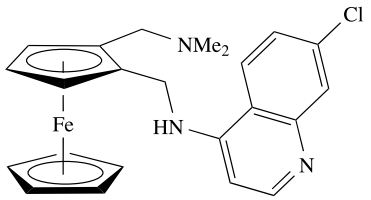
24.39 Suggest possible products for the following reactions:



(a) 

(b) 

(c) 



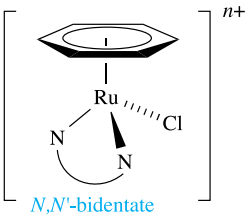
(d) 

(e) 

(f) 

INORGANIC CHEMISTRY MATTERS

24.40 Ferroquine has passed clinical phase II trials as an antimalarial drug. Both enantiomers of ferroquine are equally active *in vitro*. Explain why the molecule is chiral, and draw the structure of (*S*)-ferroquinone.

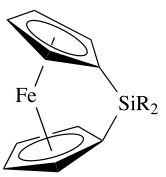


(*R*)-Ferroquine

24.41 Around 10 Mt per year of acetic acid are manufactured worldwide and ≈25% of this is produced using the Cativa™ process. The reaction:

$$MeOH + CO \longrightarrow MeCO_2H$$

is catalysed by *cis*-$[IrI_2(CO)_2]^-$. Methanol is first converted to MeI by reaction with HI, and the catalyst undergoes oxidative addition of MeI to give a *fac*-**A**. In the presence of an I^- abstractor, substitution of I^- for CO leads to *fac*-**B**, which undergoes methyl migration. Reaction with I^- results in elimination of MeCOI and regeneration of the catalyst. (a) What is the stereochemistry of *cis*-$[IrI_2(CO)_2]^-$? (b) Show what happens during the oxidative addition of MeI to *cis*-$[IrI_2(CO)_2]^-$, and give the structure of *fac*-**A**. (c) Draw the structure of *fac*-**B** and describe the mechanism of the methyl migration step. (d) How does the valence electron count and the oxidation state of the Ir atom change during the catalytic cycle, starting and ending with the catalyst?



24.42 Ruthenium(II) complexes of the general type shown below are potential anticancer drugs:

N,*N*'-bidentate ligand

The cytotoxicity of such complexes relies upon the replacement of the chlorido ligand by H_2O, and is pH dependent. (a) Write an equilibrium that defines the K_a value of the hydrolysis product of the above complex. (b) How does the introduction of electron-withdrawing substituents into the arene ring affect the pK_a value of the complex? (c) Suggest why the cytotoxicity is pH dependent.

24.43 The compound drawn below is an example of a ferrocenophane:

It undergoes ring-opening polymerization (ROP) to yield a high molecular weight polymer in which the Cp rings in each ferrocene are parallel to one another. Potential applications of these polymers include those in materials and nano-sciences. (a) Starting from Cp_2Fe, suggest a synthesis of the compound shown above. (b) Give a reaction scheme for the ROP reaction, showing the repeat unit of the polymer. Comment on the driving force for the polymerization.

Reduction of N_2 to NH_3
Alkene hydrogenation
Monsanto and Cativa processes
Hydroformylation
Alkene oligomerization
Developing new catalysts
Heterogeneous catalysis
Ziegler–Natta catalysis
Fischer–Tropsch reactions
Haber process
Contact process
Catalytic converters
Zeolites

25.1 Introduction and definitions

Numerous applications of catalysts in small-scale synthesis and the industrial production of chemicals have been described in this book. Now we discuss catalysis in detail, focusing on commercial applications. Catalysts containing *d*-block metals are of immense importance to the chemical industry: they provide cost-effective syntheses, and control the specificity of reactions that might otherwise give mixed products. The chemical industry (including fuels) is worth hundreds of billions of US dollars per year. The search for new catalysts is one of the major driving forces behind organometallic research, and the chemistry in many parts of this chapter can be understood in terms of the reaction types introduced in Chapter 24. Current research also includes the development of environmentally friendly 'green chemistry', e.g. the use of supercritical CO_2 ($scCO_2$, see Section 9.13) as a medium for catalysis.[†]

A ***catalyst*** is a substance that alters the rate of a reaction without appearing in any of the products of that reaction; it may speed up or slow down a reaction. For a reversible reaction, a catalyst alters the rate at which equilibrium is attained; it does *not* alter the position of equilibrium.

The term *catalyst* is often used to encompass both the *catalyst precursor* and the *catalytically active species*. A catalyst precursor is the substance added to the reaction, but it may undergo loss of a ligand such as CO or PPh_3 before it is available as the catalytically active species.

Although one tends to associate a catalyst with *increasing* the rate of a reaction, a *negative catalyst* slows down a reaction. Some reactions are internally catalysed (*autocatalysis*) once the reaction is under way, e.g. in the reaction of $[C_2O_4]^{2-}$ with $[MnO_4]^-$, the Mn^{2+} ions formed catalyse the forward reaction.

In an ***autocatalytic reaction***, one of the products is able to catalyse the reaction.

Catalysts fall into two categories, homogeneous and heterogeneous, depending on their relationship to the phase of the reaction in which they are involved.

A ***homogeneous catalyst*** is in the same phase as the components of the reaction that it is catalysing.
A ***heterogeneous catalyst*** is in a different phase from the components of the reaction for which it is acting.

25.2 Catalysis: introductory concepts

Energy profiles for a reaction: catalysed versus non-catalysed

A catalyst operates by allowing a reaction to follow a different pathway from that of the non-catalysed reaction. If the activation barrier is lowered, then the reaction proceeds more rapidly. Figure 25.1 illustrates this for a

[†] For example, see: W. Leitner (2002) *Acc. Chem. Res.*, vol. 35, p. 746 – 'Supercritical carbon dioxide as a green reaction medium for catalysis'; I. P. Beletskaya and L.M. Kustov (2010) *Russ. Chem. Rev.*, vol. 79, p. 441 – 'Catalysis as an important tool of green chemistry'.

THEORY

Box 25.1 Energy and Gibbs energy of activation: E_a and $\Delta G^{\ddagger}$

The Arrhenius equation:

$$\ln k = \ln A - \frac{E_a}{RT} \quad \text{or} \quad k = A\,e^{\left(\frac{-E_a}{RT}\right)}$$

is often used to relate the rate constant, k, of a reaction to the activation energy, E_a, and to the temperature, T (in K). In this equation, A is the pre-exponential factor, and R = molar gas constant. The activation energy is often approximated to $\Delta H^{\ddagger}$, but the exact relationship is:

$$E_a = \Delta H^{\ddagger} + RT$$

The energy of activation, $\Delta G^{\ddagger}$, is related to the rate constant by the equation:

$$k = \frac{k'T}{h}\,e^{\left(\frac{-\Delta G^{\ddagger}}{RT}\right)}$$

where k' = Boltzmann's constant, h = Planck's constant.

In Section 26.2 we discuss activation parameters, including $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, and show how these can be determined from an Eyring plot (Fig. 26.2) which derives from the equation above relating k to $\Delta G^{\ddagger}$.

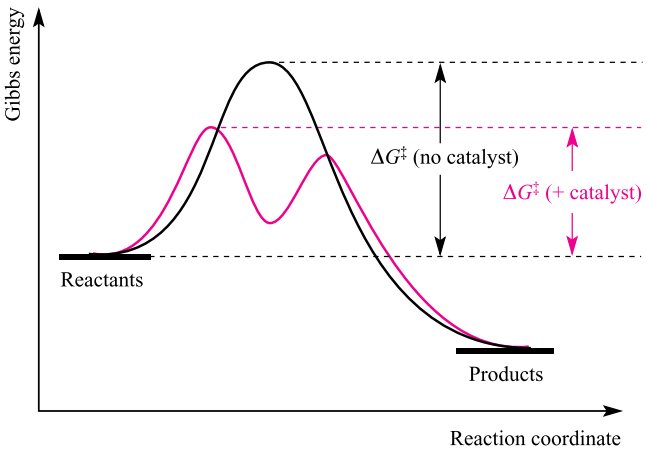

Fig. 25.1. A schematic representation of the reaction profile of a reaction without and with a catalyst. The pathway for the catalysed reaction has two steps, and the first step is rate determining.

reaction that follows a single step when it is non-catalysed, but a 2-step path when a catalyst is added. Each step in the catalysed route has a characteristic Gibbs energy of activation, $\Delta G^{\ddagger}$, but the step that matters with respect to the rate of reaction is that with the higher barrier. For the catalysed pathway in Fig. 25.1, the first step is the rate-determining step. (See Box 25.1 for the relevant equations for and relationship between E_a and $\Delta G^{\ddagger}$.) Values of $\Delta G^{\ddagger}$ for the controlling steps in the catalysed and non-catalysed routes are marked in Fig. 25.1. A crucial aspect of the catalysed pathway is that it must not pass through an energy minimum *lower* than the energy of the products. Such a minimum would be an 'energy sink', and would lead to the pathway yielding different products from those desired.

Catalytic cycles

A catalysed reaction pathway is usually represented by a *catalytic cycle*.

A ***catalytic cycle*** consists of a series of stoichiometric reactions (often reversible) that form a closed loop. The catalyst must be regenerated so that it can participate in the cycle of reactions more than once.

For a catalytic cycle to be efficient, the intermediates must be short-lived. The downside of this for understanding the mechanism is that short lifetimes make studying a cycle difficult. Experimental probes are used to investigate the kinetics of a catalytic process, isolate or trap the intermediates, attempt to monitor intermediates in solution, or devise systems that model individual steps so that the product of the model-step represents an intermediate in the cycle. In the latter, the 'product' can be characterized by conventional techniques (e.g. NMR and IR spectroscopies, X-ray diffraction, mass spectrometry). For many cycles, however, the mechanisms are not firmly established.

Self-study exercises

These exercises review types of organometallic reactions (see Section 24.8) and the 18-electron rule (Section 24.3).

1. What type of reaction is the following, and by what mechanism does it occur?

   $Mn(CO)_5Me + CO \longrightarrow Mn(CO)_5(COMe)$

   [*Ans.* See eq. 24.40]

2. Which of the following compounds contain a 16-electron metal centre: (a) $Rh(PPh_3)_3Cl$; (b) $HCo(CO)_4$; (c) $Ni(\eta^3\text{-}C_3H_5)_2$; (d) $Fe(CO)_4(PPh_3)$; (e) $[Rh(CO)_2I_2]^-$?

   [*Ans.* (a), (c), (e)]

3. Write an equation to show β-hydrogen elimination from $L_nMCH_2CH_2R$. [*Ans.* See eq. 24.44]

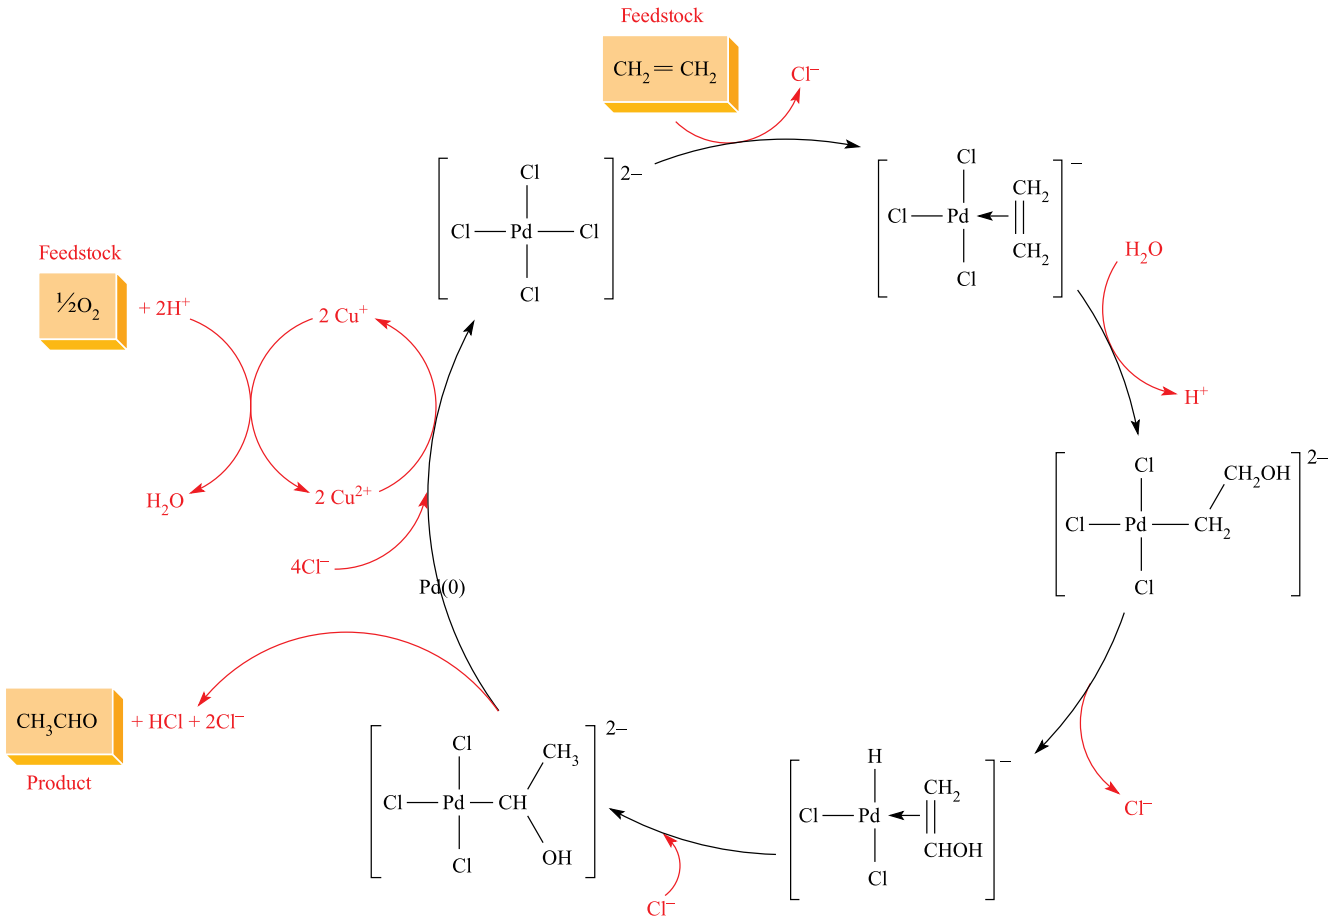

Fig. 25.2. Catalytic cycle for the Wacker process. For simplicity, we have ignored the role of coordinated H_2O, which replaces Cl^- *trans* to the alkene.

4. What is meant by 'oxidative addition'? Write an equation for the oxidative addition of H_2 to $RhCl(PPh_3)_3$.

[*Ans.* See eq. 24.34 and associated text]

5. What type of reaction is the following, and what, typically, is the mechanism for such reactions?

$$Mo(CO)_5(THF) + PPh_3 \longrightarrow Mo(CO)_5(PPh_3) + THF$$

[*Ans.* See eq. 24.29 and associated text]

We now study one cycle in detail to illustrate the notations. Figure 25.2 shows a simplified catalytic cycle for the Wacker process which converts ethene to acetaldehyde (eq. 25.1). The process was developed in the 1950s and although it is not of great industrial significance nowadays, it provides a well-studied example for close examination.

$$CH_2{=}CH_2 + \tfrac{1}{2}O_2 \xrightarrow{[PdCl_4]^{2-}\ \text{catalyst}} CH_3CHO \qquad (25.1)$$

The *feedstocks* for the industrial process are highlighted along with the final product in Fig. 25.2. The catalyst in the Wacker process contains palladium: through most of the cycle, the metal is present as Pd(II) but is reduced to Pd(0) as CH_3CHO is produced. We now work through the cycle, considering each step in terms of the organometallic reaction types discussed in Section 24.8.

The first step involves substitution by $CH_2{=}CH_2$ in $[PdCl_4]^{2-}$ (eq. 25.2). At the top of Fig. 25.2, the arrow notation shows $CH_2{=}CH_2$ entering the cycle and Cl^- leaving. One Cl^- is then replaced by H_2O, but we ignore this in Fig. 25.2.

$$[PdCl_4]^{2-} + CH_2{=}CH_2 \longrightarrow [PdCl_3(\eta^2\text{-}C_2H_4)]^- + Cl^- \qquad (25.2)$$

The next step involves nucleophilic attack by H_2O with loss of H^+. Recall that coordinated alkenes are susceptible to nucleophilic attack (see eq. 24.86). In the third step, β-elimination occurs and formation of the Pd–H bond results in loss of Cl^-. This is followed by attack by Cl^- with H atom migration to give a σ-bonded $CH(OH)CH_3$ group. Elimination of CH_3CHO, H^+ and Cl^- with reduction of Pd(II) to Pd(0) occurs in the last step. To keep the cycle going, Pd(0) is now oxidized by Cu^{2+} (eq. 25.3). The

secondary cycle in Fig. 25.2 shows the reduction of Cu^{2+} to Cu^{+} and reoxidation of the latter by O_2 in the presence of H^{+} (eq. 25.4).

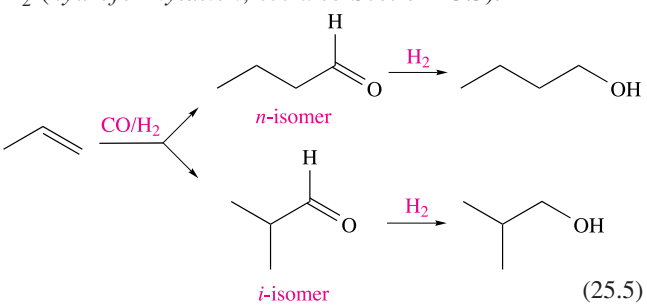
$$Pd + 2Cu^{2+} + 8Cl^{-} \longrightarrow [PdCl_4]^{2-} + 2[CuCl_2]^{-} \quad (25.3)$$

$$2[CuCl_2]^{-} + \tfrac{1}{2}O_2 + 2HCl \longrightarrow 2CuCl_2 + 2Cl^{-} + H_2O \quad (25.4)$$

If the whole cycle in Fig. 25.2 is considered with species 'in' balanced against species 'out', the *net reaction* is reaction 25.1.

Choosing a catalyst

A reaction is not usually catalysed by a unique species and a number of criteria must be considered when choosing the most effective catalyst, especially for a commercial process. Moreover, altering a catalyst in an industrial plant already in operation may be costly (e.g. a new plant design may be required) and the change must be guaranteed to be financially viable. Apart from the changes in reaction conditions that the use of a catalyst may bring about (e.g. pressure and temperature), other factors that must be considered are:



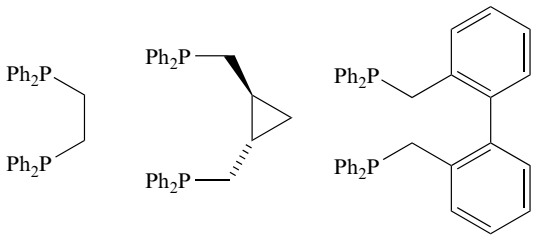
- the concentration of catalyst required;
- the catalytic turnover;
- the selectivity of the catalyst to the desired product;
- how often the catalyst needs renewing.

The ***catalytic turnover number*** (TON) is the number of moles of product per mole of catalyst. This number indicates the number of catalytic cycles for a given process, e.g. after 2 h, the TON was 2400.

The ***catalytic turnover frequency*** (TOF) is the catalytic turnover per unit time: the number of moles of product per mole of catalyst per unit time, e.g. the TOF was 20 min^{-1}.

Defining the catalytic turnover number and frequency is not without problems. For example, if there is more than one product, one should distinguish between values of the total TON and TOF for all the catalytic products, and specific values for individual products. The term catalytic turnover number is usually used for batch processes, whereas catalytic turnover frequency is usually applied to continuous processes (flow reactors).

Now we turn to the question of selectivity, and the conversion of propene to an aldehyde provides a good example. Equation 25.5 shows the four possible products that may result from the reaction of propene with CO and H_2 (*hydroformylation*; see also Section 25.5).



(25.5)

The following ratios are important:

- the $n:i$ ratio of the aldehydes (*regioselectivity* of the reaction);
- the aldehyde : alcohol ratio for a given chain (*chemoselectivity* of the reaction).

The choice of catalyst can have a significant effect on these ratios. For reaction 25.5, a cobalt carbonyl catalyst (e.g. $HCo(CO)_4$) gives ≈80% C_4-aldehyde, 10% C_4-alcohol and ≈10% other products, and an $n:i$ ratio ≈3 : 1. For the same reaction, various rhodium catalysts with phosphane co-catalysts can give an $n:i$ ratio of between 8 : 1 and 16 : 1, whereas ruthenium cluster catalysts show a high chemoselectivity to aldehydes with the regioselectivity depending on the choice of cluster, e.g. for $Ru_3(CO)_{12}$, $n:i \approx 2:1$, and for $[HRu_3(CO)_{11}]^{-}$, $n:i \approx 74:1$. Where the hydroformylation catalyst involves a bisphosphane ligand (e.g. $Ph_2PCH_2CH_2PPh_2$, dppe), the ligand bite angle (see structure **7.16**) can significantly influence the product distribution. For example, the $n:i$ ratios in the hydroformylation of hex-1-ene catalysed by a Rh(I)-bisphosphane complex are ≈2.1, 12.1 and 66.5 as the bite angle of the bisphosphane ligand increases along the series:[†]

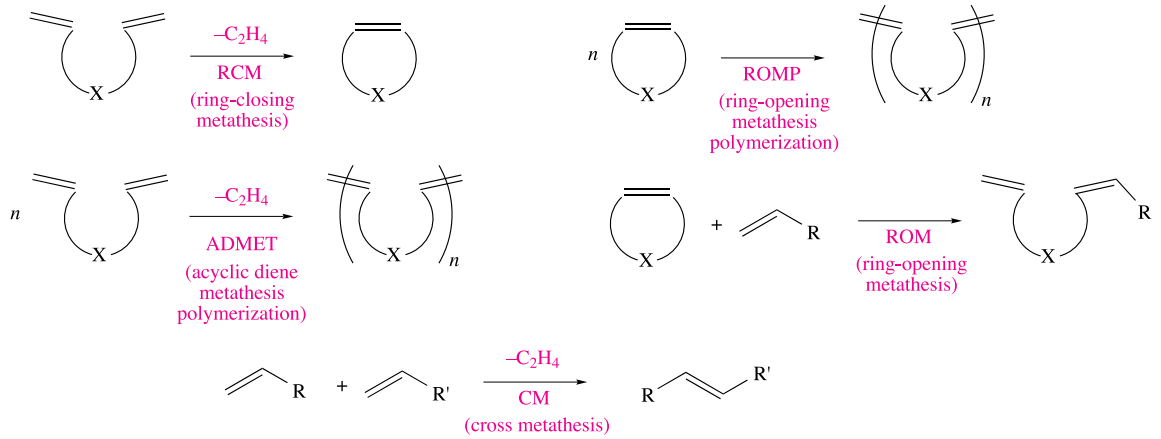
Bite angle: 84.4° 107.6° 112.6°

Although a diagram such as Fig. 25.2 shows a catalyst being regenerated and passing once more around the cycle, in practice, catalysts eventually become exhausted or are *poisoned*, e.g. by impurities in the feedstock.

25.3 Homogeneous catalysis: alkene (olefin) and alkyne metathesis

In Section 24.13, we introduced *alkene (olefin) metathesis*, i.e. metal-catalysed reactions in which C=C bonds are redistributed. The importance of alkene and alkyne metathesis was recognized by the award of the 2005 Nobel Prize in Chemistry to Yves Chauvin, Robert H. Grubbs and Richard R. Schrock 'for the development of the metathesis method in organic synthesis'. Examples of alkene metath-

[†] For further discussion of the effects of ligand bite angles on catalyst efficiency and selectivity, see: P. Dierkes and P.W.N.M. van Leeuwen (1999) *J. Chem. Soc., Dalton Trans.*, p. 1519; J.A. Gillespie, D.L. Dodds and P.C.J. Kamer (2010) *Dalton Trans.*, vol. 39, p. 2751 – 'Rational design of diphosphorus ligands – a route to superior catalysts'.



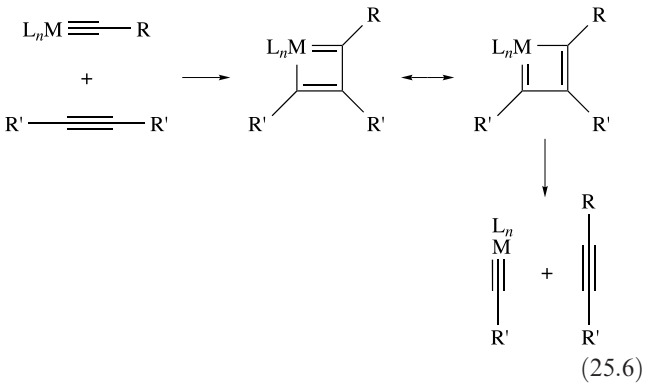


Fig. 25.3. Examples of alkene (olefin) metathesis reactions with their usual abbreviations.

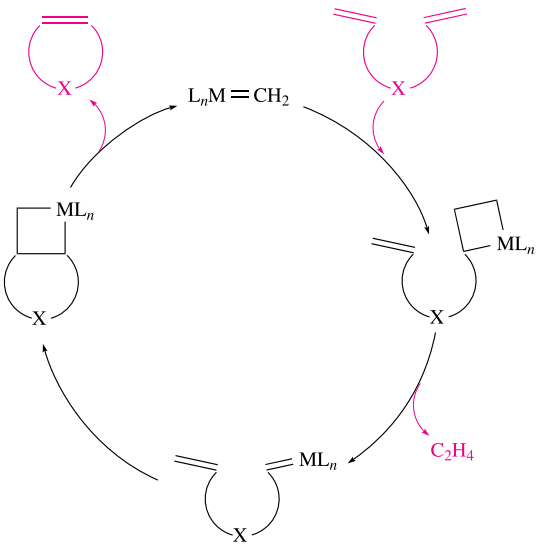
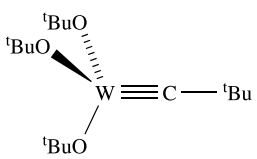
esis are shown in Fig. 25.3. The Chauvin mechanism for metal-catalysed alkene metathesis involves a metal alkylidene species and a series of [2 + 2]-cycloadditions and cycloreversions (Fig. 25.4). Scheme 25.6 shows the mechanism for alkyne metathesis which involves a high oxidation state metal alkylidyne complex, $L_nM{\equiv}CR$.

(25.6)





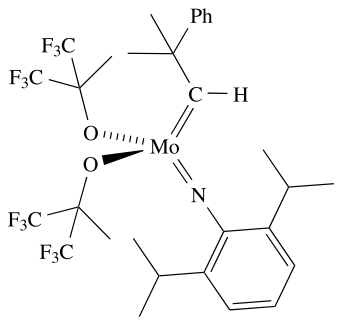


Fig. 25.4. A catalytic cycle for ring-closure metathesis (RCM) showing the Chauvin mechanism which involves [2 + 2]-cycloadditions and cycloreversions.

The catalysts that have played a dominant role in the development of this area of chemistry are those designed by Schrock (e.g. catalysts **25.1** and **25.2**) and Grubbs (catalysts **25.3** and **25.4**). Catalyst **25.3** is the traditional 'Grubbs' catalyst', and related complexes are also used. The 'second generation' catalyst **25.4** exhibits higher catalytic activities in alkene metathesis reactions. Catalysts **25.1–25.4** are commercially available. There are around 15 modifications of Grubbs' catalysts which are optimized for different catalytic roles. This includes the 'third generation' catalyst (see structure **24.68**) and Hoveyda–Grubbs' second generation catalyst (structure **24.69**).

(25.3)

(25.4)

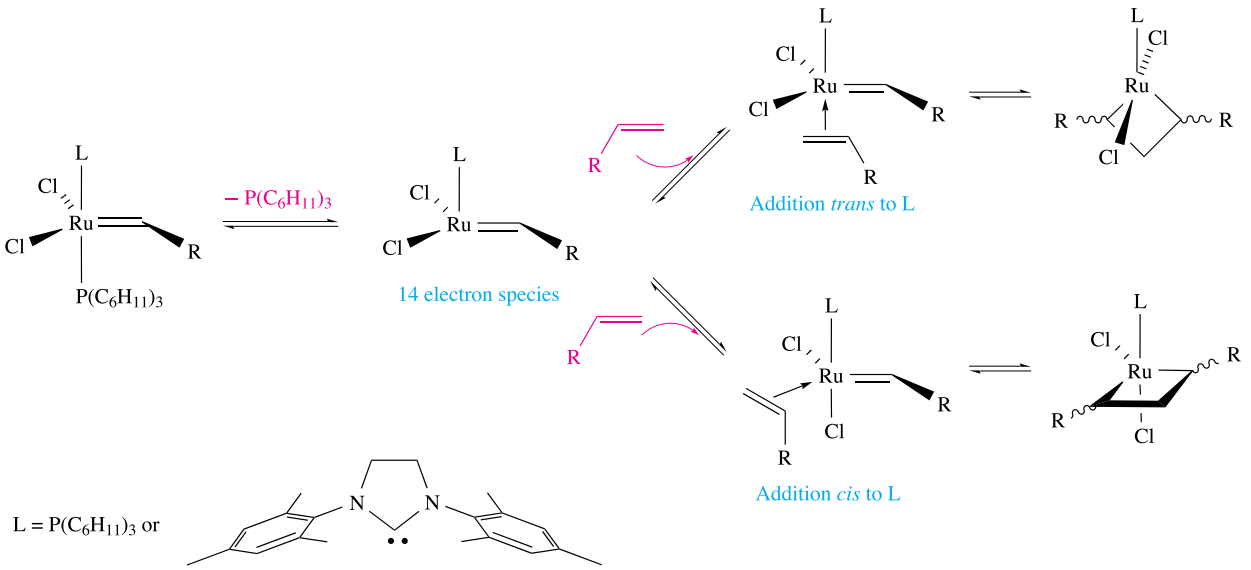

Fig. 25.5. Initial steps in the mechanism of alkene metathesis involving first and second generation Grubbs' catalysts. Two possibilities for the formation of the metallocyclobutane intermediates are shown.

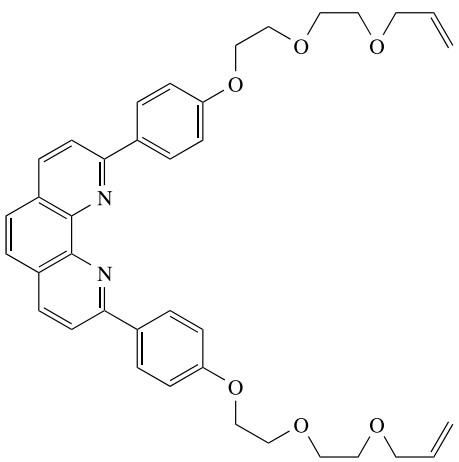
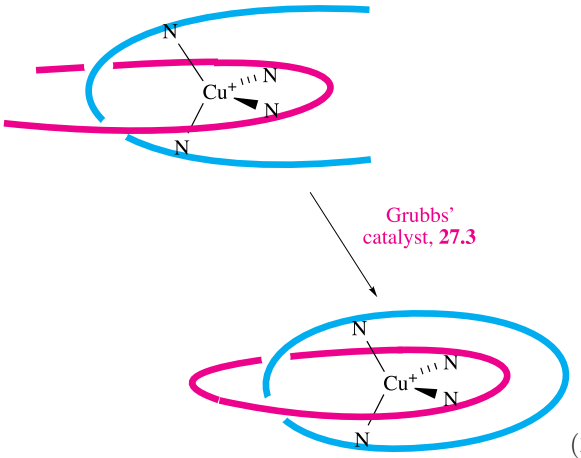


In Grubbs' catalysts, tricyclohexylphosphane is chosen in preference to other PR_3 ligands because its steric hindrance and strongly electron-donating properties lead to enhanced catalytic activity. The first step in the mechanism of alkene metathesis involving Grubbs' catalysts is the dissociation of a $P(C_6H_{11})_3$ ligand to give a coordinatively unsaturated, 14-electron species (Fig. 25.5). The choice of the phosphane ligand is crucial for this initiation step: PR_3 ligands that are less sterically demanding than $P(C_6H_{11})_3$ bind too strongly to Ru, whereas those that are more bulky than $P(C_6H_{11})_3$ are too labile and a stable starting complex is not formed. The activated complex now enters the catalytic cycle by binding an alkene. This may coordinate to the Ru centre either *cis* or *trans* to $P(C_6H_{11})_3$ (first generation catalyst) or the *N*-heterocyclic carbene ligand (second generation catalyst). In keeping with the general Chauvin mechanism, the next step involves formation of metallocyclic intermediates (Fig. 25.5).[†]

A great advantage of Grubbs' catalysts is that they are tolerant of a large range of functional groups, thus permitting their widespread application. We highlight a laboratory example that combines coordination chemistry with the use of catalyst **25.3**: the synthesis of a *catenate*.

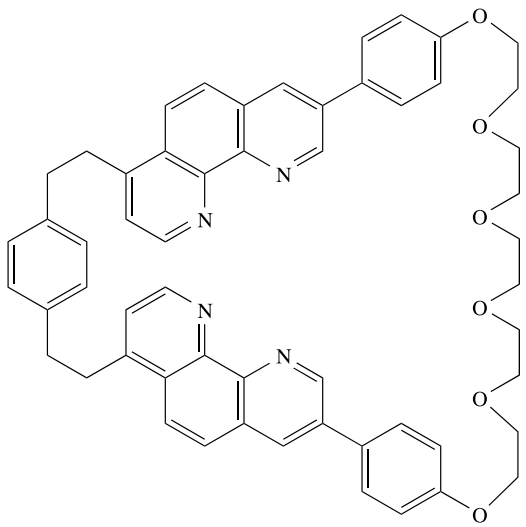
A ***catenand*** is a molecule containing two interlinked chains. A ***catenate*** is a related molecule that contains a coordinated metal ion.



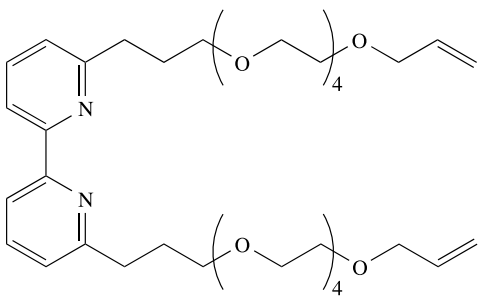
[†] For elucidation of the mechanisms see, for example: R.H. Grubbs (2004) *Tetrahedron*, vol. 60, p. 7117; D.R. Anderson, D.D. Hickstein, D.J. O'Leary and R.H. Grubbs (2006) *J. Am. Chem. Soc.*, vol. 128, p. 8386; A.G. Wenzel and R.H. Grubbs (2006) *J. Am. Chem. Soc.*, vol. 128, p. 16048; J.I. du Toit, C.G.C.E. van Sittert and H.C.M. Vosloo (2013) *J. Organomet. Chem.*, vol. 738, p. 76.

Topologically, the chemical assembly of a catenand is non-trivial because it requires one molecular chain to be threaded through another. Molecule **25.5** contains two terminal alkene functionalities and can also act as a bidentate ligand by using the *N*,*N*'-donor set.

(25.5)



The complex $[Cu(\mathbf{25.5})_2]^+$ is shown schematically at the top of eq. 25.7. The tetrahedral Cu^+ centre acts as a template, fixing the positions of the two ligands with the central phenanthroline units orthogonal to one another. Ring closure of *each* separate ligand can be achieved by treating $[Cu(\mathbf{25.5})_2]^+$ with Grubbs' catalyst, and the result is the formation of a catenate, shown schematically as the product in eq. 25.7. The relative orientations of the two coordinated ligands in $[Cu(\mathbf{25.5})_2]^+$ is important if competitive reactions between *different* ligands are to be minimized.



(25.7)

Self-study exercise

Ligand L_1 reacts with $Ru(DMSO)_4Cl_2$ in MeCN to give $[RuL_1(NCMe)_2]^{2+}$. Reaction of this complex with ligand L_2, followed by treatment with first generation Grubbs' catalyst, results in the formation of a catenate. (a) Draw a scheme for the reaction, paying attention to the coordination environment and stereochemistry of the Ru centre. (b) What type of alkene metathesis reaction is involved in the last step? (c) What complications can arise in this type of reaction?

25.4 Homogeneous catalytic reduction of N_2 to NH_3

In nature, the fixation of nitrogen by bacteria involves the reduction of N_2 to NH_3 (eq. 25.8) catalysed by an iron- and molybdenum-containing nitrogenase (see Section 29.4). In contrast to this natural process, the industrial production of NH_3 (eq. 25.9) requires harsh conditions and a heterogeneous catalyst (see Section 25.8). Given the massive scale on which NH_3 is manufactured, the conversion of N_2 to NH_3 using a homogeneous catalyst under ambient conditions is a goal that many chemists have tried to achieve.

$$N_2 + 8H^+ + 8e^- \rightleftharpoons 2NH_3 + H_2 \quad (25.8)$$

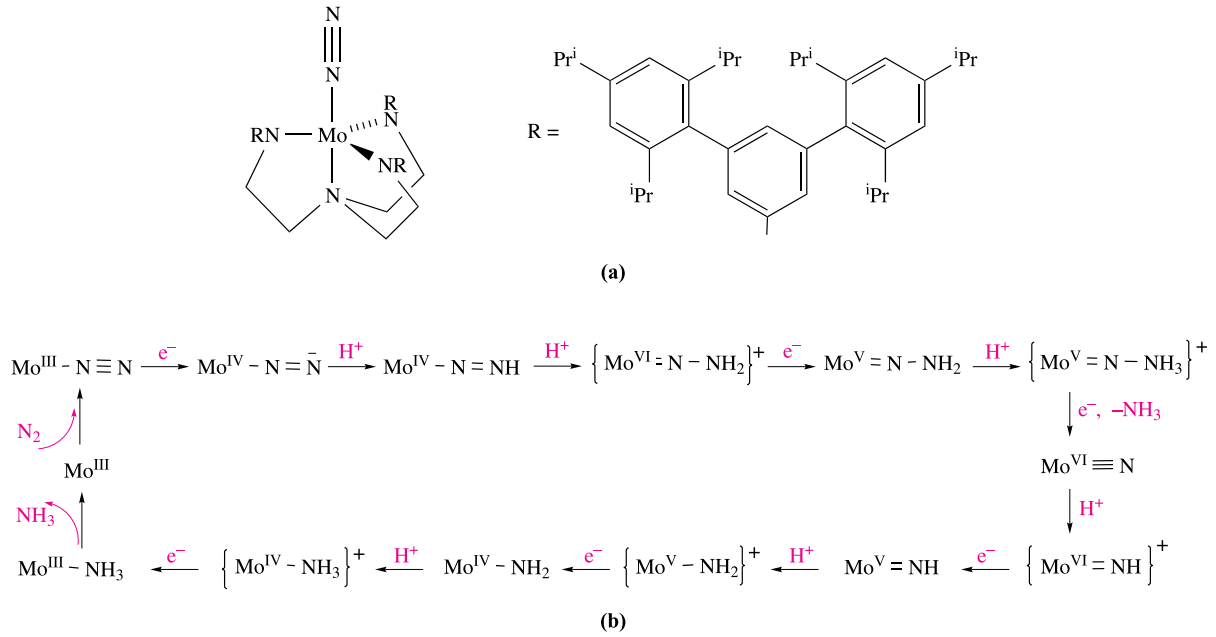
$$N_2 + 3H_2 \rightleftharpoons 2NH_3 \quad (25.9)$$

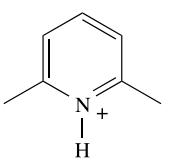
Since nature depends on FeMo-nitrogenase, complexes containing these metals are of particular interest in terms of investigating N_2 to NH_3 conversion. Complexes of type **25.6** have been a starting point for a number of studies involving intermediates such as **25.7** and **25.8**. However, such interconversions produce only moderate yields of NH_3 when **25.8** is protonated.[†]

(25.6) **(25.7)** **(25.8)**

Despite the large number of dinitrogen metal complexes known, their use for the catalytic production of NH_3 has not been an easy target to achieve. In 2003, Schrock reported the catalytic reduction of N_2 to NH_3 at a single Mo centre, carried out at room temperature and pressure. The reduction is selective (it does not give any N_2H_4). The catalyst is represented in Fig. 25.6a in the state in which N_2 is bound. The tripodal ligand $[N(CH_2CH_2NR)_3]^{3-}$ shown bound to the Mo(III) centre is designed to maximize steric crowding around the active metal site, creating a pocket in which small-molecule transformations occur. The substituents R increase the solubility of the complexes shown in Fig. 25.6b. Each step in the proposed catalytic cycle

[†] For discussion, see: J. Rittle and J.C. Peters (2016) *J. Am. Chem. Soc.*, vol. 138, p. 4243 – 'An Fe–N_2 complex that generates hydrazine and ammonia via Fe=NNH_2: Demonstrating a hybrid distal-to-alternating pathway for N_2 reduction'.





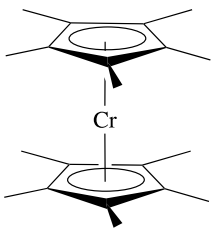


Fig. 25.6. (a) Dinitrogen bound to the single Mo(III) centre in the complex that is the starting point for the catalytic conversion of N_2 in NH_3 at room temperature and pressure. (b) The proposed scheme in which six protons and six electrons generate two equivalents of NH_3 from one equivalent of N_2. The complex shown in part (a) is abbreviated to $Mo^{III}N_2$, and so on.

involves either proton or electron transfer. Of the intermediates shown, eight have been fully characterized.[†] In practice, a heptane solution of the complex $Mo^{III}N_2$ (defined in Fig. 25.6) is treated with an excess of 2,6-dimethylpyridinium ion (**25.9**) as the proton source and $(\eta^5\text{-}C_5Me_5)_2Cr$ (**25.10**) as the electron source. Decamethylchromocene is a very strong reducing agent, undergoing 1-electron oxidation to $[(\eta^5\text{-}C_5Me_5)_2Cr]^+$. The reagents must be added in a slow and controlled manner. Under these conditions, the efficiency of NH_3 formation from N_2 is ≈60%.

(25.9)

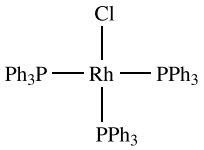
(25.10)

Although this example of the catalytic conversion of N_2 to NH_3 under ambient conditions in a well-defined molecular system remains at the research stage, it establishes that such conversions are possible.

Chem. Soc.*, vol. 131, p. 12829; M.R. Reithofer, R.R. Schrock and P. Müller (2010) *J. Am. Chem. Soc.*, vol. 132, p. 8349; T. Munisamy and R.R. Schrock (2012) *Dalton Trans.*, vol. 41, p. 130.

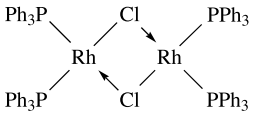
25.5 Homogeneous catalysis: industrial applications

In this section, we describe selected homogeneous catalytic processes that are of industrial importance. Many more processes are applied in industry and detailed accounts can be found in the suggested reading at the end of the chapter. Two advantages of homogeneous over heterogeneous catalysis are the relatively mild conditions under which many processes operate, and the selectivity that can be achieved. A disadvantage is the need to separate the catalyst at the end of a reaction in order to recycle it, e.g. in the hydroformylation process, volatile $HCo(CO)_4$ can be removed by flash evaporation. The use of polymer supports or biphasic systems (Section 25.6) makes catalyst separation easier, and the development of such species is an active area of current research.



Throughout this section, the role of *coordinatively unsaturated 16-electron species* (see Section 24.8) and the ability of the metal centre to change coordination number (essential requirements of an active catalyst) should be noted.

Alkene hydrogenation



The most widely used procedures for the hydrogenation of alkenes nearly all employ heterogeneous catalysts, but for certain specialized purposes, homogeneous catalysts are used. Although addition of H_2 to a double bond is thermodynamically favoured (eq. 25.10), the kinetic barrier is high and a catalyst is required for the reaction to be

carried out at a viable rate without the need for high temperatures and pressures.

$$CH_2{=}CH_2 + H_2 \longrightarrow C_2H_6 \quad \Delta G^{\circ} = -101\,\text{kJ mol}^{-1} \tag{25.10}$$

(25.11)

(25.12)

Wilkinson's catalyst (**25.11**) has been widely studied, and in its presence alkene hydrogenation can be carried out at 298 K and 1 bar H_2 pressure. The red, 16-electron Rh(I) complex **25.11** can be prepared from $RhCl_3$ and PPh_3, and is commonly used in benzene/ethanol solution, in which it dissociates to some extent (equilibrium 25.11). A solvent molecule (solv) fills the fourth site in $RhCl(PPh_3)_2$ to give $RhCl(PPh_3)_2(solv)$. The 14-electron $RhCl(PPh_3)_2$ (or its solvated analogue) is the active catalyst for the hydrogenation of alkenes. Dimerization of $RhCl(PPh_3)_2$ to **25.12** leads to a catalytically inactive species, and may occur when the concentrations of H_2 and alkene are low (e.g. at the end of a batch process).

$$RhCl(PPh_3)_3 \rightleftharpoons RhCl(PPh_3)_2 + PPh_3 \quad K = 1.4 \times 10^{-4} \tag{25.11}$$

The *cis*-oxidative addition of H_2 to $RhCl(PPh_3)_3$ (top left-hand side of Fig. 25.7) yields a coordinatively unsaturated 16-electron species (eq. 25.12).

$$\underset{\text{14-electron}}{RhCl(PPh_3)_2} + H_2 \rightleftharpoons \underset{\text{16-electron}}{RhCl(H)_2(PPh_3)_2} \tag{25.12}$$

The addition of an alkene to $RhCl(H)_2(PPh_3)_2$ is probably the rate-determining step of the catalytic cycle shown in Fig. 25.7. The stereochemistry of octahedral $RhCl(H)_2(PPh_3)_2(\eta^2\text{-alkene})$ is such that the alkene is *cis* with respect to the two *cis*-hydrido ligands. Hydrogen migration then occurs to give a σ-bonded alkyl ligand, followed by reductive elimination of an alkane and regeneration of the active catalyst. The process is summarized in Fig. 25.7, the role of the solvent being ignored. The scheme shown should not be taken as being unique. For example, for some alkenes, experimental data suggest that $RhCl(PPh_3)_2(\eta^2\text{-alkene})$ is an intermediate. Other catalysts such as $HRuCl(PPh_3)_3$ and $HRh(CO)(PPh_3)_3$ (which loses

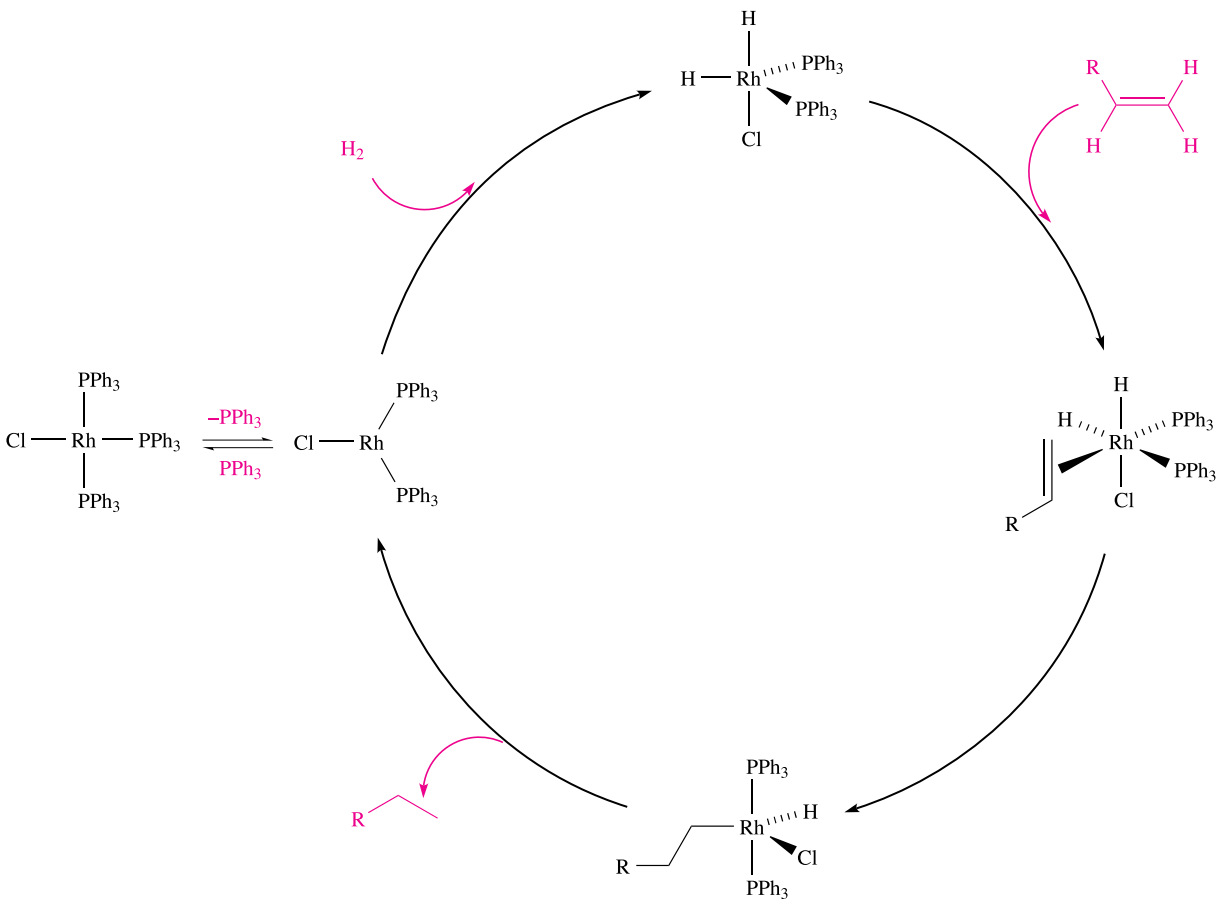


Fig. 25.7. Catalytic cycle for the hydrogenation of $RCH{=}CH_2$ using Wilkinson's catalyst, $RhCl(PPh_3)_3$.

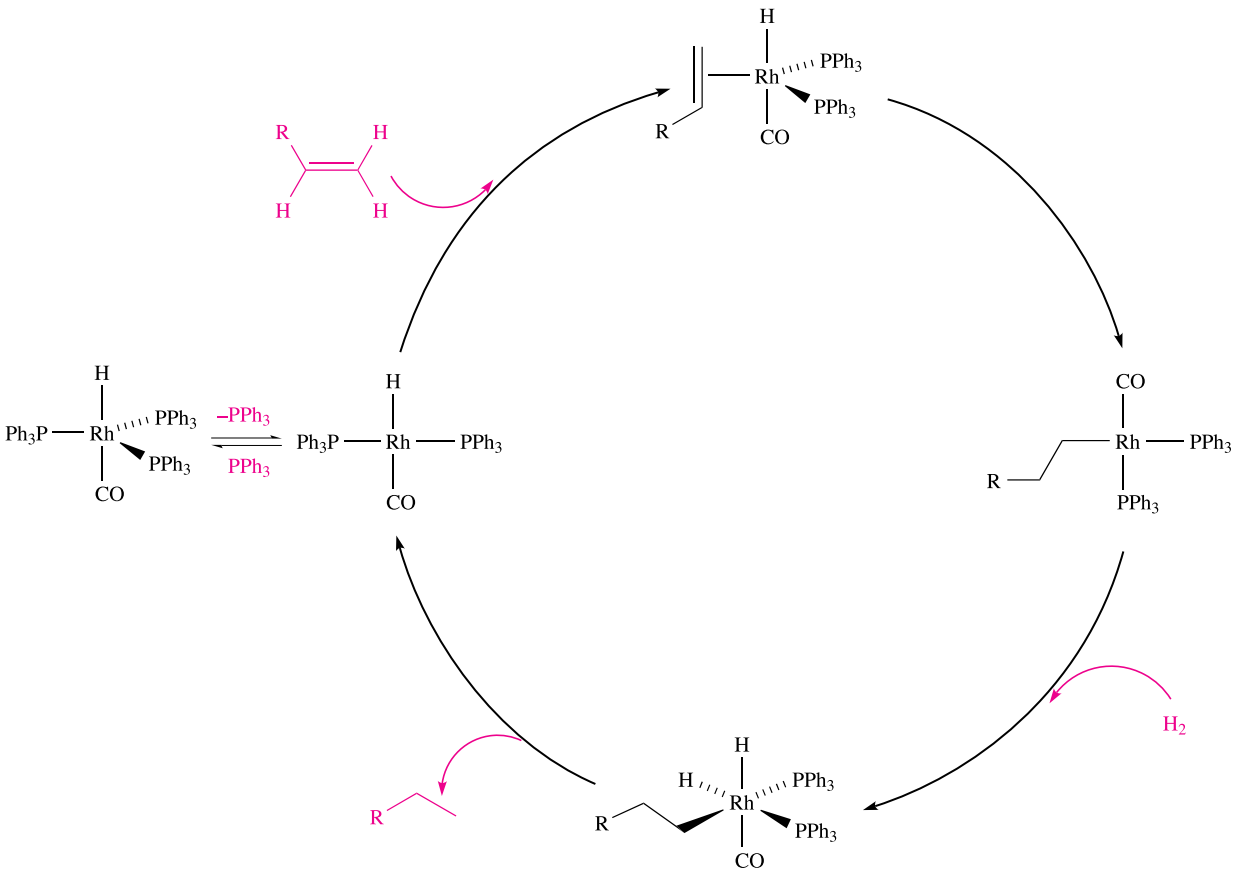

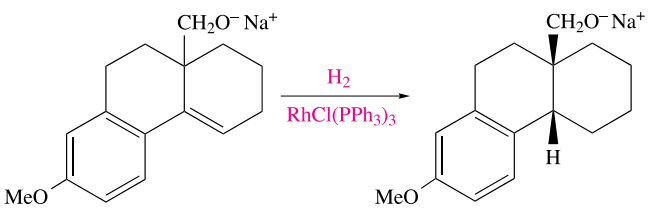

Fig. 25.8. Catalytic cycle for the hydrogenation of RCH=CH_2 using $HRh(CO)(PPh_3)_3$ as catalyst.

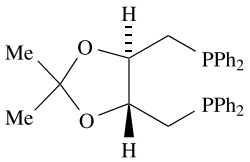
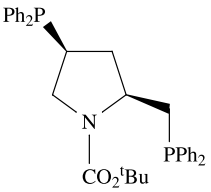
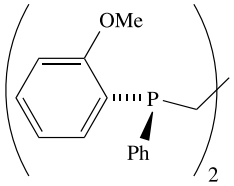
PPh_3 to give an active 16-electron complex) react with alkene, rather than H_2, in the first step in the catalytic cycle. Figure 25.8 summarizes the route by which $HRh(CO)(PPh_3)_3$ catalyses the hydrogenation of an alkene. The rate-determining step is the oxidative addition of H_2 to the σ-bonded alkyl complex.

Substrates for hydrogenation catalysed by Wilkinson's catalyst include alkenes, dienes, allenes, terpenes, butadiene rubbers, antibiotics, steroids and prostaglandins. Significantly, ethene actually poisons its own conversion to ethane, and catalytic hydrogenation using $RhCl(PPh_3)_3$ cannot be applied in this case. For effective catalysis, the size of the alkene is important. The rate of hydrogenation is hindered by sterically demanding alkenes (Table 25.1). Many useful *selective* hydrogenations can be achieved, e.g. reaction 25.13.

(25.13)







Biologically active compounds usually have at least one *asymmetric centre* and dramatic differences in the activities of different enantiomers of chiral drugs are commonly observed. Whereas one enantiomer may be an effective therapeutic drug, the other may be inactive or highly toxic as was the case with

Table 25.1 Rate constants for the hydrogenation of alkenes (at 298 K in C_6H_6) in the presence of Wilkinson's catalyst.[†]

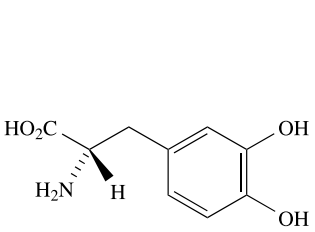
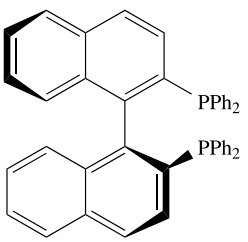
thalidomide.[†] *Asymmetric synthesis* is therefore an active field of research.[‡]



Asymmetric synthesis is an enantioselective synthesis and its efficiency can be judged from the ***enantiomeric excess*** (ee):

$$\%\ \text{ee} = \left(\frac{|\text{R} - \text{S}|}{|\text{R} + \text{S}|}\right) \times 100$$

where R and S = relative quantities of *R* and *S* enantiomers.



An enantiomerically pure compound has 100% enantiomeric excess (100% ee). In ***asymmetric catalysis***, the catalyst is chiral.
